

MINUTES OF THE 46th GENERAL ASSEMBLY OF THE EUROPEAN ASSOCIATION FOR THE STUDY OF DIABETES

held in Stockholmsmässan, Stockholm, Sweden on 23 September 2010

Present:	Dr. U. Smith	(President)
	Dr. G. Spinas	(Honorary Treasurer)
	Dr. M. Stumvoll	(Honorary Secretary)
	Dr. E. Gale	(Editor-in-Chief, Diabetologia)
	Dr. J. Nolan	(Chair, PGEC)
	Dr. V. Jörgens	(Executive Director)
	Dr. M. Grüsser	(Vice Director)
	and 51 members	

The Vice President, Dr. Boulton, welcomed everyone to the 46th General Assembly as the President had unexpectedly to attend a press conference.

was held on 6 September 2010 with representatives from ESC, ERS, ECCO and EASD. Dr. Smith thanked all members of the Programme Committee 2010 for their commitment and hard work.

1. MINUTES 45th GENERAL ASSEMBLY 2009

Since there were no comments, the minutes were approved unanimously and officially signed as a correct record.

2. REPORTS

a) President

The President's report to the members on the activities of EASD was given in the President's Address before the Minkowski Lecture. It is available under:

<http://easd.conference2web.com/content/590>

This report covered the following topics:

The President reported on the various activities and grant programmes of the Foundation and expressed his thanks to all partners. He reported that the DIAMAP project had been finalised and the results had been presented to the international press during the Annual Meeting. He said the postgraduate courses continued to be successful and attracted many young researchers. Dr. Smith reported that recently the Alliance for Biomedical Research in Europe had been founded 'to promote the best interests and values of researchers across all medical disciplines in Europe, in those general areas where common interest is identified' (quoted from the Mission Statement). He reported that the founding assembly of the Alliance

b) Honorary Treasurer

Dr. Spinas reported that the income had increased slightly in 2009 due to the payment from Interplan for the Rome Annual Meeting. He said expenditure had decreased in 2009 because no transfer of funds had been made to the Foundation. This was done in the early part of 2010.

Dr. Spinas expressed his thanks to Drs. Grüsser and Jörgens for their support and advice and to the team in Düsseldorf in general and to Mrs. Klee, Ms. Deparade and Ms. Weiss in particular for the precise handling of the accounts.

(The President took over the General Assembly)

The President thanked the Honorary Treasurer for his diligence and asked if there were any questions. Dr. A. Pfeiffer queried if there were too many assets. Dr. Spinas explained that these assets were planned for and were all allocated. There were no further comments.

c) Honorary Auditors

The President asked the Honorary Auditors, Drs. Pater-son and Tack, for their report. Dr. Tack confirmed that the accounts had been checked carefully and were in

perfect order. Dr. Smith asked for the vote to accept the accounts.

The Honorary Treasurer was unanimously discharged (42 votes for and 5 abstentions).

d) Honorary Secretary

Dr. Stumvoll reported that 2159 abstracts had been submitted; of the 1352 which were accepted 264 were orals. The top three countries for abstract submission were USA, UK and Italy and the top three countries for abstract acceptance were USA, UK and Sweden.

Dr. Stumvoll closed his report by thanking all members of the EASD staff, in particular Ms. H. Goliberzuch and Mrs. M. Toledo, for their outstanding help and support with the organisation of the EASD Annual Meetings.

Dr. Smith thanked Dr. Stumvoll for his diligence and asked if there were any questions. Dr. Halban expressed his sincere thanks to Dr. Stumvoll for a fantastic job done. No further questions were asked.

e) Editor-in-Chief, Diabetologia

Dr. Gale briefly reported that the impact factor of Diabetologia was steadily increasing and the journal continued to be successful. As his term of office was coming to an end, he thanked the Executive Committee for their support and said it had been a tremendous privilege for him to serve as Editor-in-Chief for 7 years. He also expressed his thanks to the team in Bristol and handed over to Dr. Zierath and Dr. Nolan and wished them both all the best.

Dr. Smith thanked Dr. Gale for his dedication, active involvement in and contribution to the journal.

f) Chair, Postgraduate Education Committee

Dr. Nolan reported that a second course had been held in Kiev in April 2010 and another course was being planned in Ukraine in April 2011. The 3rd Oxford - Thessaloniki Diabetes Forum for 2011 would also be endorsed as an 'under the auspices of EASD' course. Another successful Minkowski EASD Advanced Postgraduate Course in Clinical Diabetes had been held in Wroclaw, Poland in March 2010. Future courses were being planned in Belgrade (Serbia), Riga (Latvia) and Sarajevo (Bosnia & Herzegovina).

Dr. Nolan reported that the web education sessions were progressing very well. Dr. Nolan will continue to plan

these activities until Dr. Kerr returns from his sabbatical.

Dr. Nolan closed his report by thanking the EASD staff for their friendly assistance. Dr. Smith thanked Dr. Nolan for his diligence in his role as Chair of the Postgraduate Education Committee.

g) Chair, Extra-European Postgraduate Activities

Dr. Boulton reported on the successful ventures in India: The Best of EASD India Diabetic Foot Seminars and the annual Best of EASD-India Courses. The 5th EASD/ADA/IDF Advanced Postgraduate Course held in Dar es Salaam, Tanzania had been very well attended. Dr. Boulton reported that courses were being planned in Nepal in November 2010 and in China in December 2010. Another Best of EASD-India Course will be held in Cochin and Bangalore in February 2011. Dr. Boulton said he was looking into the possibilities of holding courses in Addis Ababa and Cuba in 2011.

Dr. Smith thanked Dr. Boulton for his hard work in organising the extra-European activities.

3. ELECTIONS

Extension, Honorary Treasurer (2010 - 2011)

The General Assembly unanimously approved Dr. Spinass' extension until 2011, with 42 votes and 1 abstention.

Honorary Secretary (2010 - 2013)

The election of Dr. M. Walker was unanimously approved with 44 votes and 1 abstention.

Chair, PGEC (2010 - 2013)

The election of Dr. C. Tack was unanimously approved with 50 votes and 1 abstention.

Council Members (2011 - 2014)

The election of Drs. K. Birkeland, H. J. Bodansky, C. Levy-Marchal and P. Nawroth was unanimously approved with 49 votes and 1 abstention.

Honorary Auditor (2010 - 2013)

The election of Dr. M. Roden was unanimously approved with 49 votes and 1 abstention.

4. STUDY GROUPS

Dr. Boulton reported that he, together with Dr. Bosch, had taken over the organisation of the EASD Study Groups and representatives from all of them had been invited to a forum during the Annual Meeting. At the forum he had suggested that the Study Groups supply him with a list of their most experienced speakers which he could make use of for the postgraduate courses. He also proposed that the Study Groups make suggestions to the Honorary Secretary for symposia during the Annual Meeting; he had of course emphasised that the decision would lie with the Honorary Secretary regarding the final programme. At the Forum he had reiterated that the Study Groups did not receive financial support from the EASD.

5. HONORARY MEMBERSHIP

The nominations for Drs. C. Mogensen and P. Zimmet were unanimously approved.

6. ANY OTHER BUSINESS

Dr. Smith thanked the industry for their support. He also expressed his sincere gratitude to the Local Organising Committee for their outstanding contribution to the organisation of the 46th EASD Annual Meeting. He again thanked Drs. Stumvoll, Gale and Nolan for their hard work. The President warmly thanked Dr. Jörgens and the EASD team in Düsseldorf for their dedicated work.

Dr. Smith brought the General Assembly to a close at 18:55.

Agenda for the 47th General Assembly of the European Association for the Study of Diabetes

to be held in the Sanches Hall, Lisbon International Fair, Portugal on Thursday 16 September 2011 at 18:00

1. Minutes of the 46th General Assembly, Stockholm, Sweden 2010

2. Reports

a) President	U. Smith
b) Honorary Treasurer	G. Spinass
c) Honorary Auditors	M. Roden
	K. Paterson
d) Honorary Secretary	M. Walker
e) Editor-in-Chief, Diabetologia	J. Zierath
f) Chair, Postgraduate Education Committee	C. Tack
g) Chair, Extra-European Postgraduate Activities	A. J. M. Boulton

3. Elections

a) President (2011-2014)	in place of U. Smith
b) Vice President (2011 – 2014)	in place of A. J. M. Boulton
c) Honorary Treasurer (2011 – 2014)	in place of G. Spinass
d) Council Members (2012 - 2015)	in place of J.-M. Boavida C.-G. Östenson A. Pfeiffer N. Wareham
e) Honorary Auditor (2011 - 2014)	in place of K. Paterson in place of M. Roden

4. Study Groups

F. Bosch
A. J. M. Boulton

5. Honorary Membership

6. Any other business

47th EASD Annual Meeting of the European Association for the Study of Diabetes

Lisbon, Portugal, 12–16 September 2011

Abstracts

Index of Oral Presentations

- OP 01 Assessing cardiovascular risk
- OP 02 Diabetic foot and acute osteoarthropathy
- OP 03 Nutrition and diet
- OP 04 Brown adipose tissue and mitochondria
- OP 05 Genetics of type 1 diabetes
- OP 06 Insulin secretion and exocytosis
- OP 07 Nephropathy: epidemiology and clinical trials
- OP 08 Stem cells and regeneration
- OP 09 Prediction of complications in type 2 diabetes
- OP 10 Exploring mechanisms of insulin resistance
- OP 11 Education
- OP 12 Vascular actions, new and established therapies
- OP 13 GLP-1 receptor agonists
- OP 14 Diabetes in childhood
- OP 15 Gestational diabetes mellitus
- OP 16 Nephropathy: experimental
- OP 17 GWAS and next generation sequencing
- OP 18 Signal transduction
- OP 19 Insulin therapy
- OP 20 Regulation of hepatic glucose production
- OP 21 Novel cardiovascular biomarkers
- OP 22 Gastro-entero-pancreatic hormones
- OP 23 Brain metabolism and food intake
- OP 24 Beta cell damage
- OP 25 SGLT-2 inhibitors
- OP 26 Glycaemia and cardiovascular disease
- OP 27 Diagnosis and natural history of type 1 diabetes
- OP 28 Genetics of type 2 diabetes
- OP 29 Adipose tissue inflammation
- OP 30 Neuropathy: experimental and clinical
- OP 31 Metabolic effect of bariatric surgery
- OP 32 Novel agents for type 2 diabetes
- OP 33 Immunology
- OP 34 Hypoxia and remodelling of adipose tissue
- OP 35 Health care delivery
- OP 36 Psychological aspects
- OP 37 Diabetes and cancer
- OP 38 Adiposity and cardiovascular disease
- OP 39 Prediction of type 2 diabetes
- OP 40 Transplantation
- OP 41 Retinopathy: experimental
- OP 42 Postprandial metabolism
- OP 43 DPP-4 inhibitors
- OP 44 Nonalcoholic fatty liver disease
- OP 45 Hypoglycaemia
- OP 46 Islet electrophysiology

OP 47 Socio-economic aspects

OP 48 Devices

OP 01 Assessing cardiovascular risk

1

An examination of multiple cardiovascular endpoints in individuals with screen-detected type 2 diabetes in the ADDITION-Europe trial: intervention effects and methodological insights

R.K. Simmons¹, S.J. Sharp¹, A. Sandbæk², K. Borch-Johnsen³, M. Davies⁴, K. Khunti⁵, T. Lauritzen², G.E.H. Rutten⁶, M. van den Donk⁶, N.J. Wareham¹, S.J. Griffin¹

¹MRC Epidemiology Unit, Cambridge, UK, ²School of Public Health, Aarhus, Denmark, ³Institute of Public Health, Odense, Denmark, ⁴Department of Cardiovascular Sciences, Leicester, UK, ⁵Department of Health Sciences, Leicester, UK, ⁶Julius Center for Health Sciences and Primary Care, Utrecht, Netherlands.

Background and aims: Intensive treatment of multiple cardiovascular (CV) risk factors can halve mortality among people with established type 2 diabetes. The modest but significant increases in the intensity of treatment in the *ADDITION-Europe* trial were not associated with a reduction in first CV events in screen-detected individuals during five years of follow-up. We aimed to (i) describe the total CV burden in *ADDITION-Europe*; (ii) quantify the impact of the intervention on multiple CV events; and (iii) explore the methodological implications of using first or multiple events to estimate effects.

Materials and methods: In a pragmatic, cluster-randomised, parallel group trial in four centres (Denmark, Cambridge UK, the Netherlands and Leicester UK), 343 general practices were randomised to screening plus routine care of diabetes according to national guidelines (RC; 1,379 patients), or screening and promotion of target-driven, intensive treatment of multiple risk factors (IT; 1,678 patients). The Wei, Lin, and Weissfeld method was used to estimate the effect of the intervention on the hazard of independently adjudicated cardiovascular events (cardiovascular mortality, cardiovascular morbidity, revascularisation, and non-traumatic amputation) over a mean follow-up of 5.3 years.

Results: 238 individuals had a first CV event, 71 a second event, and 25 three or more events. The most frequent first events were revascularisations (n=88; 37%), non-fatal MI (n=61; 26%) and CV death (n=48; 20%). The corresponding numbers for second events were 55 (77%), 5 (7%) and 8 (11%) respectively. There was a 17% reduction in the risk of a first primary endpoint (HR 0.83, 95% CI: 0.65 to 1.05). Reduction in the risk of a second primary endpoint was 30% (HR 0.70, 95% CI 0.43 to 1.12).

Conclusion: An intervention achieving modest changes in treatment of screen-detected patients was not associated with significant reductions in the incidence of first or second CV events over five years. Focussing on first events in CVD prevention trials underestimates the total CV burden to patients and the health service. However, the lack of independence between many of the first and second CV events suggests that we should continue to focus on first events when estimating effects of interventions on composite endpoints.

Clinical Trial Registration Number: NCT00237549

Figure 1 The effect of the intervention on the hazard of experiencing 1, 2, 3 and 4 events. Each intervention effect is presented as a hazard ratio within each country and combined across countries using fixed-effects meta-analysis.

2

Lower incidence of cardiovascular events in a recently recruited cohort of Japanese type 2 diabetes patients in primary care settings

M. Oishi¹, H. Yokoyama², K. Kawai³, K. Hirao⁴, H. Takeda⁵, M. Minami⁶, H. Sugimoto⁷, H. Sone⁸, M. Matsushima⁹, A. Kashiwagi¹⁰, Japan Diabetes Clinical Data Management study group;

¹Oishi clinic, Kyoto, ²Jiyugaoka Medical Clinic, Obihiro, ³Kawai Clinic, Tsukuba, ⁴HEC Science Clinic, Yokohama, ⁵Takeda Clinic, Isehara, ⁶Minami Masae Clinic, Fukuoka, ⁷Sugimoto Clinic, Kitakyushu, ⁸University of Tsukuba, ⁹Division of Clinical Epidemiology, Jikei University School of Medicine, Tokyo, ¹⁰Shiga University of Medical Science, Otsu, Japan.

Background and aims: Major changes in treatment regimens over the past years, with more stringent goals for metabolic control and cardiovascular risk management, may yield improvement of cardiovascular morbidity in subjects with type 2 diabetes. The aim was to investigate whether a reduced incidence of cardiovascular disease can be achieved in a newly recruited cohort following the recently advanced concept of multifactorial treatment and followed in primary care settings as compared with previously reported cohorts.

Materials and methods: A prospective study was performed at 17 nationwide clinics of the Japan Diabetes Clinical Data Management (JDDM) study group. Subjects were 2,984 patients with type 2 diabetes without prevalent cardiovascular disease. The main outcome was non-fatal or fatal coronary heart disease, ischemic stroke, or peripheral artery disease and the incidence was compared with previously reported cohorts. The following 4 cohorts dealing with type 2 diabetes without prevalent cardiovascular disease with an observation period of more than 4 years were employed to compare: the Diabetes and Informatics Study Group (DAI), Atherosclerosis Risk in Communities Study (ARIC), Fenofibrate Intervention and Event Lowering in Diabetes Study (FIELD) and United Kingdom Prospective Diabetes Study (UKPDS).

Results: There were 90 cardiovascular events over 10,827 person years of follow-up with a drop-out rate of 6%. The incidences (per 1,000 person years) of composite, coronary heart disease, ischemic stroke and peripheral artery disease in the JDDM were 8.3, 4.4, 3.1, and 0.7, respectively. As shown in the table, each incidence was lowest in the JDDM compared with other cohorts ($p < 0.01$ vs. each cohort). In the JDDM, significant variables predictive of the occurrence of a cardiovascular event were age, duration of diabetes, hemoglobin A_{1c}, high density lipoprotein cholesterol, and urinary albumin by Cox multivariate regression analysis.

Conclusion: The incidence of cardiovascular disease is likely to be reduced in patients with type 2 diabetes followed in primary care settings with a recently-advanced concept of treatment as compared to earlier large-scale cohorts. The novel finding of low cardiovascular disease occurrence may be conferred by the feasibility at primary care settings for providing patients with type 2 diabetes with favorable controls in blood glucose, blood pressure, and lipids, coupled with unique ethnicity/country factors.

Cardiovascular outcomes in different cohort studies of patients with type2 diabetes

	JDDM	DAI	ARIC	FIELD	UKPDS
Number of patients	2,984	11,644	1,460	9,795	2,693
Recruitment year	2004	1998	1987	1998	1977
Incidence(per 1,000 person-years, 95% CI)					
Coronary heart disease	4.4	30.3	10.8	11.1	13.2
Stroke	3.1	NA	5.6	6.8	6.1
Peripheral artery disease	0.7	NA	NA	2.3	4.2

3

Comparison of ACCORD trial outcomes with outcomes estimated from modelled and meta-analysis studies

V. Foos¹, A. Lloyd², N. Freemantle³, D. Grant², W. Herman⁴;

¹IMS Health, Basel, Switzerland, ²IMS Health, London, ³University College London, UK, ⁴University of Michigan, Ann Arbor, USA.

Background and aims: The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial reported significantly higher mortality in type 2 diabetes patients treated with intensive glucose lowering (target HbA1c < 6%) versus standard treatment (target HbA1c 7% - 7.9%). These findings have been interpreted as changing our understanding of the relationship between HbA1c and Cardiovascular (CV) risk at levels of HbA1c below 7. We wished to put the ACCORD findings in context by comparing them with outcomes estimated from other data sources.

Materials and methods: The IMS CORE Diabetes model (CDM) is a validated and widely used computer simulation model that predicts the development and consequences of diabetes complications. The CDM uses data from the UKPDS to predict the relationship between HbA1c and cardiovascular end points as well as all cause mortality. UKPDS risk equations assume that continuing to reduce HbA1c below 7 brings continued reduction in CV risk. We compared outcomes observed in the ACCORD trial with i) predictions from the CDM when the baseline characteristics of the ACCORD population were entered into the model and UKPDS equations were used; ii) predictions by the CDM as above but after modifying the UKPDS equations so that continuing to reduce HbA1c below 7 causes no further reduction in CV risk; iii) a random effects meta analysis of data from three recent large trials: ACCORD, ADVANCE and VADT.

Results: Relative risks of non fatal MI; non fatal stroke; heart failure and all cause mortality are shown in the table. Relative risk of all cause mortality in the intensive treatment group of ACCORD was significantly higher than that predicted by the model based on UKPDS. However, for non fatal stroke, non fatal AMI, and heart failure the model predictions were within 95% CIs derived from ACCORD. Adjusting the model so continuing to reduce HbA1c below 7 causes no further reduction in CV risk brought the model estimates closer to the ACCORD findings for all outcomes, but the difference in all cause mortality remained outside the confidence interval. Predictions from the adjusted model fell within confidence intervals predicted by the meta-analysis for all four events. Table: Relative Risk of important DM events from different data sources (intensive vs standard treatment, point estimate, 95% CI)

Outcome	ACCORD observed	Modelled CDM (i)*	Modelled CDM (ii)**	ACCORD/ADVANCE/VADT Pooled
Non fatal MI	0.79 (0.62-0.92)	0.82	0.76	0.86 (0.74-0.99)
Non fatal stroke	1.10 (0.75-1.5)	0.91	0.83	0.97 (0.83-1.12)
Heart failure	1.23 (0.93-1.49)	0.97	0.93	1.03 (0.86-1.23)
All cause mortality	1.27 (1.01-1.46)	0.95	0.94	1.07 (0.87-1.32)

* HbA1c benefits from UKPDS: ** Continuing to reduce HbA1c below 7 causes no further reduction in CV risk

Conclusion: Relative risk of all cause mortality in ACCORD was significantly different from that modelled based on previous data. This difference was not seen in other endpoints, was not consistent across recent studies, and was not fully explained by hypothesising a lower limit of 7 for HbA1c benefit. Observed mortality effects in the ACCORD trial may be related to factors other than glucose lowering.

4

An improved model to estimate lifetime health outcomes of patients with type 2 diabetes using 30-year follow-up data from the United Kingdom prospective diabetes study

A.J. Hayes¹, P. Clarke¹, J. Leal², M.L. Alva², R. Coleman³, A. Gray², R.R. Holman²;

¹Sydney School of Public Health, University of Sydney, Australia, ²Health Economics Research Centre, University of Oxford, ³Diabetes Trials Unit, University of Oxford, UK.

Background and aims: To extend and enhance the existing United Kingdom prospective diabetes study (UKPDS) Outcomes simulation model for type 2 diabetes by using additional patient-level data from the ten-year post-trial monitoring phase of the UKPDS to re-estimate risk equations for diabetic complications and death.

Materials and methods: Equations for forecasting the occurrence of ten diabetes-related complications and death were estimated using data from 5102 UKPDS patients followed for up to 30 years. Covariates included in the risk equations were demographic characteristics, smoking status, classical risk factors (systolic blood pressure, HbA1c, lipid levels and history of other comorbidities). New risk factors examined as potential covariates were micro/macro albuminuria, heart rate, white blood cell count, haemoglobin and estimated glomerular filtration rate. Also available as updated, rather than just baseline covariates, were peripheral venous disease (PVD), body mass index and atrial fibrillation. In addition to the six complications modelled previously (1st myocardial infarction (MI), 1st stroke, ischaemic heart disease, heart failure, blindness and renal failure) and death, we have now included diabetic ulcer, renal impairment, 2nd MI and 2nd stroke. Parametric proportional hazards models equations were estimated to predict absolute and relative risks associated with each event type. These were then combined in a simulation model to predict event rates, life expectancy and quality adjusted life expectancy for individuals and populations with different characteristics.

Results: All event equations utilised more than 60,000 patient years of data. For each of the original outcomes we have approximately twice as many total events as used in the estimation of the previous risk equations, for example the 1st MI equation has 925 events compared with 495 previously. The additional outcomes are 175 2nd MIs, 47 2nd strokes, 86 ulcer events and over 2000 cases of renal impairment. In terms of the new risk factors, micro/macro albuminuria was a significant covariate in 8 of the equations with hazard ratios (HR) ranging from 1.3 (95%CI 1.1-1.5) for death to 4.8 (95%CI 2.8-8.5) for renal failure. PVD was a significant covariate in 7 equations with HRs ranging from 1.3 (95%CI 1.1-1.5) for death to 6.3 (95%CI 2.9-6.9) for amputation. White blood cell count was a significant covariate in 4 equations with HRs ranging from 1.05 (95%CI 1.02-1.07) for 1st stroke to 1.06 (95%CI 1.03-1.10) for blindness. Notably, atrial fibrillation was associated with a high risk of 1st stroke (HR 4.4, 95%CI 2.9- 6.6) and heart failure (HR 4.7, 95%CI 2.7-8.2).

Conclusion: The new UKPDS Outcomes Model, with its additional risk factors and increased number of events, can simulate a wider range of long-term outcomes and more reliably estimate risk, particularly for older people with diabetes. Improved prediction of likely clinical outcomes will permit more accurate future economic evaluations of interventions in type 2 diabetes.

Calculating risk in patients with type 2 diabetes in The Netherlands: UKPDS versus ZODIAC risk engine performance (ZODIAC-26)

N. Kleefstra^{1,2}, G.W.D. Landman¹, K.J.J. van Hateren¹, R.O.B. Gans², K.H. Groenier³, H.J.G. Bilo^{1,2};

¹Diabetes Centre, Isala Clinics, Zwolle, ²Department of Internal Medicine, University Medical Center Groningen, ³Department of General Practice, University Medical Center Groningen, Netherlands.

Background and aims: Risk prediction models obtained in samples from the general population do not perform well in type 2 diabetic patients. Therefore, specific diabetes risk engines such as the UKPDS risk engine have been developed. This study presents an alternative diabetes-specific equation for estimation of the absolute 10 year risk of fatal cardiovascular disease (CVD) in type 2 diabetic patients and compares it to the more commonly used UKPDS. **Materials and methods:** This study was based on the ZODIAC cohort, including 1353 diabetes patients treated in primary care in the Netherlands,

with a median follow-up period of 9.6 years. The UKPDS risk engine was evaluated by comparing observed CVD mortality to expected CVD mortality as calculated by the UKPDS risk engine. The alternative risk equation was calculated with Cox proportional hazard models. Calibration was tested with the Hosmer-Lemeshow test, and discrimination capacities were calculated with the C-statistic. Possible predictors were: age, gender, smoking, blood pressure, BMI, diabetes duration, HbA1c, creatinine, albumin to creatinine ratio, macrovascular complications, lipid lowering therapy and antihypertensive medication use.

Results: During a median follow-up of 10 years, 570 (42%) patients died, 280 of whom died of cardiovascular disease (49%), average age at baseline was 68 (SD 12) years, and average HbA1c was 7.5% (SD 1.2). The predicted UKPDS fatal event rate was 29% as opposed to the observed rate of 18%. The alternative risk calculator eventually incorporated age, HbA1c, smoking, serum creatinine, urinary albumin to creatinine ratio and macrovascular complications. Calibration was sufficient, May and Hosmer test of fit; p-value = 0.29 (see figure 1) and discrimination was excellent with a C-statistic of 0.80. 10-year risk (CVD) = $1 - \exp\left\{-(0.089 \cdot \text{age}-60) + (0.418 \cdot \text{smoking}) + (0.230 \cdot \text{HbA1c}-7) + (0.647 \cdot \text{macrovascular complications}) + (0.016 \cdot \text{creatinine}-80) + (0.233 \cdot \log \text{urinary albumin creatinine ratio})\right\}$

Conclusion: The UKPDS risk engine overestimated CVD mortality risk considerably in this population. An alternative risk equation, which includes creatinine and albuminuria and excludes lipid profile and blood pressure, is nowadays probably more precise in type 2 diabetes patients treated in primary care in The Netherlands. Our model needs external validation. Figure. Observed and Expected deaths from cardiovascular disease.

Health-related quality of life predicts survival in patients with type 2 diabetes and myocardial infarction: a report from the DIGAMI2 trial

B. Kjellström¹, L. Venskutnyte¹, K. Brismar², J. Öhrvik¹, L. Rydén¹;

¹Cardiology, Medicine, ²Molecular Medicine and Surgery, Stockholm, Sweden.

Background and aims: Diabetes is a major risk factor for cardiovascular (CV) disease and has a considerable impact on survival as well as health-related quality of life (HRQL). A prognostic link between self-reported HRQL and unfavourable outcome has been reported but is not well explored in patients with type 2 diabetes (T2DM) and acute myocardial infarction (AMI).

Materials and methods: The DIGAMI-2 HRQL sub-study recruited 509 AMI patients with T2DM (median age 67.7 years, interquartile range 59.9–74.1; male 68%). Self-reported HRQL was evaluated at hospital admission by a graded rating scale (RS) where 0 is death and 100 is perfect health. The median follow-up was 2.1 years (interquartile range 1.03–3.00). Prospective associations between all-cause, CV death (CVD) and CV events (CVE = CVD, nonfatal AMI or stroke) were assessed applying logistic regression.

Results: During follow-up 152 (30%) patients had a CVE and 86 (17%) died (70 CVD and 16 other). The RS scores at admission were significantly lower in patients who experienced a CVE (69 ± 19 vs. 62 ± 18 , $p < 0.001$), CVD (68 ± 19 vs. 62 ± 18 , $p = 0.012$) or all-cause mortality (68 ± 18 vs. 62 ± 19 , $p < 0.01$) than in those free from events. The RS score was a significant predictor for CVE (Odds ratio (OR) per 10 units increase in RS: 0.83, 95% Confidence Interval (95%CI): 0.75–0.93), CVD (OR: 0.85, 95%CI: 0.73–0.98) and all-cause mortality (OR: 0.84, 95%CI: 0.74–0.96). Women scored somewhat lower than men (64 ± 20 vs. 68 ± 19 ; $p = 0.034$). The RS score significantly predicted CVE (OR:

0.81, 95%CI: 0.71–0.93), CVD (OR: 0.80, 95%CI: 0.68–0.95) and all-cause mortality (OR: 0.77, 95%CI: 0.66–0.91) in men, however, not in women.

Conclusion: A low RS score is of prognostic significance in patients with type 2 diabetes and acute myocardial infarction thereby serving as an easily obtained indicator of patients at high risk for all-cause and CV mortality. The predictive value seems to be higher in men.

OP 02 Diabetic foot and acute osteoarthropathy

7

Potential explanation for lower incidence of foot ulceration in Asian compared to European patients with type 2 diabetes

H. Fadavi¹, M. Tavakoli¹, I.N. Petropoulos¹, N. Caturvedi², M. Jeziorska³, A.J.M. Boulton⁴, R.A. Malik¹, C.A. Abbott¹;

¹Cardiovascular Research Group, University of Manchester, ²National Heart and Lung Institute, Imperial College of London, ³Tissue Injury and Repair Group, University of Manchester, ⁴Manchester Royal Infirmary, University of Manchester, UK.

Background and aims: Diabetic patients of South Asian origin in the UK have about one-third the risk of foot ulceration compared to Europeans. Neuropathy and vascular disease are primary determinants of the risk of foot ulceration. To define differences in predisposing risk factors for ulceration, 73 South Asian (age: 60 ± 11 ; duration of diabetes: 12.9 ± 0.769 ; BMI: 30.1 ± 0.6) and 79 European (age: 63 ± 8 , duration of diabetes: 11.9 ± 0.7 ; BMI: 33.6 ± 0.6) patients with Type 2 diabetes underwent assessment of neuropathy using: neuropathy symptoms (NSP) and severity (NDS), electrophysiology (NCS), Vibration Threshold (VPT), Thermal threshold (warm and cold sensation), heart rate variability (HRV), Neuropad, and corneal confocal microscopy. Vascular integrity was assessed using laser Doppler and TCPO2.

Results: Comparing Asians with Europeans: They had a significantly higher HbA1c (8.2 ± 0.2 v 7.6 ± 0.2 , $P=0.02$) but comparable BP: Systolic/Diastolic ($133/72 \pm 1.9$ v $135/70 \pm 1.9$), $P=0.56$). Triglycerides were significantly lower in Asians (1.9 ± 0.11) compared to Europeans (2.4 ± 0.2), $P=0.008$, whilst HDL and total cholesterol were comparable. NSP (7.0 ± 0.8 v 6.5 ± 0.6), NDS (3.4 ± 0.4 v 3.8 ± 0.3 , $P=0.43$) and VPT (14.7 ± 1.2 v 17.5 ± 1.3), $P=0.10$) were comparable. Sural conduction velocity (45.5 ± 0.9 v 44.9 ± 0.81) was comparable but amplitude (11.8 ± 1.0 v 8.3 ± 0.7 , $P=0.004$) was better in Asians. WS (41.6 ± 0.5 v 42.0 ± 0.4 , $P=0.54$), CS (24.4 ± 0.7 v 23.9 ± 0.6 , $P=0.62$) did not differ. Corneal confocal microscopy showed no difference in corneal nerve fibre density (23.7 ± 1.6 v 24.8 ± 1.1 , $P=0.56$ or tortuosity (17.5 ± 0.7 v 20.4 ± 0.9 , $P=0.39$) but nerve fibre length (19.5 ± 1.2 v 18.3 ± 0.8 , $P=0.03$ and nerve branch density (36.1 ± 4.1 v 28.1 ± 2.0 , $P=0.05$) were better in Asians. HRV response to deep breathing was non significantly better in Asians compared to Europeans (8.3 ± 0.7 v 6.9 ± 0.5 , $P=0.11$). TCPO2 was significantly higher in Asians (63.2 ± 1.3) v Europeans (57.6 ± 1.43), $P=0.005$. The laser Doppler hyperaemic response (648.1 ± 53.4 v 531.7 ± 34.9), $P=0.06$ was higher in Asian compared to European diabetic patients.

Conclusion: In conclusion we demonstrate that despite worse glycaemic control, Asian patients have better small fibre function and structure compared to European patients with Type 2 diabetes. Furthermore they have higher foot skin oxygenation and hyperaemic blood flow response to heating, which may protect from the development of foot ulceration.

Imaging by white light absorption spectroscopy to assess peripheral limb blood flow in diabetes

W.J. Jeffcoate¹, A. Musgrove¹, E.L. Game¹, R.J. Hinchliffe², D. Clark³, N. Savic³, P. Rodmell⁴;

¹Diabetes and Endocrinology, Nottingham University Hospitals Trust, ²Vascular Surgery, St George's Hospital, London, ³Medical Physics and Clinical Engineering, Nottingham University Hospitals Trust, ⁴Department of Electrical and Electronic Engineering, University of Nottingham, UK.

Background and aims: When white light is reflected back from skin, its spectral characteristics depend on the oxygenation of the blood in the soft tissues, and this can be determined using hyperspectral (HS) imaging. The use of the technique has hitherto been hampered by the scattering of light which makes the relationship between absorption and attenuation non-linear. The aim of this study was to determine if a new algorithm might enable the use of HS imaging to predict clinical outcome in diabetic foot disease. **Materials and methods:** The method was validated *in vitro* by bubbling nitrogen through blood from healthy volunteers and measuring oxygen saturation both by blood gas analysis and by HS imaging of a sample trapped between two microscope slides. HS imaging was also undertaken in patients with diabetic foot ulcers presenting consecutively to a specialist out-patient

centre, and an association was sought clinical outcome at 12 and 24 weeks. The studies had ethical committee approval and participants gave written informed consent. Clinical researchers and those analysing the HS images were each blind to the results of the other.

Results: There was a very close positive correlation ($r=0.9939$, linear regression) between *in vitro* HS assessment of oxygenation in blood of known saturation between 2% and 100%. An index ulcer was selected in 43 people newly presenting to the clinic. Mean age was 62.7 (SD 12.2) years; 12 women, 31 men; 6 type 1 DM, 37 type 2. 18 ulcers were infected. There was no difference in oxygenation assessed by HS imaging at different sites on the foot at baseline, and no correlation between HS imaging and either ABPI or skin temperature. 26 ulcers healed by 12 weeks. There was a negative correlation between healing by this time and the results of baseline HS imaging ($r=-0.392$, $p=0.009$; Pearson): indicating that greater degrees of oxygenation of haemoglobin were associated with worse clinical outcome. Regression analysis revealed a positive correlation between the results of HS imaging and time to healing ($r=0.527$, $p=0.03$), with higher oxygenation again being associated with a worse outcome. This was observed in those either with ($p=0.009$) or without ($p=0.044$) clinical infection. No correlation was observed between healing and time to healing and either skin temperature or ABPI. 28 ulcers healed by 24 weeks (one patient died with ulcer unhealed). No correlation was observed between any baseline measure and either healing or time to healing at 24 weeks.

Conclusion: Although the result is superficially counterintuitive, the negative relationship between clinical outcome and oxygenation determined by HS imaging is explained by the fact that HS imaging is a measure of the intravascular oxygen saturation of haemoglobin. Neuropathy is associated with higher oxygen saturation of venous blood, with implied lower oxygenation of the extravascular tissues. In patients with abnormal microvasculature, HS imaging will therefore have an inverse relationship with both extravascular oxygenation and healing. HS imaging could prove a valuable predictor of 12 week outcome in newly presenting foot disease in diabetes.

Neurotensin downregulates the pro-inflammatory properties of skin-dendritic cells and increases epidermal growth factor expression

L. da Silva^{1,2}, L. Moura^{1,2}, B.M. Neves^{1,3}, M.T. Cruz^{1,3}, E. Carvalho¹;

¹Center for Neurosciences and Cell Biology, ²Faculty of Sciences and Technology, ³Faculty of Pharmacy, Coimbra, Portugal.

Background and aims: Diabetic foot ulcer is a painless and harmful disease that delays skin wound healing in diabetic patients. This illness is a consequence of differential causes, like neuropathy, impaired angiogenesis and decreased blood flow supply to the site of injury, cytokines deregulation, impaired expression of extracellular matrix (ECM) proteins and ECM remodeling by metalloproteinases. In the last three decades, neuropeptides received much attention by the scientific community, as their impairment, for instance by neuropathy, may induce delayed WH. Neuropeptides modulate skin cells function, particularly skin inflammation. As recent reports have revealed the neuropeptide neurotensin (NT) as an immune mediator in the Central Nervous System and the gastrointestinal tract and its effects in the skin have not been identified, in this study we investigated the effects of NT on signal transduction and on pro/anti-inflammatory function of skin dendritic cells in the presence/absence of the inflammatory stimuli lipopolysaccharide (LPS).

Materials and methods: Fetal-skin dendritic cells (FSDC) were maintained in IMDM medium (control) or incubated with 10 nM of NT alone or simultaneously with LPS for 5 to 60 min to analyze the activation of signaling pathways by WB and during 6 to 30 h to determine neurotensin receptors (NTRs), cytokines and growth factors expression by real time RT-PCR. FSDC viability was determined by the MTT assay while the cytoskeleton and nuclei morphology of FSDC was determined by immunostaining for actin and nuclei.

Results: We observed that FSDC constitutively express NTR1 and NTR2 and that LPS treatment diminishes NTR1 (-1.14 ± 0.55 , $n=3$), NTR2 (-1.88 ± 0.77 , $*p<0.05$, $n=3$), while expression of NT was increased by 3.75 ± 0.50 ($***p<0.0001$, $n=3$) relatively to control. In LPS stimulated cells, NT downregulated significantly the activation of the inflammatory signaling pathways NF- κ B and JNK, while the survival pathway ERK was upregulated. Neurotensin alone downregulated the expression of the cytokines IL-6 (-0.34 ± 0.26 , $n=3$), TNF- α (-1.10 ± 0.62 , $*p<0.05$, $n=3$), IL-10 (-1.77 ± 0.91 , $*p<0.05$, $n=3$) and the vascular endothelial growth factor (VEGF) (-0.29 ± 0.18 , $*p<0.05$, $n=4$) fold

relatively to control, while the epidermal growth factor (EGF) (1.45 ± 1.18 , $*p < 0.05$, $n=4$) was significantly upregulated. Simultaneous cell exposure to LPS and NT induced a similar cytokine profile to that one induced by NT alone. **Conclusion:** Overall, our results give new perspectives in the design of new therapies for skin diseases, like diabetic wound healing. Moreover, once NT levels are determined in skin pathologies and if NT is then defective, a treatment with NT may promote WH. Further similar studies should be performed both in other skin cells and in *in vivo* conditions, in order to disclose the potential benefic therapeutic role of NT on skin pathological conditions. *Supported by: SAU-MII/098567/2008 and EFSD/JDRF/Novo Nordisk grant SFRH/BD/60837/2009 (LM).*

Histological features of acute Charcot neuroarthropathy in diabetes

R.G. Pearson¹, K.S.S. Shu¹, J. Lowe², F.L. Game³, W.J. Jeffcoat³, B.E. Scammell¹;

¹Orthopaedic & Accident Surgery, University of Nottingham,

²Histopathology, University of Nottingham, ³Diabetes and Endocrinology, Nottingham University Hospitals Trust, Nottingham, UK.

Background and aims: To provide a description of the histological features of bone affected by acute Charcot neuropathic osteoarthropathy (CN; acute Charcot foot).

Materials and methods: As part of a study of pro-inflammatory cytokines and signalling pathways in CN, needle biopsies were taken with full aseptic precautions, using a 14 g needle and yielding a sample approximately 2x8 mm. Nine of 17 patients newly presenting between Feb 2009 and Jan 2010 to a single specialist unit with active CN gave informed consent to undergo bone biopsy, under local anaesthesia where necessary. Control samples were examined from nine non-diabetic patients who were undergoing elective corrective surgery of the foot.

Results: There were no operative complications. There were two women and seven men with CN and mean age was 60.1 years (SD 8.31). The total median (range) duration of the active disease at the time of biopsy was estimated to be 10 (4–46) weeks. Histological examination revealed bone surface remodelling to be active in CN bone as assessed by osteoclast and osteoblast numbers. Some CN bone exhibited regions of chondroid material forming woven bone. The marrow space tended to show replacement of adipose tissue by loose spindle cells in the majority of CN specimens. In some cases this was vascular, resembling vascular granulation tissue. In other cases the marrow space was replaced by collagenous tissue with low vascularity. There was moderate hypercellularity of the periosteum in a number of biopsies. No sample showed features of an acute inflammatory reaction suggesting osteomyelitis. Overall, cases could be divided into three groups, but with some overlap in individual samples.

- Lamellar bone with active surface remodelling of trabeculae associated with microfractures. Marrow space replaced by loose spindle cells.
- Active remodelling of woven bone, with vascularity of the marrow space associated with increased vascularity, possibly suggesting a response to fracture.
- Sclerosis of bone characterised by broad lamellar trabeculae with collagenous replacement and a low vascularity of the marrow space.

Microbiological examination on the CN patients revealed no bacteria on Gram stain, although scanty polymorphs were observed in two cases. Coagulase negative *Staphylococcus aureus* was cultured from three cases and MSSA was cultured from a fourth. This fourth case had clinical and radiological evidence of osteomyelitis affecting the middle and distal phalanges of the third toe, but the bone sample was taken from the second metatarsal head. Histological examination of the biopsy from this last case revealed no features of acute osteomyelitis.

Conclusion: Given the occasional difficulty encountered in distinguishing between CN and osteomyelitis both clinically and on imaging, as well as their occasional concurrence, and given the increased emphasis currently placed on the use of histological and microbiological examination of bone to confirm the diagnosis of osteomyelitis of the foot in diabetes, it is important to document the results of histological and microbiological examination of bone in CN. This study also indicated that bone biopsy can be undertaken without apparent complication in this condition and examination of bone could therefore be used more frequently in order to explore the pathogenesis of this condition.

11

The proinflammatory cytokines TNF- α and IL-6 modulate RANKL-mediated osteoclastic resorption *in vitro* in patients with acute Charcot osteoarthropathy

N.L. Petrova¹, C. Shanahan², M. Edmonds¹;

¹Diabetic Foot Clinic, King's College Hospital, London, ²Cardiovascular Department, King's College London, UK.

Background and aims: The mechanisms of pathological bone resorption in acute Charcot osteoarthropathy are not fully understood. Recently, using a technique to generate functional human osteoclasts from peripheral blood mononuclear cells, we demonstrated that receptor activator of nuclear factor κ B ligand (RANKL) plays an important role as an activator of osteoclastic resorption in acute Charcot osteoarthropathy. However, it is not known whether RANKL-mediated osteoclastic resorption can be modulated by the proinflammatory cytokines TNF- α and IL-6. Thus the aim of this study was to investigate whether TNF- α and IL-6 can modulate RANKL-mediated osteoclastic activity *in vitro* in acute Charcot osteoarthropathy by using neutralising antibodies to TNF- α and IL-6.

Materials and methods: We have studied 6 patients with acute Charcot osteoarthropathy, 6 patients with diabetes and 4 healthy subjects with no history of diabetes. Peripheral blood mononuclear cells, which act as osteoclast precursors, were cultured *in vitro* on bovine disks in the presence of (1) macrophage-colony stimulating factor (M-CSF) and RANKL, (2) M-CSF, RANKL and neutralising antibody to TNF- α and (3) M-CSF, RANKL and neutralising antibody to IL-6. After 21 days in culture, the bovine discs were stained with toluidine blue and osteoclastic resorption was determined and expressed as percentage of the eroded surface.

Results: The newly generated osteoclasts in patients with acute Charcot osteoarthropathy exhibited increased resorbing activity in cultures with M-CSF and RANKL compared with diabetic and healthy controls ($p=0.004$). The percentage of bone resorption of the bovine disks was significantly greater in Charcot patients compared with diabetic patients ($35.9\% \pm 3.7$ versus $14.9\% \pm 4.4$, mean \pm SEM; $p=0.005$) and also greater in Charcot patients compared with healthy subjects ($35.9\% \pm 3.7$ versus $17.3\% \pm 3.5$, $p=0.007$). The addition of neutralising antibody to TNF- α to the cultures with M-CSF and RANKL led to a marked decrease in the osteoclastic resorption only in patients with Charcot osteoarthropathy (from $35.9\% \pm 3.7$ to $25.4\% \pm 12.4$, $p=0.009$) but not in patients with diabetes (from $14.9\% \pm 4.4$ to $14.9\% \pm 3.3$, $p=0.984$) nor in healthy subjects (from $17.3\% \pm 3.5$ to $17.1\% \pm 3.1$, $p=0.851$). The addition of neutralising antibody to IL-6 had a variable effect on the osteoclastic resorption in the three groups: it led to a significant decrease in osteoclastic resorption in patients with acute Charcot osteoarthropathy (from $35.9\% \pm 3.7$ to $29.3\% \pm 1.9$, $p=0.49$) and to a non-significant decrease in healthy controls (from $17.3\% \pm 3.5$ to $10.8\% \pm 32.3$, $p=0.261$). Unexpectedly, it led to a significant increase of bone resorption in patients with diabetes (from $14.9\% \pm 4.4$ to $22.7\% \pm 5.6$, $p=0.022$).

Conclusion: In acute Charcot osteoarthropathy, RANKL-mediated osteoclastic resorption is modulated *in vitro* by the proinflammatory cytokines TNF- α and IL-6.

Local and systemic concentrations of pro-inflammatory cytokines, osteoprotegerin, sRANKL and bone turnover markers in acute Charcot foot and in controls

H. Divyateja¹, K.S.S. Shu², R.G. Pearson², B.E. Scammell², F.L. Game³, W.J. Jeffcoat³;

¹Clinical Chemistry, Nottingham University Hospitals Trust, ²Division of Orthopaedic and Accident Surgery, University of Nottingham, ³Diabetes and Endocrinology, Nottingham University Hospitals Trust, Nottingham, UK.

Background and aims: It is thought that the pathogenesis of the acute Charcot foot (CN) is dependent on activation of the osteoprotegerin (OPG)/RANKL signalling pathway by pro-inflammatory cytokines and this stimulates increased bone breakdown. As part of a study designed to investigate these processes in greater detail, we sought to determine the differences that may exist between the concentrations of pro-inflammatory cytokines, OPG/sRANKL and bone turnover markers in the local and systemic circulation in order to determine the usefulness or otherwise of forearm vein sampling in future studies in this area.

Materials and methods: The study had ethical approval and patients with active CN managed at a single specialist centre between February 2009 and January 2010 gave informed consent to have samples of venous blood taken from the dorsal veins of both the affected and contralateral foot, as well as a forearm vein. Serum was aliquotted and stored at -20°C until assayed in batches for CRP, alkaline phosphatase (ALP), CTX, IL-6, IL-1, TNF- α , OPG and sRANKL. The results were compared with those of 17 non-diabetic control patients who gave consent to have sampling from a dorsal vein of the foot immediately prior to elective corrective surgery to the foot.

Results: 17 patients with CN (mean age 57.7, range 44–78 years; 5 T1DM, 12 T2DM) gave informed consent to participate. In patients with CN there was a significant difference ($p=0.003$, Chi square) between the concentrations of both IL-6 and CTX in local and systemic venous samples, with the highest concentrations being in blood from the affected foot (median IL-6: affected foot 7.6 pg/mL (95% CI 1.3–22.9), contralateral foot 5.8 pg/mL (8.6–12.1), arm 4.1 pg/mL (1.1–14.3); median CTX: affected foot 0.79 mcg/L (0.34–1.60), contralateral foot 0.5 mcg/L (0.14–1.10), arm 0.42 mcg/L (0.12–0.88)). No difference was observed between local and systemic samples for any other analyte in CN. When concentrations in the dorsal veins of the affected foot in CN and controls were compared, higher concentrations of CTX ($p=0.003$), ALP ($p=0.003$), OPG ($p=0.003$) and IL-6 ($p=0.000$) were observed in CN, but there were no differences in CRP, sRANKL and IL-1.

Conclusion: The present results confirm the expected increase in bone turnover markers in CN, and concentrations were highest in dorsal vein blood from the affected side. The increase in OPG may reflect the known association with diabetes. The absence of difference in concentrations from the local and systemic samples in patients with CN suggests that concentrations in forearm vein blood could be taken to reflect local concentrations of the analytes studied, with the single exception of IL-6. The marked elevation of IL-6 in dorsal vein blood of the affected foot in CN suggests that this cytokine may be particularly important in the pathogenesis of this disease.

High intake of protein and processed meat is associated with increased incidence of type 2 diabetes

U.C. Ericson, E. Sonestedt, B. Gullberg, S. Hellstrand, G. Hindy, E. Wirfält, M. Orho-Melander;
Department of Clinical Sciences in Malmö, Lund University, Malmö, Sweden.

Background and aims: Diets high in protein have shown promising results on short-term weight reduction and glycemic control. However, understanding of how dietary macronutrient composition relates to long-term risk of obesity related chronic disease, such as type 2 diabetes is limited. We examined intakes of macronutrients, fiber and different food sources of protein in relation to incidence of type 2 diabetes.

Materials and methods: In total 27 140 individuals, 45–74 years, from the population based Malmö Diet and Cancer cohort were included. Dietary data was collected with a modified diet history method, including registration of cooked meals. During 12 years follow-up, 1709 incident type 2 diabetes cases were identified. We used Cox proportional hazard model to calculate hazard ratios of diabetes incidence in quintiles of dietary intakes with adjustments for several potential confounders.

Results: High protein intake was associated with increased risk of type 2 diabetes (hazard ratio [HR] = 1.37; 95% confidence interval [CI]: 1.17 to 1.61, P for trend < 0.001). In addition, 5 energy % increased consumption of protein at the expense of carbohydrates was associated with increased risk (HR = 1.17; 95% CI: 1.06 to 1.29). High intake of processed meat was also associated with increased risk (HR = 1.17; 95% C.I. 1.00 to 1.36, P for trend = 0.005), but the positive association between protein intake and type 2 diabetes remained significant after adjustment for intake of processed meat. Intake of fiber rich breads and cereals was inversely associated with type 2 diabetes (HR = 0.95; 95% CI: 0.92 to 0.98, P for trend = 0.005).

Conclusion: Results from this large population based study indicate that high protein intake increase the incidence of type 2 diabetes. Replacing protein with carbohydrates may be favorable, especially if fiber rich breads and cereals are chosen as carbohydrate sources.

Diets poor in fibre, vegetable protein and polyunsaturated fat are associated with inflammation and endothelial dysfunction in type 1 diabetes mellitus: the EURODIAB study

B.C.T. van Bussel¹, S.S. Soedamah-Muthu², R.M.A. Henry¹, C.G. Schalkwijk¹, I. Ferreira¹, N. Chaturvedi³, M. Toeller⁴, J.H. Fuller⁵, C.D.A. Stehouwer¹, EURODIAB Prospective Complications Study Group;
¹Maastricht University Medical Centre, Netherlands, ²Wageningen University, Netherlands, ³Imperial College London, UK, ⁴Heinrich-Heine-University, Duesseldorf, Germany, ⁵Royal Free and University College London Medical School, UK.

Background and aims: To investigate the association between nutrient consumption and biomarkers of endothelial dysfunction (ED) and low-grade inflammation (LGI) in type 1 diabetes mellitus.

Materials and methods: We investigated 491 individuals. Nutrient consumption and lifestyle risk factors were measured in 1989 and 1997. Biomarkers of ED (von Willebrand factor, soluble vascular cell adhesion molecule-1 and soluble endothelial selectin) and LGI (C-reactive protein, interleukin-6 and tumour necrosis factor- α) were measured in 1997 and averaged into z scores. Nutrients were adjusted for total energy intake by the nutrient residual method. Data were analysed with generalised estimating equations. We report average 8-year differences in nutrient consumption per +1 standard deviation (SD) of 1997 ED or LGI z scores. Results are adjusted for sex, age, duration of diabetes, investigation centre, body mass index, energy intake, smoking behaviour and alcohol consumption, and other nutrients.

Results: A one SD elevation in endothelial dysfunction z score was associated with a diet over an 8-year period that was lower in fibre [β (95%CI): -0.09(-0.18;-0.004)], polyunsaturated fat [-0.18(-0.32;-0.05)] and vegetable protein [-0.10(-0.20;-0.001)]. For the low-grade inflammation z score the results showed a diet lower in fibre [-0.09(-0.17;-0.01)] and polyunsaturated fat [-0.14(-0.24;-0.03)], and higher in cholesterol [0.10(0.01;0.18)].

Conclusion: In type 1 diabetes mellitus, consumption of less fibre, polyunsaturated fat and vegetable protein and more cholesterol over an 8-year study period was associated with more ED and LGI. This supports the hypothesis that following the current dietary guidelines in type 1 diabetes mellitus may reduce cardiovascular disease risk by affecting ED and LGI favourably.

15

Post-prandial high fat intake leads to acute exposure to circulating endotoxin in type 2 diabetes mellitus subjects

A.L. Harte¹, M.V. Chittari¹, K.C. McGee¹, A. Ceriello², N. Al Daghr³, J.P. O'Hare¹, G. Tripathi¹, S. Kumar¹, P.G. McTernan¹;

¹Division of Metabolic and Vascular Health, University of Warwick, Coventry, UK, ²Institut d'Investigacions Biomèdiques, Barcelona, Spain, ³Biochemistry, King Saud University, Riyadh, Saudi Arabia.

Background and aims: Habitual post-prandial absorption of dietary fats increases systemic atherogenic lipoproteins and a pro-inflammatory response, a condition exacerbated by obesity, insulin resistance (IR) and type 2 diabetes mellitus (T2DM). In addition to the systemic influence of dietary lipids, gut derived bacteria [endotoxin or lipopolysaccharide (LPS)] is absorbed coupled to damaging lipoproteins as it crosses the mucosa. As such, atherogenic and inflammatory risk may arise through changing dietary lipoprotein patterns and increasing circulating LPS. The heightened postprandial systemic lipids and LPS could directly impact on adipose tissue as our previous *in vitro* studies suggest. However no analysis to date has examined whether metabolic state may alter lipid coupled circulating LPS post feeding. Therefore these studies sought to establish whether a SFA rich meal increases circulating endotoxin absorption and whether this is altered in disease states.

Materials and methods: All subjects (n=58) with and without T2DM were given a high-fat meal (meal: 75g fat, 5g carbohydrate, 6g protein) following an over-night fast [non-obese controls (NOC): age: 39.8(Mean±SE) 11.2yr, BMI: 25.3(mean±SD)3.3Kg/m²; n=10; Obese: age: 43.8±9.5yr; BMI: 33.3±2.6Kg/m²; n=15; impaired glucose tolerance (IGT): age: 41.7±3.3yr; BMI: 32.0±4.5Kg/m²; n=12; T2DM: age: 46.4±9.6yr; BMI: 30.1±5.2 Kg/m²; n=21]. Baseline (0 hr) and post-prandial sera (1–4 hr) were taken from subjects and LPS, inflammatory cytokines and lipid levels measured.

Results: Baseline circulating LPS was significantly higher in the T2DM, IGT, and obese subjects Vs NOC subjects (Baseline LPS: T2DM: 5.73(mean±SEM)0.85EU/mL*; Obese: 5.75±1.45EU/mL*; IGT: 5.83±0.45EU/mL* Vs NOC: 3.55±0.50EU/mL; *p<0.05). Comparatively baseline circulating LPS levels were 61.41% higher in T2DM subjects Vs NOC subjects. Ingesting a high-fat meal led to a significant rise in LPS levels in T2DM and IGT subjects over the post-prandial time period compared with baseline levels (T2DM: LPS 0 hr: 5.73±0.85 EU/mL Vs. T2DM 4 hr post-prandial (pp): 16.89±3.67EU/mL*; IGT: LPS 0 hr: 5.83±0.45 EU/mL Vs 4 hr pp: 7.69±0.72EU/mL*, p<0.05, **p<0.001); whilst only a trend was observed for obese or NOC subjects. These findings also showed that at 4hr post feed T2DM subjects exhibited a mean LPS level 118.5% higher than that of the NOC subjects. A strong positive correlation between increasing BMI and log LPS was also noted in the NOC and obese cohorts (r value= 0.501** and 0.301*, respectively; **p<0.001, *p<0.05), which was ultimately lost with either IGT or T2DM status.

Conclusion: In summary these studies highlighted that postprandial exposure to a high fat meal elevates circulating LPS irrespective of metabolic state, as early as 1 hr post meal. Post-feeding leads to a substantial increase in circulating LPS in IGT and T2DM subjects, suggesting that metabolic endotoxaemia is exacerbated post feeding as IR status increases. Our data highlight that T2DM subjects are exposed to as much as 118% more circulating LPS post-prandially, per high fat meal. Therefore a continual grazing routine will cumulatively promote their pathogenic condition more rapidly than other individuals due to the elevated exposure to endotoxin.

Plasma insulin and inflammatory markers prior to weight loss can predict dietary responders

L. Kong¹, F. Hajdouch¹, P. Wuillemin², J. Bastard³, S. Fellahi³, D. Bonnefont-Rousselot⁴, R. Bittar⁴, A. Basdevant⁵, J. Zucker¹, J. Doré⁶, K. Clément¹, S. Rizkalla¹;

¹INSERM U872 team 7 Nutrimique, ²LIP6 Département DÉSIR Équipe Décision, Université Pierre et Marie Curie-Paris6, ³Service de Biochimie et Hormonologie, Hôpital Tenon, ⁴Assistance Publique-Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, Département de Lipide, ⁵Assistance Publique-Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, Département de Nutrition et d'Endocrinologie, ⁶INRA, U910, Unité d'Ecologie et de Physiologie du Système Digestif, Paris, France.

Background and aims: The ability to identify obese subjects who will lose weight in response to energy restriction is an important strategy in obesity clinical care.

Materials and methods: Fifty obese/overweight subjects were submitted to an energy restricted high protein diet (35% protein, 25% fat and 40% carbohydrate) and rich in fibers for 6 weeks followed by a 6 weeks-maintenance diet. Body composition, plasma metabolic and inflammatory markers as well as adipose tissue inflammation marker (HAM56) were measured at baseline, 6 weeks after diet intervention and the end of the study. Baecke physical activity scores and psychological scores (BECK questionnaire, three factor eating questionnaire) were also evaluated. Gut microbiota were profiled from faecal samples by qPCR in all the subjects.

Results: Based on their trajectories of weight loss during the study, three subject clusters were identified. Cluster A (n=17) and Cluster B (n=15) lost more weight during the diet period, however during the stabilization phase cluster A continued to lose weight, whereas cluster B remained stable. Cluster C (n=17) lost less and rapidly regained weight during the stabilization. At baseline, subjects in cluster C had the highest plasma insulin (P=0.01), IL-6 (P=0.05) and adipose tissue inflammatory marker (HAM56, P=0.03). Intriguingly subjects in cluster C had the highest level of Lactobacillus/Leuconostoc/Pediococcus group before diet. During the dietary program, subjects in cluster C consumed more starchy foods and less protein and raw vegetables. Spearman correlations revealed positive relationships between weight regain after diet and HOMA-IR (P=0.0002, rs=0.5), inflammatory markers (leucocytes numbers: P=0.05, rs=0.3; Neutrophils: P=0.05, rs=0.3; IL-6: P=0.002, rs=0.43) as well as the number of Lactobacillus/Leuconostoc/Pediococcus group (p=0.005, rs=0.4) at baseline. Bayesian network (BN) was performed for prediction of the 3 clusters by using the data prior to the weight-loss dietary program. According to the learned structure of BN, the levels of 4 biomarkers (plasma insulin, IL-6, leucocytes numbers and adipose tissue HAM56) at baseline were sufficient to characterize the distribution of the 3 clusters. The prediction of clusters was 75.5% (37 among 49 subjects).

Conclusion: We concluded that individual responses to hypocaloric high protein dietary program could be predicted by plasma insulin, IL-6, leucocytes numbers and adipose tissue HAM56 levels prior to diet.

Thorough chewing stimulates postprandial increases of plasma GLP-1 and peptide YY in obese subjects

M. Saito, Y. Hattori, M. Eto;

Clinical Pharmacology and Medicine, Ohu University, Fukushima, Japan.

Background and aims: Glucagon like peptide (GLP)-1 and peptide YY (PYY) are secreted from intestinal L cells, and plasma levels of both hormones rise after a meal. GLP-1 stimulates glucose-dependent insulin secretion. PYY decreases appetite and reduces food intake by acting on receptors in the hypothalamus. GLP-1 also reduces food intake. Therefore, GLP-1 and PYY seem important to control plasma glucose and triglyceride (TG) levels and body weight. On the other hand, it has been conventionally thought that "chewing well" i.e. "thorough chewing" is good for health. Much remains unknown on the relationship between thorough chewing and GLP-1 and PYY which are secreted from intestine after a meal. The aim of this study is to investigate effects of thorough chewing on postprandial levels of plasma GLP-1 and PYY in obese subjects.

Materials and methods: Nine obese subjects were recruited. They were not diabetic. Obesity was defined as BMI above 25 according to Japanese criteria.

Mean fasting plasma glucose level was 99 mg/dl. Mean age was 40.7 years and mean BMI was 27.2. The subjects were given the test meal early in the morning after 12h fasting. They ate it for 20 minutes and chewed each mouthful 5 times (5 times chewing). On the other day the subjects ate it for 20 minutes and chewed each mouthful 30 times (30 times chewing, i.e. thorough chewing). Plasma GLP-1 and PYY were measured before and 1h after ingestion of the test meal. The test meal consisted of bread, margarine, a boiled egg, steamed vegetables, a banana, and milk. Total calories were 630 kcal, with 16% protein, 32% fat, and 52% carbohydrate. Plasma PYY was measured as PYY(3-36) using an enzyme immunoassay kit. Plasma GLP-1 was measured as GLP-1(7-36) using ELISA kit.

Results: Plasma mean PYY levels with 5 times chewing tended to increase from 35.8 pg/ml (before a meal) to 41.3 pg/ml (after a meal). Plasma PYY levels with 30 times chewing significantly increased from 35.7 pg/ml (before a meal) to 65.9 pg/ml (after a meal). Postprandial PYY level with 30 times chewing was significantly higher than with 5 times chewing. Plasma mean GLP-1 levels with 5 times chewing significantly increased from 4.6 pmol/l (before a meal) to 16.9 pmol/l (after a meal). Plasma GLP-1 levels with 30 times chewing significantly increased from 5.1 pmol/l (before a meal) to 29.3 pmol/l (after a meal). Postprandial GLP-1 level with 30 times chewing was significantly higher than with 5 times chewing.

Conclusions: This is the first report that thorough chewing stimulates postprandial increases of plasma GLP-1 and PYY in obese subjects. Thorough chewing may be clinically effective in obese subjects.

18

Diabetes specific nutrition improves post-prandial glycaemia and GLP-1 with similar appetitive responses compared to a typical healthful breakfast in persons with type 2 diabetes

A.A. Devitt, J.S. Oliver, R.A. Hegazi, V.A. Mustad;

Abbott Nutrition R & D, Abbott Laboratories, Columbus, USA.

Background and aims: For people with diabetes mellitus (DM), the frequency and/or composition of the morning meal may be especially important as the hormonal and metabolic perturbations associated with the disease contribute significantly to poor glucose control and weight gain. Few well-controlled studies have evaluated the effects of breakfast skipping or meal composition on metabolic control, post-prandial glucagon-like peptide-1 (GLP-1) release and appetite in this patient population. This study evaluated the impact of skipping breakfast compared to eating two convenient and healthful breakfast options on post-prandial blood glucose, GLP-1 and appetite.

Materials and methods: This was a randomized, controlled, non-blinded, three- treatment, crossover study conducted at two study sites. Subjects (n=32) had type 2 DM controlled by medication. On the morning of each study period, fasted subjects consumed each test meal in random order: the three nutritional interventions administered were (1) no breakfast (NB), (2) a typical whole food breakfast meal consisting of instant oatmeal (TB) and (3) calorically-matched diabetes-specific liquid nutritional formula (DSN). The energy provided from these two caloric interventions was: 200 kcals (8 g protein, 36 g CHO, 6 g fiber, 4 g fat) and 216 kcals (10 g protein, 29 g CHO, 2 g fiber and 8 g fat), respectively. Blood samples for measurement of plasma glucose, insulin, GLP-1 were collected at baseline and after consumption of the test meal over 180 minutes. Appetitive responses were assessed immediately after each blood collection by 100mm visual analog line scales appropriately anchored by modality.

Results: Post-prandial plasma glucose positive area under the curve (AUC) was significantly reduced by 38% after consumption of the DSN (Least Squares Mean (LSM) \pm Standard Error (SE); 4119 ± 461 (mg/dL)*min; repeated measures ANOVA; $p < 0.0001$) as compared to TB (7531 ± 461). The consumption of NB had the smallest mean positive AUC (437 ± 460) of all interventions. The LSM from post-prandial plasma peak glucose values were 142 ± 7 for NB, 214 ± 7 TB and 178 ± 8 for DSN and each pair wise comparison was significantly different from one another (each comparison $p < 0.0001$). GLP-1 post-prandial AUC was significantly elevated after the consumption of DSN by 246% compared to TB (Signed rank test; $p < 0.0001$; medians, 420 vs. 226) and 995% compared to NB ($p < 0.0001$; 420 vs. 111). Subjective hunger rating positive AUC was significantly elevated after NB (mean \pm SE; 2658 ± 513) compared to both the TB (820 ± 249 ; $p = 0.008$) and DSN (1005 ± 314 ; $p < 0.0001$) interventions. Subjective fullness ratings positive AUC were significantly lower from NB (mean \pm SE; 1013 ± 337) compared to TB (4047 ± 571 ; $p < 0.0001$) and DSN (3402 ± 542 ; $p < 0.0001$). No differences in hunger or fullness were observed between the DSN and TB interventions.

Conclusion: DSN had improved overall plasma glucose control and was the only caloric intervention that had a mean peak post-prandial blood glucose below the recommended value of <180 mg/dL compared to TB. Skipping breakfast was associated with excessive appetitive responses which were not observed with TB and DSN. Additionally, the DSN resulted in elevated postprandial GLP-1, which further supports the beneficial impact of nutritional interventions.

Clinical Trial Registration Number: NCT01324921

OP 04 Brown adipose tissue and mitochondria

19

Pilot study: activity of brown adipose tissue in healthy men during fasting and feeding

A. Vrieze¹, H.J. Verberne², J.E. Schopman¹, W.M. Admiraal¹, W.M. de Jong², J.B.L. Hoekstra¹, M. Nieuwdorp¹, F. Holleman¹;

¹Department of Internal Medicine, ²Nuclear Medicine, Academic Medical Centre, Amsterdam, Netherlands.

Background and aims: Brown adipose tissue (BAT), long thought to dwindle after infancy, is present and physiologically active in many adults. Its role in human metabolism is poorly understood. The aim of this pilot study was to examine the effects of feeding, a situation of physiologically raised insulin concentrations, on BAT activity.

Materials and methods: We included 10 healthy lean male volunteers (18 to 35 years; body mass index 20–24 kg/m²). BAT activity was visualised by glucose uptake in BAT using ¹⁸F-FDG PET-CT during cold exposure. The subjects had two subsequent PET-CT scans, separated by at least two weeks. The first PET-CT was performed after an overnight fast; the second PET-CT was performed after a standardised meal (545 Kcal, composition: 34 gram fat, 37 gram carbohydrates and 23 gram protein).

Results: BAT activity was observed in 6 out of 10 volunteers. These subjects were found to have a higher standardised uptake value (SUVmax) in the fasting state; mean (SD) 13.4 (9.4) compared with the non-fasting state: 6.6 (4.9) ($P=0.03$). Mean (SD) fasting glucose was 5.1 (0.2) mmol/L and mean insulin levels were 30.0 (17.9) pmol/L. On the second study day, one hour after the meal, mean (SD) glucose was 4.0 (0.8) mmol/L and mean insulin levels were 106.3 (56.0) pmol/L.

Conclusion: Glucose uptake in BAT in humans is more pronounced in the fasting state. The lower SUVmax in the non-fasting state may be explained by a steal phenomenon, as a result of increased glucose uptake in muscle.

20

Expression of brown adipose tissue markers in different human adipose tissue depots

L. Cheung¹, J. Chmielewska¹, N. Petrovic², P. Eriksson¹, J. Nedergaard², R. Fisher¹;

¹Department of Medicine, Solna, Karolinska Institutet, Stockholm,

²Wenner-Gren Institute for Experimental Biology, Stockholm University, Sweden.

Background and aims: Recent findings of brown adipose tissue (BAT) in adult humans using positron emission tomography scanning prove that BAT is still present in adult humans, at least when activated by cold exposure. While these studies focused mainly on the more common BAT depots around the neck in the cervical-supraclavicular and/or interscapular region, we aim to unveil the possible BAT characteristics in another potentially BAT depot in mediastinum (outside the heart cavity).

Materials and methods: Adipose tissue biopsies from subcutaneous (anterior upper thoracic), mediastinal and omental depots were collected from at least 30 patients (age 37–85, BMI 21–40). The mRNA expression levels of two known brown adipose tissue genes - uncoupling protein 1 (UCP1) and PR domain containing 16 (PRDM16) - were measured by TaqMan expression assay. The protein levels of UCP1 were examined by immunoblot and immunohistochemistry. Adipocyte cell sizes were computed using ImageJ software on paraffin-embedded sections.

Results: The adipocytes in mediastinal depot were significantly smaller than those in the subcutaneous and the omental depots. Moreover, adipocyte size in the mediastinal depot was positively correlated to the subjects' BMI, while a tendency of such correlation was found between omental adipocyte size and BMI. We observed mRNA expression of the BAT markers in all three depots. The expression levels were significantly higher in the mediastinal than the upper chest subcutaneous depot and the difference was more pronounced in the expression of UCP1 than that of PRDM16. Immunohistochemistry analysis examining the cell type and localization of UCP1-antibody positivity was also performed.

Conclusion: These results suggest that BAT properties might present in the adult human mediastinal adipose tissue. The difference in expression levels of

BAT markers across depots might indicate the degree of "brown-ness/whiteness" of the specific depot, which deserves further investigation to dissect its biological significance, such as in relation to insulin sensitivity.

New insulin sensitizers produce differentiation of brown-like adipose cells from a subcutaneous fat depot and increase secretion of adiponectin *in vitro*

W.G. McDonald, S.L. Cole, D.D. Holewa, A.S. Brightwell-Conrad, P.K. Harris, J.R. Colca, R.F. Kletzien;

Metabolic Solutions Development Co., Kalamazoo, USA.

Background and aims: Subcutaneous adipose depots have been suggested to play an important role in promoting insulin sensitivity in rodents and man. The subcutaneous adipose depots are also a major source of adiponectin, an adipokine with salutary hormone sensitizing effects on insulin target tissues. New insulin sensitizers that do not bind to or activate PPAR γ at micromolar concentrations [PPAR γ -sparing thiazolidinediones (PSTZDs)] have been used to evaluate the possible influence of the PSTZDs on subcutaneous adipose tissue.

Materials and methods: Progenitor cells from axillary adipose depots were isolated from CD-1 mice and placed in tissue culture under defined conditions. Treatment of these cells with PSTZDs, including clinical candidate MSDC-0160, was used to examine PPAR γ independent effects on both differentiation and the associated secretion of adiponectin.

Results: Addition of the PSTZDs such as the clinical candidate MSDC-0160, elicited a time- and dose-dependent differentiation of the progenitor cells which exhibited a brown-like morphology with multilocular fat droplets and intense oil red O staining. Assessment of expression of the mitochondrial uncoupling protein (UCP1) revealed that 3 μ M MSDC-0160 induced a greater than 2000-fold increase in UCP1 mRNA and a 20-fold increase in UCP1 protein within 7 days. Treatment with micromolar MSDC-0160 also produced a two-fold increase in mitochondrial biogenesis as measured by the mitochondrial marker, citrate synthase activity. These effects were not attenuated by the potent PPAR γ antagonists, T0070907 and GW9662, confirming the PPAR-sparing nature of the drug action. Adiponectin expression in the cultures was also studied as a function of drug treatment. MSDC-0160 treatment produced a more than 15-fold increase in adiponectin mRNA within 6 days of drug treatment. Under these conditions, the secretion of adiponectin into the medium was also increased in a PPAR γ -independent and time-dependent manner with maximal increases in secreted protein after 4 days of drug treatment in response to micromolar levels of compound.

Conclusion: In conclusion, we report that the PsTZDs elicit differentiation of progenitor cells from axillary adipose depots into brown-like adipose cells that express UCP1 message and protein in a process that includes increased mitochondrial biogenesis. Importantly, in contrast to the effects on brown adipose cells from the interscapular pad, the cells from axillary adipose depots also secreted adiponectin in response to the PsTZDs. Since activation of PPAR γ is known to be responsible for dose limiting side effects of currently available insulin sensitizers, these results have important mechanistic implications for future therapies of type 2 diabetes and provide a framework for defining the key biochemical pathways involved in the action of PsTZDs, including production and secretion of adiponectin.

22

Obesity mediates mitochondrial dysfunction in islets, liver and adipose tissue

J. Schultz, S. Baltrusch;

Institut of Medical Biochemistry and Molecular Biology, Rostock, Germany.

Background and aims: The cellular life cycle of mitochondria is mediated by fusion and fission events. Mitofusin 1 and 2 (Mfn1 and Mfn2) and optic atrophy 1 (Opa1) are proteins controlling mitochondrial fusion. Mitochondrial network elongation is terminated by fission, a process regulated through the fission protein 1 (Fis1) and the dynamin related protein 1 (Drp1). Fis1 and Drp1 play specific roles in the assembly of the fission complex and cannot replace each other. It was shown in recent studies, that high concentrations of free fatty acids evoke defects in the mitochondrial network and the integrity of the respiratory chain. Free fatty acids are elevated during obesity and contribute to the development of type 2 diabetes mellitus. Therefore the aim of this study was to analyze mitochondrial function and dynamics in obese ob/ob mice compared with normal weight control mice.

Materials and methods: Liver, muscle, pancreas and adipose tissue were taken from ob/ob (B6.V-leobob) and control mice. Islets were isolated by collagenase digestion. Gene expression of Fis1, Drp1, Opa1, Mfn1 and Mfn2 was determined by quantitative Real-Time PCR analyses. Protein production was defined by western blots and immunofluorescence analyses. The mitochondrial network was analyzed using MitoTracker Deep Red staining.

Results: All analyzed genes involved in fusion and fission were down regulated in islets of obese ob/ob mice compared with control mice. In addition to the overall reduced mitochondrial life cycle, Fis1 gene expression and protein production was significantly reduced. Only minor Fis1 immunofluorescence was detectable in insulin immunofluorescence positive cells of pancreas sections of ob/ob mice compared to control mice. Also in liver Fis1 gene expression was significantly reduced in ob/ob mice compared to control. However, in contrast to islets, Drp1 was up regulated in the liver of ob/ob mice. Further analyses of the mitochondrial network structure through fluorescence microscopy revealed an inhomogeneous pattern with concomitant elongated and fragmented mitochondria. A homogeneous mitochondrial network was present in liver of control mice. Furthermore gene and protein expression of Fis1 was significant reduced in adipose tissue of ob/ob mice in comparison to control, whereas in muscle Fis1 production was marginal changed. However, Opa1 which was least affected in liver and adipose tissue was significant down regulated in muscle. Interestingly reduced expression of complex I and 2 of the respiratory chain and the ATP synthase (complex V) was observed in liver and adipose tissue but not in muscle of ob/ob mice compared with control mice.

Conclusion: The mitochondrial network structure and the integrity of the respiratory chain are altered in islets, liver and adipose tissue of obese mice. Reduced mitochondrial dynamic and especially Fis1 down regulation were elucidated in these tissues compared with control mice. In conclusion, our study provides in vivo evidence that obesity mediates mitochondrial dysfunction in insulin secreting and insulin responsive cells and thus, contributes to the development of type 2 diabetes mellitus.

23

Mitochondrial bioenergetics changes are induced by metabolic endotoxaemia contributing to mitochondrial stress and dysfunction in human adipocytes

K.C. McGee¹, A.L. Harte¹, J. Oscarsson², A. Brown², N. Fernandes Da Silva², C. McCarthy¹, J. Clapham², S. Kumar¹, G. Tripathi¹, P.G. McTernan¹;

¹Division of Metabolic and Vascular Health (UHCW site), Warwick Medical School, Coventry, ²R&D, CVGI Bioscience, AstraZeneca, Macclesfield, UK.

Background and aims: Metabolic endotoxaemia is considered to contribute to an inflammatory state and insulin resistance (IR) in obese and type 2 diabetes mellitus (T2DM) subjects. Endotoxaemia arises through gut derived bacteria, lipopolysaccharide (LPS) and its action on innate immune response from adipose tissue (AT) exacerbated in obesity. Since we understand patients with severe IR have increased muscle derived mitochondrial dysfunction, we investigated whether LPS may, in part, influence mitochondrial function and efficiency in human AT/adipocytes. Therefore, we examined effects of LPS on mitochondrial related genes in human adipocytes and assessed the bioenergetic response to the influence of LPS on mitochondrial efficiency using Seahorse XF24 extracellular flux analyser. XF24 system enables measurements of oxygen consumption rate (OCR) and extracellular acidification rate (ECAR) in real-time.

Methods and materials: AT (Abd Sc AT; BMI: 20.1–33.9 kg/m², age: 29–48 yr; n=35) was taken from subjects undergoing elective surgery with ethical approval. Differentiated pre-adipocytes were treated (0–6 hr) with LPS 100 ng/ml or 1000 ng/ml and mitochondrial gene expression assessed by qRT-PCR. OCR and ECAR were measured via the XF24 in a human adipocyte cell line (CHUB-S7) under treatment with LPS 100 ng/ml and 1000 ng/ml, in addition to drugs influencing the respiratory chain (oligomycin, FCCP and rotenone/antimycin A).

Results: Acute LPS treatment (0–6 hr) led to up-regulation of PGC1 α (p<0.05), COX3 (p<0.05), UCP 3 (p<0.001) and NRF1 (p<0.01) compared with untreated controls. For the XF24 extracellular flux analyser differentiated CHUB-S7 cells were seeded at 2.5x10⁴ cells/well and treated with LPS, an ATP Coupler (Oligomycin), ETC Accelerator (FCCP) and a combination of Antimycin and Rotenone (inhibitors of mitochondrial respiration). LPS 1000 ng/ml compromised glycolysis and mitochondrial respiration (vs LPS 100 ng/ml) as measured by the OCR (pmole O₂/min):ECAR (mpH/min) ratio [Control (no stressor): 10.04:1; Stress control: 7.68:1; LPS (100 ng/ml): 13.9:1; LPS (1000 ng/ml): 13.63:1]. Following injection of a mitochondrial uncoupler (FCCP) onto the treated cells, respiration rate (OCR) was increased by the stressor control (201 pmole O₂/min), 100 ng/ml LPS (305.4 pmole O₂/min) and 1000 ng/ml LPS (254 pmole O₂/min). However, there was a concentration dependent reduction (16.98%↓; p<0.01) in respiration rate with increasing LPS concentration leading to increased stress.

Conclusion: In summary our current data suggest that metabolic endotoxaemia may contribute to mitochondrial dysfunction in human AT providing a further insult in the pathogenesis of obesity mediated T2DM. The use of the dynamic real-time extracellular flux analyser, highlighted the detrimental impact of LPS on mitochondrial function and metabolism. These current data show LPS induces and exhausts the respiratory reserve capacity of the uncoupled mitochondria within adipocytes leading to a dose dependent increase in mitochondrial stress. The mRNA data also affirms that LPS induced mitochondrial stress. The OCR:ECAR ratio data shows that LPS compromises glycolysis as well as mitochondrial respiration highlighting the damaging effects of endotoxaemia.

Molecular mechanisms of rosiglitazone-induced mitochondrial biogenesis in adipose tissue

J.A. Villena¹, R. Pardo¹, N. Enguix¹, J. Lasheras¹, J.E. Feliu¹, A. Kralli²;

¹Vall d'Hebron-Research Institute, Barcelona, Spain, ²The Scripps Research Institute, La Jolla, USA.

Background and aims: Several studies have shown a strong association between insulin resistance and decreased mitochondrial mass and oxidative capacity in tissues of insulin resistant patients, leading to the hypothesis that mitochondrial dysfunction may be an underlying cause for the development of type 2 diabetes. Mitochondrial mass is primarily modulated at the transcriptional level by several transcription factors whose activity is coordinated by members of the PGC-1 family of co-activators. Interestingly, decreased lev-

els of PGC-1 α have been observed in muscle and white adipose tissue (WAT) of insulin resistant patients, suggesting that reduced PGC-1 α expression, and the consequent impairment of mitochondrial function, could contribute to the onset of type 2 diabetes. Conversely, treatment with thiazolidinediones, a class of PPAR γ agonists widely used as anti-diabetic agents, increases PGC-1 α levels and promotes mitochondrial mass in WAT. Therefore, it has been proposed that thiazolidinediones may exert their beneficial effect on insulin sensitivity in part by promoting mitochondrial biogenesis in WAT through PGC-1 α . Here, we address the function of adipose PGC-1 α in regulating basal and rosiglitazone-induced mitochondrial biogenesis in WAT, as well as its effect on whole body energy balance and insulin sensitivity.

Materials and methods: To study the role of PGC-1 α on mitochondrial biogenesis in WAT, we have generated a mouse model in which the *pargc1a* gene is ablated by homologous recombination specifically in adipose tissue (PGC1 α -FAT-KO mice). Male PGC1 α -FAT-KO mice and Wild type (Wt) littermates were fed a high fat diet to induce insulin resistance and then treated with either vehicle or 10 mg/Kg rosiglitazone twice daily for 15 days.

Results: Mice lacking PGC-1 α expression in WAT were morphologically normal, although they exhibited a tendency towards a decreased body weight. Despite the well-known role of PGC-1 α in regulating mitochondrial gene expression, no differences in the expression of genes encoding for proteins of the oxphos system or involved in fatty acid oxidation were found in WAT between Wt and PGC1 α -FAT-KO mice. In Wt, rosiglitazone induced the expression of PGC-1 α by 2-fold, as well as the expression of mitochondrial genes (COXII, COXIV, ATP5b, MCAD). Consistent with an increase in mitochondrial gene expression, rosiglitazone induced mitochondrial mass and citrate synthase activity in Wt. Surprisingly, despite the lack of PGC-1 α , rosiglitazone induced mitochondrial gene expression and citrate synthase activity in PGC1 α -FAT-KO mice to levels comparable of those in Wt. No difference in insulin sensitivity was observed between WT and PGC1 α -FAT-KO. However, we found that the lack of PGC-1 α prevented the induction by rosiglitazone of UCP-1 and other brown adipocyte-specific genes, such as CIDEA or CPT1b.

Conclusion: Our results show that PGC-1 α is dispensable for basal and rosiglitazone-induced mitochondrial biogenesis in WAT, and that lack of PGC-1 α in adipose tissues does not affect whole body insulin sensitivity. However, PGC-1 α is required for the rosiglitazone-induced expression of UCP-1 and other brown adipocyte-specific genes in WAT, suggesting that PGC-1 α plays a role in the recruitment of brown adipocytes by rosiglitazone in WAT.

PTPN2, a candidate gene for type 1 diabetes, modulates pancreatic beta cell apoptosis via regulation of the BH3-only protein Bim

I. Santin, F. Moore, M.L. Colli, E.N. Gurzov, D.L. Eizirik;
Laboratory of Experimental Medicine, Université Libre de Bruxelles, Belgium.

Background and aims: In recent years genome-wide association studies allowed the identification of several robust associations between specific chromosomal *loci* and type 1 diabetes (T1D). The pathophysiological mechanisms by which most candidate genes predispose to T1D development, however, remain unclear. PTPN2, located on chromosome 18p11, is a candidate gene for T1D expressed in both immune cells and pancreatic beta cells. PTPN2 modulates interferon (IFN) γ - and double stranded (ds)RNA-induced beta cell apoptosis. We presently evaluated the mechanisms by which PTPN2 triggers pancreatic beta cell apoptosis following exposure to type I and II IFNs.

Materials and methods: INS-1E and primary FACS-purified rat beta cells were transfected with two different small interfering RNAs targeting PTPN2 (inhibition of >70 %) and subsequently exposed to type I and II IFNs. Viability assays were performed by Hoechst/Propidium Iodide staining and confirmed by Western blotting analysis of caspases 9 and 3 activation. ISRE and GAS reporter activity were measured in PTPN2-silenced beta cells after IFN α or IFN γ treatment. The mitochondrial pathways of cell death were analyzed by immunofluorescence and/or Western blot. Expression of DP5, PUMA and Bim was studied by real time RT-PCR and Bim phosphorylation was detected by Western blot. Moreover, PTPN2 and Bim were silenced in a double-knockdown approach and viability tests were performed after IFNs treatment.

Results: PTPN2 knockdown significantly exacerbated type I IFN-induced apoptosis in INS-1E and primary rat beta cells (3.8- and 2.3-fold increase respectively; $p < 0.001$). Silencing of PTPN2 increased ISRE and GAS reporter activity after IFN treatment (1.7- and 2.0-fold induction respectively; $p < 0.001$). Double knockdown of PTPN2 and STAT1 reversed the pro-apoptotic effect of PTPN2 inhibition. Furthermore, PTPN2 silencing induced BAX translocation to the mitochondria, cytochrome c release to the cytosol and caspases 9 and 3 activation after exposure to type I and II IFNs, indicating activation of the intrinsic mitochondrial pathway of apoptosis. Although mRNA expression of DP5 and PUMA was not affected by PTPN2 knockdown, Bim mRNA expression was modestly increased at 16h or 24h of IFN α or IFN γ treatment. Importantly, Bim was hyperphosphorylated at Serine 65 in PTPN2-silenced beta cells. Bim knockdown reverted the pro-apoptotic effect of PTPN2 inactivation in INS-1E cells and primary rat beta cells by 56-78% and 59-63% respectively ($p < 0.001$).

Conclusion: We demonstrate that local IFN production may interact with a genetic factor (PTPN2) to induce aberrant pro-apoptotic activity of the BH3-only protein Bim, resulting in increased beta cell apoptosis via the mitochondrial pathway. This is the first indication of a direct interaction between a candidate gene for T1D and the activation of a specific downstream pro-apoptotic pathway of beta cells.

Variants in PTPN22 and HLA-DQ haplotypes are associated with presence of autoantibodies but not with progression to diabetes in non-diabetic adults

M.K. Andersen^{1,2}, V. Lundgren^{1,2}, B. Isomaa^{2,3}, L. Groop^{1,4}, T. Tuomi^{1,2};
¹Research Program for Molecular Medicine, Helsinki University and Department of Medicine, Helsinki University Hospital, Finland, ²Folkhälsan Research Center, Helsinki, Finland, ³Department of Social Services and Health Care, Jakobstad, Finland, ⁴Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, Malmö, Sweden.

Background and aims: The significance of positivity for GAD-antibodies (GADA) at population level is unclear. We have previously shown that GADA and family history of type 1 diabetes increase the risk of non-insulin dependent diabetes. The aim for this study was to assess whether gene variants predisposing to type 1 diabetes were associated with GADA, decreased insulin secretion, or development of diabetes in a non-diabetic adult population. Furthermore, we investigated whether these variants explained the association of type 1 diabetes family history with progression to non-insulin dependent diabetes.

Materials and methods: Polymorphisms in *INS* (rs689), *PTPN22* (rs2476601), *CTLA4* (rs3087243) and the *HLA-DQA1-DQB1* region (rs2187668 and rs7454108 tagging HLA-DQ2.5 and HLA-DQ8, respectively) were genotyped in the Botnia prospective study (n=2764). The participants were followed for a median time of 8.1 years.

Results: At baseline HLA-DQ high risk (DQ2.5/DQ8, DQ8/DQ8, DQ8/DQX) and *PTPN22* CT/TT genotypes were associated with GADA (GADA- vs. GADA+; HLA high risk: 22.6% vs. 31.2%, $p=0.002$; *PTPN22* CT/TT: 19.9% vs. 28.0%, $p=0.003$). This association was dependent on GADA concentration (GADA- vs. GADA middle quartiles vs. GADA highest quartile; HLA-DQ2.5/DQ8: 3.2% vs. 3.8% vs. 15.4%, $p<0.000001$; *PTPN22* CT/TT: 19.9% vs. 26.5% vs. 32.3%, $p=0.007$). HLA-DQ2.5/DQ8 was especially associated with GADA in subjects aged < 40 yrs. Furthermore, association was observed between HLA-DQ high risk and *PTPN22* CT/TT genotypes and family history of type 1 diabetes irrespective of GADA (GADA-: $p<0.000001$ and $p=0.03$; GADA+: $p=0.002$ and $p=0.03$, respectively). At baseline subjects having a high genetic risk score showed increased insulin sensitivity [median (interquartile range) Insulin Sensitivity Index: 142 (111) vs. 144 (118) vs. 157 (127), $p=0.01$; HOMA_{IR}: 1.06 (0.90) vs. 1.10 (0.88) vs. 0.97 (0.79), $p=0.02$] and decreased insulin secretion [Insulinogenic index: 13.27 (16.27) vs. 12.69 (15.27) vs. 10.98 (13.06), $p=0.02$; Corrected Insulin Response: 115 (125) vs. 106 (124) vs. 97 (107), $p=0.082$, df2]. At follow-up subjects having a high genetic risk score were less able to compensate for the increased insulin demand. The investigated gene variants did not individually or as a combined genetic risk score predict development of diabetes, neither did the variants explain the previously observed association between family history of type 1 diabetes and development of type 2 diabetes.

Conclusion: Variants in HLA and *PTPN22* were associated with GADA and family history of type 1 diabetes in a non-diabetic population. None of the investigated variants was associated with development of diabetes or explained the association between family history of type 1 diabetes and progression to type 2 diabetes.

The type 1 diabetes risk variant rs3825932 correlates with cathepsin H expression and disease progression in newly diagnosed children

T. Fløyel¹, C.A. Brorsson¹, L.B. Nielsen², C.H. Bang-Berthelsen¹, L. Hansen², A. Møllerup³, J. Størling^{1,3}, R. Bergholdt³, H.B. Mortensen³, F. Pociot^{1,4}

¹Department of Clinical Experimental Research, Glostrup Research Institute, Denmark, ²Herlev Hospital & University of Copenhagen, Herlev, Denmark, ³Hagedorn Research Institute, Gentofte, Denmark, ⁴University of Lund, CRC, Skåne University Hospital, Malmö, Sweden.

Background and aims: Recent studies have identified association of over 50 chromosomal regions with type 1 diabetes. Here, we focus on the region 15q25 containing four candidate genes (*ADAMTS7*, *CTSH*, *MORF4L1* and *RASGRF1*). The risk-associated single nucleotide polymorphism (SNP) rs3825932 in this region has previously been reported to affect the gene expression level of *CTSH* encoding the lysosomal protease cathepsin H. The aim was to examine how rs3825932 affects *CTSH* expression as well as disease mechanisms and progression. Since *CTSH* has been implicated in endoplasmic reticulum (ER) stress, an effect of rs3825932 on ER stress was examined as well.

Materials and methods: The genotype effect of rs3825932 on the gene and protein expression level of *CTSH* was investigated in 59 and 16 HapMap CEU lymphoblastoid cell lines (LCLs), respectively. The effect of the rs3825932 CC and TT genotypes was examined on the gene expression levels of six ER stress response genes (*ATF6*, *EDEM1*, *HERPUD1*, *HSPA5*, *SELS* and *XBP1*) using 14 HapMap LCLs. Genotype effects on gene and protein expression were evaluated using two-way analysis of variance and comparison between specific genotypes was done using t-test. Further, the gene expression level of *CTSH* was examined in human pancreatic islet preparations (n=13) in response to cytokine exposure and expression changes between untreated and cytokine-treated preparations were evaluated using paired t-test. Additionally, rs3825932 was examined for genotype effects on residual β -cell function and glycemic control in newly diagnosed type 1 diabetic children (n=257) using multiple regression models.

Results: We identified a significant allele-dosis effect of rs3825932 on *CTSH* mRNA ($p=1.3 \times 10^{-7}$) as well as protein ($p=0.014$) level in HapMap LCLs and found the risk-associated major C allele correlated with higher expression levels. Furthermore, the C allele of rs3825932 was correlated with a higher expression level of *XBP1* that mediates transcriptional induction during ER stress, compared to the T allele ($p<0.05$). In human pancreatic islets,

the expression of *CTSH* was decreased in response to cytokine stimulation ($p<0.01$). In children with newly diagnosed type 1 diabetes, the TT genotype of rs3825932 was associated with a higher daily insulin dose ($p<0.01$) and a more rapid disease progression.

Conclusion: Our study strengthens *CTSH* as a type 1 diabetes risk candidate gene. Further investigations will elucidate the functional implication of *CTSH* in type 1 diabetes.

The effect of GWAS risk variants on disease progression within the first year after disease onset in children with type 1 diabetes

C.A. Brorsson¹, L.B. Nielsen¹, M. Max Andersen¹, T. Fløyel¹, C.H. Bang-Berthelsen¹, L.A. Berchtold², J. Størling², R. Bergholdt², H.B. Mortensen¹, F. Pociot¹, The Hvidoere Study Group on Childhood Diabetes;

¹Glostrup Research Institute, Glostrup, ²Hagedorn Research Institute, Gentofte, Denmark.

Background and aims: Genome-wide association scans (GWAS) in type 1 diabetes (T1D) have highlighted predominantly classical immune-regulatory pathways as being involved in the pathogenesis of disease. However, it appears that T1D does not develop unless initial β -cell damage has taken place. We hypothesize that candidate genes linked to the genetic risk variants may be involved in disease mechanisms within the β -cells rendering them less able to withstand an attack from the immune system. The main objective of this study was to investigate whether genetic risk variants identified in GWAS of T1D could be associated with measures of disease progression and metabolic control in children within the first year after T1D onset.

Materials and methods: Expression profiles for pin-pointed candidate genes within 42 associated loci were investigated in nine human islet preparations (TaqMan, Applied Biosystems) and compared between the untreated control and cytokine treated (IL1- β , IFN- γ , TNF- α for 48h) condition using paired t-tests. Candidate genes with significant regulation were prioritized for analysis of their potential role in disease progression in an international prospective cohort of newly diagnosed children followed for one year after diagnosis. SNPs corresponding to the candidate genes were genotyped in 257 children (KASPar, KBioscience), 126 girls and 131 boys with mean age at clinical onset 9.1 ± 3.7 years. Using linear regression the effect of each SNP was tested on stimulated C-peptide levels 1, 6 and 12 months after diagnosis. Insulin dose-adjusted HbA1c (IDAA1c) defined as actual HbA1c + (4 x insulin dose (U/kg/24h)) was calculated and used as a surrogate marker of residual β -cell function at 1, 3, 6 and 12 months after diagnosis. A calculated IDAA1c below 9% was used to define clinical remission. Furthermore, a genetic risk score will be calculated based on the number of risk alleles carried by each child to assess whether the risk score can predict clinical remission within the first year after diagnosis.

Results: A total of 11 candidate genes were significantly regulated by cytokines in human islets and the corresponding risk SNPs analysed in the pediatric cohort. Among the SNPs tested carriers of the risk allele for TNFAIP3 were predicted to have significantly lower C-peptide 12 months after diagnosis ($p=0.02$, adjusted for age, sex and C-peptide at 1 month) as well as significantly higher IDAA1c 9 and 12 months after diagnosis ($p=0.01$ and 0.04 respectively). The expression of TNFAIP3 was significantly upregulated in human islets after cytokine stimulation ($p<0.001$), in line with its protective function in response to cytokines.

Conclusion: The identification of genetic risk variants that affect disease progression will not only increase the knowledge of disease mechanisms involved in the decline of β -cell function. It will also enable the possibility for intervention by enhancing protective effects, such as the effect of TNFAIP3, as well as minimizing deleterious effects of genes and genetic variants.

Interferon induced with helicase 1 (IFIH1) gene polymorphisms, frequency of human enterovirus infections and islet autoimmunity: longitudinal birth cohort studyE. Witsoe¹, O. Cineke², G. Tapia¹, C.A. Brorsson³, R. Bergholdt⁴, F. Pociot³, L. Stene¹, K. Skjold Ronningen⁵;¹Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway, ²Second faculty of medicine, Charles University Prague, Czech Republic, ³Glostrup Hospital, Denmark, ⁴Hagedorn Research Institute, Gentofte, Denmark, ⁵Oslo University Hospital, Norway.

Background and aims: Interferon induced with helicase C domain 1 (IFIH1) is involved in recognition of and initiation of antiviral activity against enteroviruses. Several polymorphisms of the IFIH1 gene are associated with risk for type 1 diabetes, but it is not established whether these polymorphisms predicts enterovirus frequency in healthy humans. Alleles associated with type 1 diabetes were generally loss of function variants, and were thus hypothesized to predict higher risk of enterovirus infection.

Materials and methods: After screening of 46939 Norwegian newborns, 421 children carrying HLA-DRB1*04:01-DQA1*03-DQB1*03:02/DRB1*03:01-DQA1*05-DQB1*02 genotype (DR4-DQ8/DR3-DQ2, conferring risk for type 1 diabetes) and 375 children without this genotype were included for monthly fecal collections (range 3–35 months). A total of 7793 fecal samples were tested for presence of enterovirus RNA using real time reverse transcriptase PCR.

Results: There was no association of rs1990760, rs35744605, rs35667974, or rs35337543 and enterovirus. For rs35732034 which is predicted to disrupt normal splicing resulting in loss of function, we observed a possible association with frequency of enterovirus of borderline significance: Enterovirus was detected in 26.1% (18/69) of samples from the eight children carrying the A allele, and in 12.4% (955/7724) of samples from the 788 children who were homozygous for the G allele (odds ratio 2.47 (95% CI 1.0–6.3), $p=0.06$. When infections were restricted to those with above median quantity of enterovirus RNA in feces, the odds ratio was 3.27, 95% CI 1.4–7.8, $p=0.01$). Our previously published lack of association between enterovirus frequency and islet autoimmunity was not materially influenced by the IFIH1 SNPs.

Conclusion: We found only partial support for the hypothesis that SNPs in the IFIH1 gene associated type 1 diabetes is a major predictor of enterovirus in healthy young children. This is in contrast to assumptions based on in vitro studies and knock-out mice.

Family history of autoimmune diseases and genotype and phenotype of children with newly diagnosed type 1 diabetesA. Mäkinen¹, T. Härkönen¹, S. Ryhänen¹, J. Ilonen^{2,3}, M. Knip^{1,4}, the Finnish Pediatric Diabetes Register;¹Scientific Laboratory, Children's Hospital, University of Helsinki and Helsinki University Central Hospital, ²Immunogenetics Laboratory, University of Turku, ³Department of Clinical Microbiology, University of Eastern Finland, Kuopio, ⁴Department of Pediatrics, Tampere University Hospital, Finland.

Background and aims: The aim of this study was to examine the burden of other autoimmune diseases (AID) in the extended families of children with newly diagnosed type 1 diabetes (T1D). We tested the hypothesis that a positive family history of other AID would increase the prevalence of the HLA-DR3-DQ2 haplotype in the children with T1D, and that these children would have a stronger autoimmune reactivity against beta cells reflected by a more frequent and intense autoantibody response (ICA, IAA, GADA, IA-2A).

Materials and methods: We included 1488 children with T1D diagnosed before the age of 15 years (median 8.2, 57% male) from the Finnish Pediatric Diabetes Register. The Register includes over 90% of children annually diagnosed with T1D in our country. Data on clinical markers and the family history of other AID in 1st and 2nd degree relatives at the time of diagnosis were collected with a structured questionnaire, and HLA genotypes and beta cell autoantibodies were analyzed.

Results: Twenty-three children (1.5%) had some other AID already at the time of diagnosis of T1D. The most common diseases were celiac disease ($n=10$) and thyroid dysfunction ($n=9$). These children had ICA less often ($P=0.01$) and had longer duration of symptoms ($P=0.03$), lower beta-OH-butyrate ($P=0.004$) and plasma glucose levels ($P=0.004$), and higher pH

($P=0.001$) at the time of diagnosis compared to the children with T1D only. HLA genetics did not differ between the groups. 31.4% of children had at least one relative with AID other than T1D (thyroid dysfunction: $n=253$, rheumatoid diseases: $n=178$). 11.2% had an affected 1st degree relative and 24.0% had an affected 2nd degree relative. 8.1% had a mother with another AID and 2.8% had an affected father ($P=0.02$). The children with a positive family history of other AID had higher levels of ICA ($P=0.01$) and IA-2A ($P=0.05$). Also the number of children in these families was higher ($P=0.007$). The HLA-DR3-DQ2 haplotype was more common in children with 1st degree relatives affected by other AID ($P=0.01$). Celiac disease in the extended family associated with HLA-DR3-DQ2 haplotype in the index child ($P<0.001$), and rheumatoid diseases with higher levels of ICA ($P=0.003$) and IA-2A ($P=0.007$) and a higher frequency of IAA ($P=0.02$).

Conclusion: Only a small proportion of the index cases had other AID at the time of diagnosis of T1D. One third of the children had a positive family history of AID other than T1D in the extended family. In keeping with the accumulation of many AID among females mothers with other AID were overrepresented in relation to fathers. The HLA-DR3-DQ2 haplotype was associated with a positive family history of other AID, especially celiac disease. There was some support for the hypothesis that children with other AID in the extended family might have stronger beta cell autoimmunity. High ICA titers, in particular, were associated with a positive family history of other AID.

OP 06 Insulin secretion and exocytosis

31

Transcription factor B1 mitochondrial in beta cells and type 2 diabetes

V.V. Sharoyko¹, I. Alessandrini¹, N. Wierup², H. Mulder¹;

¹Clinical Sciences, ²Department of Experimental Medical Science, Lund University, Malmö, Sweden.

Background and aims: Recently, we have used information from Genome-wide Association Studies of type 2 diabetes (T2D) and its associated traits, and identified a novel potential culprit in the pathogenesis of the disease: Transcription/translational Factor B1 Mitochondrial (TFB1M). This protein controls mitochondrial protein translation and therefore the expression of mitochondrially encoded genes. We observed that carriers of a common variant of Tfb1m are at increased risk of developing T2D, due to impaired insulin secretion and elevated glucose levels during an oral glucose tolerance test. Perturbed mitochondrial metabolism and impaired insulin secretion were found in Tfb1m^{-/-} mice. To resolve the regulatory role of TFB1M in β -cells and its pathogenetic role in T2D islets, we performed *in vivo* and *in vitro* studies in a murine model of β -cell-specific Tfb1m deficiency (β -Tfb1m^{-/-}).

Materials and methods: To create β -cell Tfb1m^{-/-} mice, RIP-cre transgenic mice were cross-bred with floxed Tfb1m^{+/+} mice. β -cell-specific knock out of TFB1M was assessed by TaqMan qRT-PCR and immunocytochemistry. Plasma glucose concentrations were measured by Infinity Glucose Oxidase Liquid Stable Reagent. Insulin secretion was determined by Ultrasensitive Mercodia ELISA kit.

Results: Quantitative RT-PCR analysis demonstrated a 74% reduction in Tfb1m mRNA expression in pancreatic islets of β -Tfb1m^{-/-} mice compared to controls (floxed Tfb1m^{+/+} mice Cre^{-/-}). Immunocytochemical analysis revealed β -cell specific complete deficiency of TFB1M at the protein level in β -Tfb1m^{-/-} mice. Plasma glucose levels were monitored: at 2.5 month of age β -Tfb1m^{-/-} mice showed retarded elimination of glucose and no increase in insulin secretion during intraperitoneal glucose tolerance test; after 4 months, we found that virtually all β -Tfb1m^{-/-} mice had developed diabetes. Moreover, insulin secretion in response to glucose and α -ketoisocaproic acid is markedly reduced in islets from 2–3 month old β -Tfb1m^{-/-} mice.

Conclusion: Taken together our results obtained with β -Tfb1m^{-/-} mice suggest that Tfb1m deficiency plays a major role in insulin secretion conferring to this protein, identified as a genetically associated T2D risk factor, a specific biological role in the pathogenesis of the disease. We suggest that the final effect on insulin secretion due to Tfb1m deficiency may underline how perturbation in the mitochondrial proteome homeostasis is a condition which finally leads to the development of T2D. Further work will help in the validation of potentially new therapeutic targets.

Reduced expression of genes involved in exocytosis in type 2 diabetic human islets

S.A. Andersson, A.H. Olsson, J.L.S. Esguerra, C. Ladenvall, A.S. Salehi, J. Taneera, L. Groop, C. Ling, L. Eliasson;
Dept. of Clinical Sciences, Lund University, Malmö, Sweden.

Background and aims: Recent studies suggest that impaired insulin secretion occurs already before the onset of type 2 diabetes (T2D). This makes processes involved in the exocytosis of insulin critical during the development of the disease. Exocytosis precedes insulin secretion by means of targeting the insulin-containing granules to the plasma membrane and mechanical fusion of the granular membranes to the cell plasma membrane. Successful β -cell exocytosis involves gene expression of several proteins such as SNAP-25, STX1A, VAMP2 and STXBP. We hypothesise that expression of genes involved in the exocytotic process is altered in T2D individuals, and that changes in gene expression would correlate to changes in HbA1c and GSIS (glucose stimulated insulin secretion).

Material and methods: Human pancreatic islets from 55 non-T2D and 9 T2D deceased donors in Scandinavia were obtained and processed onto a microarray chip measuring the expression of 21 000 genes where 1300 was found to be down-regulated in T2D subjects. We then compared the mRNA expression of 23 exocytotic genes on the microarray between T2D human

donors and non-T2D subjects using Mann-Whitney U-test. The resulting number of nominally down-regulated genes was surveyed by a Chi-2 test where $p < 0.05$ was considered adequate to determine if a significant difference exists between the expected frequencies and the observed frequencies. Where the expression pattern differed technically, three genes were replicated using quantitative RT-PCR. The gene expression was further correlated to HbA1c *in vivo* and measurements of GSIS *in vitro* from the same donors, using Spearman correlation coefficient.

Results: In the microarray, 5 out of the 23 genes were nominally down regulated ($p < 0.05$) e.g. STX1A expression was reduced by 26 % ($p = 0.010$) in T2D individuals as compared to the control group. The Chi-2 test established that the number of down-regulations in our data set was higher than could be expected ($p < 0.05$) from the total number of down-regulations on the microarray. Three of these genes, one being STX1A, were additionally selected for replication in qPCR which strengthened the trend seen in the microarray such as STX1A expression being reduced by 40% ($p = 0.027$) in human islets from T2D donors compared to healthy individuals. Further, the gene expression of all five genes correlated negatively to HbA1c ($p < 0.04$) where STX1A had a p -value of 0.005, and positively to GSIS ($p < 0.05$) where STX1A had a p -value of 0.004. None of the genes were associated to basal insulin secretion. **Conclusion:** Our study implies that mRNA expression of genes important for exocytosis is down-regulated in T2D individuals. Further, we can correlate these genes to HbA_{1c} and GSIS. In combination, these findings show that decreased expression of exocytotic genes may contribute to the deregulated glucose stimulated insulin secretion in T2D.

Nor-1 is a novel incretin-sensitive regulator of the rat insulin genes

A.-M. Ordelheide, I. Thielker, C. Haas, F. Machicao, H.-U. Häring;
Internal Medicine IV, UKT Tübingen, Germany.

Background and aims: The nuclear receptor subfamily NR4A (nuclear receptor subfamily 4, group A), comprising Nur-77 (NR4A1), Nur-1 (NR4A2), and Nor-1 (NR4A3), is a highly conserved group of ligand-independent transcription factors and early-response genes. They are rapidly regulated at the transcriptional level by various stimuli and modulate differentiation, proliferation, apoptosis, and lipid and glucose metabolism. We could recently show that common genetic variation within the NR4A3, but not within the NR4A1 or NR4A2, locus affects insulin secretion in humans providing evidence for an important role of Nor-1 in human β -cell function. In keeping with this, we detected relevant NR4A3 expression levels in human islets. In this study, we aimed to investigate Nor-1's molecular function in pancreatic β -cells.

Materials and methods: We used RNA interference-mediated gene knock-down, chromatin immunoprecipitation, and pharmacological activators and inhibitors to study the molecular role of Nor-1 in the rat insulinoma cell line INS-1E.

Results: Nr4a3 knock-down significantly reduced Ins1 mRNA expression ($p < 0.05$) and tended to reduce Ins2 mRNA expression ($p = 0.07$, $n = 4$). In addition, Nr4a3 knock-down resulted in reduced glucose-stimulated insulin secretion ($p < 0.05$). Conversely, incubation of INS-1E cells with the Nor-1 activator 6-mercaptopurine significantly induced Ins1 and Ins2 mRNA expression ($p < 0.05$ both). Furthermore, we were able to demonstrate Nor-1 binding to a specific binding site in the Ins1 promoter. Having shown Nr4a3 involvement in insulin expression and secretion, we asked how Nr4a3 expression is regulated in INS-1E cells. Since Nr4a3 is known to be induced in the liver via cAMP/PKA, a pathway activated by incretins in the pancreatic β -cell, we analysed Nr4a3 expression after incubation with exendin-4. The Nr4a3 mRNA content significantly increased upon exendin-4 treatment, and this increase was even larger in cells co-incubated with high glucose concentrations ($p < 0.05$ all). The adenylate cyclase activator forskolin and dibutyryl-cAMP significantly induced the mRNA expression of Nr4a3, while the PKA inhibitor H89 reduced its expression ($p < 0.05$ all). Furthermore, Creb1 knock-down abolished the exendin-4/high glucose-mediated Nr4a3 induction.

Conclusion: Nor-1 represents a novel transcriptional regulator of the rat insulin genes which can be induced by incretins plus high glucose via the cAMP/PKA/Creb-1 pathway. Since Nor-1 binding sites were also identified in the human insulin gene, the proposed role of Nor-1 in insulin expression/secretion may also hold for human β -cells.

34

Deletion of the Cited2 gene in beta cells causes impaired insulin secretion and glucose intolerance in miceJ. Cantley¹, A. Davenport¹, S.L. Dunwoodie², T.J. Biden¹;¹Diabetes and Obesity Program, Garvan Institute of Medical Research,²Developmental Biology Division, Victor Chang Cardiac Research Institute, Sydney, Australia.

Background and aims: Beta cell failure is a hall mark of type2 diabetes (T2D). Two of the key questions in the aetiology of T2D are: What are the molecular mechanisms controlling normal beta cell function? And how do these fail during T2D? We have recently implicated the gene Cbp/p300-interacting transactivator 2, with Glu/Asp-rich carboxy-terminal domain, 2 (Cited2) as being potentially involved in controlling beta cell function. Cited2 has been reported to act as a transcriptional cofactor in a number of different cell types, and to regulate the activity of a number of transcription factors, some of which are known to play an important role in beta cell function. Despite Cited2 being highly expressed, its role in beta cell function has not been investigated. Therefore, the aim of our study was to investigate the role of Cited2 in beta cells.

Materials and methods: We have deleted Cited2 in the beta cells of mice (β Cited2KO) by crossing Cited2 floxed mice with Ins2cre mice expressing cre-recombinase under the control of the insulin2 promoter. We assessed glucose homeostasis and islet morphology. We also measured Cited2 expression in models of beta cell dysfunction by RT-PCR or gene array.

Results: β Cited2KO mice were indistinguishable from control mice (Ins2cre and Cited2floxed) in terms of body mass, insulin action and appearance. However, when we performed an i.p. glucose tolerance test (GTT) at 12 weeks of age, we found that both male and female β Cited2KO mice were significantly glucose intolerant relative to controls (Male GTT AUC mean \pm SEM: Control 1547 \pm 58.4 n=16; β Cited2KO 2367 \pm 78.7 n=8; $P<0.001$ by ANOVA with bonferroni post-test). β Cited2KO mice were found to have reduced insulin levels during the glucose tolerance test relative to control mice, which indicated that beta cell Cited2 deletion was disrupting normal beta cell function. Morphometric histological analysis revealed normal beta cell mass (mg mean \pm SEM: Control 1.562 \pm 0.275; β Cited2KO 1.856 \pm 0.232mg; n=3, NS by t-test) but altered islet architecture, suggesting that Cited2 may regulate insulin secretion and islet organisation, rather than beta cell mass. Further indication of the important role Cited2 plays in beta cells came from observations that the Cited2 transcript was down regulated by 50% in Min6 cells treated with the saturated fatty acid palmitate, a model of lipotoxicity and secretory dysfunction, using gene expression arrays (n=2). We also studied Db/Db mice which are a model of beta cell dysfunction and type2 diabetes, and found a 38% downregulation of Cited2 mRNA in isolated Db/Db islets relative to controls (n=12, $P<0.01$ by t-test). Moreover, Cited2 expression was unaltered in islets isolated from Ob/Ob mice which show obesity but have preserved beta cell function and do not develop diabetes.

Conclusion: Our data clearly show that Cited2 is required for normal beta cell function, and that reduced Cited2 expression levels are associated with beta cell dysfunction in models of diabetes. Although more work is needed to fully explore the role of Cited2 in the beta cell, we propose that Cited2 is a critical regulator of gene expression in beta cells, exerting control over beta cell function, insulin secretion and glucose homeostasis.

The Ser473 AKT specific phosphatase PHLPP plays a key role in beta cell dysfunction

M.L. Hribal, T. Procopio, A. Greco, M. Ruffo, T.V. Fiorentino, G. Sesti; University of Catanzaro Magna Graecia, Italy.

Background and aims: Chronic exposure of pancreatic beta-cells to high glucose levels is associated with reduced insulin secretion and synthesis, and decreased cell survival as well as with the impairment of several steps along the insulin signaling pathway, including a reduced phosphorylation of the kinase Akt on the Serine 473 (Ser473), but not on the Threonine 308 (Thr308) residue. We thus hypothesized that the Ser473 specific phosphatase PHLPP1/2 may have a role in glucose-induced beta-cell dysfunction. In addition, since it has been reported that glucagon-like peptide 1 (GLP-1) and its analogues improve beta-cell homeostasis promoting Akt phosphorylation, we wished to test the hypothesis that down-regulation of PHLPP1/2 may be an additional mechanism underlying GLP-1 action.

Materials and methods: INS-1 rat beta-cells were cultured at physiological (11.1 mmol/L, INS-1 LG) or high (30 mmol/L, INS-1 HG) glucose concentrations for 10-15 passages. To evaluate GLP-1 ability to reduce PHLPP1/2 expression, time-course and dose-response experiments were performed treating INS-1 HG with 0.3, 3 and 30 mmol/L GLP-1 for 24, 48, 72, 96 hrs, the treatment was carried out in the presence of 20nmol/L dipeptidyl peptidase-IV inhibitor to prevent GLP-1 degradation. Real-Time RT-PCR was used to assess mRNA levels and Western blots were performed to evaluate protein expression and the activation state of Akt and its substrates. Statistical differences were assessed by Student's t test or Two-Way Anova, a p value of 0.05 was considered statistically significant.

Results: We confirmed that, in our cellular model, chronic exposure to high glucose significantly impairs glucose-stimulated insulin secretion ($p<0.0001$, n= 3), insulin synthesis ($p<0.0001$, n=6) and cell survival, assessed using the expression levels of the pro-apoptotic protein Bad, which showed a 1.75-fold increase, and of the anti-apoptotic protein BclxL, which by contrast was decreased by 62%, as a read-out for apoptosis ($p<0.05$, n=3, for both markers). Notably, in INS-1 HG the expression of PHLPP1/2 was significantly increased both at mRNA (PHLPP1 250 \pm 22%; PHLPP2 320 \pm 24%, $p<0.05$, n=10) and protein (PHLPP1 132 \pm 22%; PHLPP2 176 \pm 34%, $p<0.05$, n=4) level. This increase was paralleled by a significant decrease of Akt phosphorylation on Ser473 after stimulation with insulin 100 nmol/L for 10 mins (-50 \pm 12%, $p<0.05$, n=6); by contrast the phosphorylation of Thr308 was only slightly, and not significantly, reduced. The decreased activation of Akt was mirrored by a decreased insulin-stimulated phosphorylation of the major Akt substrates: -44.4 \pm 9% for p70S6K ($p=0.0011$, n=6), -57.5 \pm 2.12% for pElF2alpha ($p=0.013$, n=3), -48 \pm 2.82% for mTOR ($p=0.0026$, n=3), and -58.67 \pm 11.2% for Foxo-1 ($p=0.0009$, n=3) in INS-1 HG. These results suggest that PHLPP1/2 may indeed play an important role in glucose-induced beta-cell dysfunction, we therefore proceeded to evaluate if GLP-1 ability to counteract the effects of hyperglycemia could be mediated by the down-regulation of PHLPP1/2 expression; indeed our results show that GLP-1 treatment significantly reduces PHLPP1/2 mRNA levels in INS-1 HG cells, with a maximal effect for the 0.3 mmol/L GLP-1 dose at 24h (PHLPP1 -40 \pm 19%; PHLPP2 -33 \pm 12%, $p<0.01$, n=8).

Conclusion: Our results, contributing to the elucidation of the mechanisms by which hyperglycemia affects the multiple functions controlled by Akt, could provide indications for novel therapeutic approach to deal with beta-cell failure.

Beta-arrestin 2 is required for insulin signalling in pancreatic beta-cells

M.A. Ravier, N. Linck, M. Agen, C. Broca, C. Bonnans, S. Dalle, G. Bertrand; Institut de Genomique Fonctionnelle, CNRS UMR-5203, INSERM U661, Universités de Montpellier 1 & 2, Montpellier, France.

Background and aims: The autocrine action of insulin on its own receptor was shown to be critical for the maintenance of normal pancreatic β -cell function and mass. Recently, it has been reported that in the downstream signalling of the insulin receptor (IR), besides the conventional IRS/PI3K/Akt pathway, a second pathway involving β -arrestin 2 (β -arr2) is required to induce a full Akt activation in hepatocytes. So, β -arr2 was shown to scaffold a complex with Akt, Src and IR in response to insulin and any deficiency of this signal contributed to the development of insulin resistance. The aim of our study was to investigate the implication of the β -arr2/Src signalling complex in insulin-mediated Akt activation in pancreatic β -cells.

Materials and methods: To examine the mechanism(s) by which insulin activates Akt, we assessed the Akt phosphorylation status by Western blotting with phospho-specific antibodies that recognize phosphorylated Akt on Ser473 or Thr308. Free cytosolic [Ca²⁺] changes from mouse islets were recorded using Fura2-AM and insulin secretion was measured using perifused islets.

Results: In INS-1E cells, insulin dose-dependently (1-100nM) induced a rapid Akt phosphorylation on both Thr308 and Ser473, with a maximum (~3 to 4-fold increase) reached after 10 min of stimulation. Interestingly, while wortmannin, a PI3K inhibitor, completely abolished the Akt phosphorylation, PP2, a selective inhibitor of the tyrosine kinase Src, reduced the Akt phosphorylation on both Ser473 and Thr308 by 40% and 20%, respectively. Besides, β -arr2 depletion using short interfering RNA reduced by 40% the Akt phosphorylation. These results suggest that not only PI3K but also Src and β -arr2 are required for insulin-induced full Akt activation. In addition, we showed by immunoprecipitation that insulin induced an association between Akt and

the IR as well as β -arr2 and Src at 5 min for at least 30 min in INS-1E cells. Finally, the biological relevance of both Src and β -arr2 involvements were confirmed in mouse pancreatic islets. Indeed, inhibition of Src (with PP2) as well as knockdown of β -arr2 (β -arr2 KO mice) decreased by 40–80%; respectively, the insulin-induced Akt activation. Moreover, insulin-induced phosphorylations of the transcription factor FoxO1 and the glycogen synthase kinase 3, two downstream targets of Akt, were reduced in β -arr2 KO mouse islets. At last, since we observed that insulin can recruit β -arr2 through its receptor, and that insulin was reported to regulate its own secretion, we have assessed the role of β -arr2 in β -cell function using β -arr2 KO mice. Female β -arr2 KO mice exhibited slight glucose intolerance and lower fed plasma insulin level. Nevertheless, glucose-induced free cytosolic $[Ca^{2+}]$ changes and insulin secretion from perfused islets were not affected. However, the insulin content of both the whole pancreas and isolated islets were significantly decreased in β -arr2 KO mice (~25%), suggesting a role of β -arr2 in the modulation of β -cell mass.

Conclusion: We report a new process in pancreatic β -cells by which insulin recruits β -arr2 to scaffold Src to IR for full Akt activation and thus provide new insights concerning the mechanisms of insulin action in pancreatic β -cells.

Chronic kidney disease and mortality risk among elderly diabetic individuals (ZODIAC-24)

I. Drion¹, K.J.J. van Hateren¹, H. Joosten², K.H. Groenier³, N. Kleefstra¹, J.F. Wetzels⁴, H.J.G. Bilo^{1,2};

¹Diabetes Centre, Zwolle, ²University Medical Center Groningen, ³General Practice, University Medical Center Groningen, ⁴Radboud University Medical Center, Nijmegen, Netherlands.

Background and aims: A decreased renal function and albuminuria are associated with increased mortality in patients with type 2 diabetes mellitus (T2DM). Since it is unclear whether these associations remain similar in elderly it was our aim to study these associations in elderly patients with T2DM.

Materials and methods: Between 1998 and 1999, 1022 primary care patients ≥ 60 years with T2DM participated in the ZODIAC study, a prospective observational study. Data on mortality were collected in 2009. A Cox proportional hazard model was used to investigate the association of the modification of diet in renal disease formula (MDRD), the Cockcroft-Gault formula (CG) and albuminuria with mortality. Analyses were performed in strata according to age: 60–75 ($n=648$) and >75 ($n=374$) years. Age, gender, smoking (dichotomous), body mass index, systolic blood pressure, diabetes duration, macro vascular complications (dichotomous), total cholesterol-HDL ratio, and HbA1c were selected as possible confounders. Three different models were used. Model 1 was the crude model, model 2 included all selected confounders, model 3 used all selected confounders except for those variables which were already used in the eGFR prediction equations itself.

Results: After a median follow-up time of 10 years, 537 of 1022 patients died (42% was due to cardiovascular causes). In patients aged 60–75 years, a MDRD <45 and 45–60 ml/min/1.73m² were associated with increased cardiovascular mortality: HR 3.05 (95%CI 1.44–6.47) and HR 1.69 (95%CI 1.02–2.79), respectively; for CG hazard ratios were HR 6.21 (95%CI 2.76–13.95) and HR 2.33 (95%CI 1.35–4.05), respectively. In patients >75 years increased cardiovascular mortality was only observed when CG or MDRD were <45 ml/min/(1.73m²); HRs 1.93 (95%CI 1.93–3.64) and 2.27 (95%CI 1.37–3.78), respectively. Compared to participants aged 60–75 years with a MDRD >60 ml/min/1.73m² without albuminuria, the fully adjusted HRs for cardiovascular mortality were 2.59 (95%CI 1.23–5.45) for impaired MDRD (45–60 ml/min/1.73m²) without albuminuria, and 3.91 (95%CI 1.91–8.02) for those with a MDRD of 45–60 ml/min/1.73m² with albuminuria. For participants aged >75 years, the HRs were 1.23 (0.61–2.42) and 2.12 (1.06–4.25), respectively. Figure 1 il

illustrates the increased cardiovascular mortality rates for patients >75 years with an eGFR <45 ml/min/1.73m².

Conclusion: Patients >75 years with a MDRD or a CG of 45–60 ml/min/(1.73m²) are not at increased risk for all-cause or cardiovascular mortality. Albuminuria on the other hand, is strongly associated with increased all-cause and cardiovascular mortality at all levels of eGFR, also in elderly patients.

Background and aims: In type 2 diabetes, prevalence of nonalbuminuric renal impairment, as identified by an estimated glomerular filtration rate (eGFR) <60 ml/min/1.73 m² without albuminuria, is increasing worldwide, though the prognostic implications of this phenotype in terms of both cardiovascular disease (CVD) risk and renal outcome are poorly defined. This study was aimed at evaluating the reciprocal association of nonalbuminuric renal impairment with CVD risk factors and prevalent major acute CVD events, in patients with type 2 diabetes.

Materials and methods: We used baseline data from the Renal Insufficiency And Cardiovascular Events (RIACE) Italian Multicenter Study. The RIACE cohort consists of 15,773 patients with type 2 diabetes, consecutively visiting 19 Diabetes Clinics in years 2007–2008. Exclusion criteria were dialysis or renal transplantation. GFR was estimated from serum creatinine using the simplified Modification of Diet in Renal Disease equation, albuminuria was measured by immunonephelometry or immunoturbidimetry. Chronic kidney disease (CKD) was defined as an eGFR <60 ml/min/1.73 m² and/or micro/macroalbuminuria. Previous major acute CVD events were recorded based on hospital discharge records.

Results: No CKD was detected in 9,865 patients (62.6%), CKD stages 1–2 (i.e. eGFR ≥60 ml/min/1.73 m² and albuminuria) in 2,949 (18.7%), and CKD stages 3–5 (i.e. eGFR <60 ml/min/1.73 m² with or without albuminuria) in 2,959 (18.8%). Among subjects with renal impairment, 56.6% were nonalbuminuric and 43.4% were albuminuric (30.8% microalbuminuric and 12.6% macroalbuminuric). At least one major acute CVD event was adjudicated in 3,654 patients, who were older, more frequently male and on insulin treatment, and with longer diabetes duration, higher HbA_{1c}, triglycerides and prevalence of albuminuria, CKD, and retinopathy, and lower HDL-cholesterol and eGFR than those without events. Reduced eGFR without albuminuria was more strongly associated with CVD events than normal eGFR with micro or macroalbuminuria (OR 1.52, 95%CI 1.34–1.73 vs. 1.20, 1.08–1.33), but less strongly than reduced eGFR with albuminuria (1.90, 1.66–2.19). Interestingly, nonalbuminuric renal impairment was associated with coronary events (myocardial infarction and/or coronary revascularization) more strongly than albuminuric renal impairment and albuminuria with normal eGFR, whereas the association of the nonalbuminuric phenotype with cerebro-vascular (stroke and/or carotid revascularization) and peripheral (ulcer/gangrene/amputation and/or lower limb revascularization) events was lower than for the other two forms of CKD.

Conclusion: This large-cohort study shows that nonalbuminuric renal impairment in type 2 diabetes, though encumbered by lower cardiovascular risk and prevalence of CVD than the albuminuric phenotype, is strongly associated with coronary events.

Intensive glucose lowering and end stage kidney disease: new data from the ADVANCE trial

S. Zoungas^{1,2}, H.J. Lambers Heerspink¹, J. Chalmers¹, M. Woodward¹, M. Jun¹, A. Cass¹, S. MacMahon¹, M.E. Cooper³, P. Hamet⁴, M. Marre⁵, C.E. Mogensen⁶, V. Perkovic¹;

Public Health and Preventive Medicine, Monash University, Melbourne,

Australia, ³The Baker International Diabetes Institute, Melbourne, Australia,

⁴University of Montreal, Canada, ⁵Université Paris 7, France, ⁶Medical

Department M, Aarhus Sygehus, Denmark.

Background and aims: Blood glucose levels have been linked to the risk of kidney disease, but the effects of intensive glucose control on major kidney outcomes among people with diabetes are not known.

Materials and methods: This analysis from the ADVANCE trial compared the effects of an intensive glucose lowering target (HbA_{1c} < 6.5%) using a glizalide MR based regimen to a standard target (HbA_{1c} < 7%) on major renal events. The outcomes assessed were end-stage kidney disease (ESKD, defined as maintenance dialysis or transplantation), renal death, confirmed doubling of creatinine to above 200 µmol/L, and sustained doubling of creatinine to the same level (final recorded value consistent with the doubling criteria).

Results: 11,140 patients were randomised to intensive or standard glucose lowering. The mean achieved HbA_{1c} levels were 6.5% in the intensive arm, and 7.3% in the standard arm. After an average follow up of 5 years, the risk of ESKD was significantly lower in the intensive compared to the standard glucose lowering arm: hazard ratio [HR] 0.35, 95% confidence interval [CI] 0.15–0.83, p = 0.02. There was a non-significant trend towards benefit for renal death (HR 0.85, CI 0.45–1.63, p = 0.63) and the composite of ESKD and renal death (HR 0.64, CI 0.38–1.08, p = 0.09). No clear effect on doubling of creatinine (HR 1.15, CI 0.82–1.63, p = 0.42) or sustained doubling of creatinine 0.83 (0.54–1.27, p = 0.39) was observed.

Conclusions: An intensive blood glucose lowering regimen based on glizalide MR reduced the risk of ESKD in the ADVANCE study, but the effects on other renal outcomes were less clear. The interpretation of doubling of creatinine as a component of renal endpoints requires further consideration. Additional studies of glucose lowering in people with diabetes at high risk of ESKD are needed.

Medicine, Bronx, USA.

Background and aims: Reduction of blood pressure (BP) and blood glucose diminish some microvascular complications of type 2 diabetes, but data on the combined effects of these interventions are sparse. Here we report effects of intensive BP control alone and in combination with intensive glycemic control on microvascular complications in the ACCORD BP trial.

Materials and methods: 4733 adults with type 2 diabetes (T2DM) and systolic BP (SBP) 130–180 mm Hg on 0–3 BP medications were randomized to intensive (target SBP <120 mm Hg) or standard (SBP <140 mm Hg) BP control, and separately randomized to intensive (target HbA_{1c} <6.0%) or standard (HbA_{1c} 7.0–7.9%) glycemic control. Pre-specified outcomes included one composite microvascular outcome measure (dialysis or renal transplantation, high serum creatinine [>3.3 mg/dL], or retinal photocoagulation or vitrectomy) and 9 single measures of kidney, eye, or peripheral nerve function. Proportional hazards regression models were used to assess two-way interactions

between glycemia and BP treatment arm assignment for each microvascular complication.

Results: Over a mean follow-up of 4.7 years, the primary microvascular outcome occurred in 527 of 4733 participants, including 11.4% in the intensive BP arm and 10.9% in the standard BP arm (HR=1.08, 95% CI: 0.91–1.28). Whereas intensive glycemic control reduced the incidence of macroalbuminuria and a few other microvascular outcomes, intensive BP control only reduced development of microalbuminuria (HR=0.84, 95% CI:0.72–0.97). The observed reductions in microvascular outcomes by intensive glycemic control were not affected by the BP treatment arm (no interaction).

Conclusion: Intensive BP control improved only 1 of 10 pre-specified microvascular outcomes. None of the pre-specified outcomes were further significantly reduced in participants intensively treated for both glycemia and BP compared to those treated with either regimen alone, signifying the lack of an additional beneficial effect from combined intensive treatment.

Association of renal status and cardiovascular risk, and safety of fenofibrate in renal impairment in the FIELD study of 9,795 subjects with type 2 diabetes

R. Ting, T.M.E. Davis, A.J. Jenkins, P.L. Drury, M.W. Donoghoe, J.K. Rajamani, A.Y. Kesaniemi, J.D. Best, A.C. Keech;
c/o NHMRC Clinical Trials Centre, The University of Sydney, Camperdown, Australia.

Background and aims: Renal function predicts cardiovascular disease in Type 2 diabetes. Fenofibrate treatment raises plasma creatinine. In the Fenofibrate and Event Lowering in Diabetes (FIELD) study, we examined the effect of renal status changes on CVD risk and the consequences of fenofibrate administration in subjects with moderate renal impairment, where safety of treatment has been uncertain.

Materials and methods: In FIELD, 9795 patients, 50–75 years with type 2 diabetes, were randomly assigned to co-micronised fenofibrate 200mg daily or matching placebo over 5 years. The pre-specified outcome for subgroup analysis was total cardiovascular events. Renal status (eGFR [MDRD-4 variable] and albuminuria [albumin:creatinine ratio]) was examined (baseline, year 2 and close-out). End-stage renal events were recorded. Analysis was by intention-to-treat.

Results: Higher CVD risk was strongly associated with lower baseline eGFR (HR for eGFR<60: 1.44 [95%CI 1.2–1.8, p<0.001]) and with albuminuria (HR 1.3 [95%CI 1.2–1.5], p<0.001); and was modified by renal status changes over the first 2 years. In those on placebo whose albuminuria status changed from normal to abnormal, risk significantly increased (by about 30%, p=0.006) whereas it reduced when albuminuria resolved (by about 25%, p=0.01). A similar pattern was observed for changing eGFR status between < 60 and ≥ 60 ml/min/1.73m². Overall, fenofibrate reduced total cardiovascular events by 11% (p=0.035), with comparable benefits seen in all eGFR subgroups (p-interaction=0.2). The greatest absolute CVD risk reduction (7.5%) with fenofibrate was observed in those with moderate renal impairment, eGFR 30–59 ml/min/1.73m² (HR 0.68, p=0.035), without any safety concerns. Lesser loss of renal function (1.0 ml/min/ 1.73m² less per annum) occurred over 5 years among those allocated fenofibrate than placebo (p=0.0003; wash-out study, n=661). End-stage renal disease events were no more common with fenofibrate, including among those with moderate renal impairment (see table), or those with the greatest early creatinine rise on fenofibrate.

Conclusion: Lower eGFR and albuminuria are both strongly independently associated with CVD risk. Improvements over time are associated with lower CVD risk. Fenofibrate slows eGFR loss and does not cause renal injury in diabetes or reduce cardiovascular benefits when creatinine rises. There were large cardiovascular benefits and no renal issues when used in those with moderate (eGFR 30–59 ml/min/1.73m²) renal impairment.

Simultaneous kidney and pancreas transplantation, compared to hyperglycaemia, improves long-term (>8 yrs) outcome in the transplanted kidney

T.G. Jenssen¹, J.P. Lindahl¹, F. Reinholdt², H. Hestvaag¹, A. Stranda³, S.O. Kolset³, A. Hartmann³;

¹Department of Organ Transplantation, Oslo University Hospital Rikshospitalet, ²Department of Pathology, Oslo University Hospital Rikshospitalet, ³University of Oslo, Norway.

Background and aims: To assess the impact of long-term glycemic control on renal transplant function and structure, we compared type 1 diabetes patients who had either received combined kidney-pancreas grafts from deceased donors, or a single kidney graft from live donors (LD), more than 8 years ago.

Materials and methods: Eighteen type 1 diabetes patients transplanted with simultaneous pancreas and kidney grafts (SPK) were compared to 16 patients transplanted with single kidneys (SK) from LD. These two categories of patients tend to be comparable in terms of age and comorbidity at transplantation, and the patients were randomly selected among living subjects. The immunosuppressive regimen was CNi-based and essentially the same in both groups. Estimated GFR (eGFR) was calculated in a stable phase 6 months after transplantation and then after 8–15 years. At follow-up a kidney graft biopsy was also obtained, and measurements of glomerular basement membranes by interactive computerized image analysis of electron micrographs (EM) were performed.

Results: Age at baseline was similar (mean (SEM)): SPK: 40.3 (1.3) SK: 39.3 (2.5) years. Baseline BMI and eGFR were also similar: 23.0 (0.6) kg/m² vs 23.9 (0.8), and 51.3 (3.2) vs. 53.0 (4.0) ml/min/1.73 m², respectively. The SPK group was followed for 13.6 (1.1) years, and the SK group 10.8 (0.6) years. HbA1c at follow-up was 5.7 (0.2) % and 8.3 (0.5) % in the SPK and SK groups, respectively (p<0.01). At follow up, eGFR had increased 4.8 (5.9) ml/min/1.73 m² in the SPK group, and fallen 10.3 (4.2) ml/min/1.73 m² in the SK group (p=0.03). EM showed a 30% thicker basement membrane in the SK patients: SPK: 295 (17.1) nm, SK: 380 (31.3) nm (p=0.08). Serum metalloproteinase-9 (MMP-9) was lower in the SPK patients compared to the SK patients; MMP-9: 37.3 (8.9) vs 56.3 (11.4) ng/ml, while its inhibitor TIMP-1 was the same in each group.

Conclusion: Long-term GFR is better preserved in kidney transplanted type 1 diabetes patients when glucose homeostasis is maintained with a functional pancreas graft. The glomerular basement membrane apparently remains thinner in these patients.

Gestational glucose intolerance resulting from impaired beta cell mass expansion in the absence of survivin in female mice

X. Wu¹, X. Wang¹, J. Zhu¹, Q. Zhang¹, K. Xu¹, T. Yang¹, H. Okada², M. Woo³;

¹Department of Endocrinology, First Affiliated Hospital of Nanjing Medical University, China, ²Division of Signaling Biology, Ontario Cancer Institute, Toronto, Canada, ³Institute of Medical Science, Ontario Cancer Institute, University of Toronto, Canada.

Background and aims: Adaptive beta cell mass expansion ensures metabolic balance in pregnancy, a physiological state marked by increased insulin demand due to the insulin resistance. Beta cell proliferation is the principal mechanism of beta cell mass expansion in pregnancy, but the molecular mechanisms responsible for this process is elusive. Our previous data showed that survivin regulates beta cell mass and beta cell proliferation during perinatal period and after duct ligation. We predicted that decreased survivin activity could result in an inability to expand beta cell mass during times of increased metabolic demand. This study was designed to determine whether survivin was required for glucose homeostasis and beta cell mass expansion in maternal islets during pregnancy.

Materials and methods: Using the Cre-loxP recombination system, we generated a rat insulin promoter (RIP)-driven survivin knockout mouse with a specific deletion of survivin in pancreatic beta cells. Survivin expression profile, beta cell mass, beta cell proliferation and glucose homeostasis were assessed in adult female RIPCre⁺survivin^{lox/lox} mice and their control littermates (RIPCre⁺survivin^{+/+}) during pregnancy.

Results: In pregnant control mice, maternal beta cell mass increased by two-fold and beta cell replication peaked at gestational day(GD)14.5. Transient re-expression of survivin was detected in the islets from GD10.5 to GD18.5 with the peak at GD14.5, which closely mirrored the beta cell proliferative profile during pregnancy. Targeted deletion of survivin in beta cells, female mutant mice maintained glucose homeostasis at eight weeks, despite a 50% reduction in beta cell mass due to the lack of survivin during perinatal period. However, pregnant female mutant mice at GD14.5 exhibited markedly higher glucose excursions during an IPGTT and compromised insulin secretion after i.p. glucose injection compared with controls, with specific impairment in beta cell mass expansion and the failure of the increase of beta cell proliferation.

Conclusion: Our results indicate that transient reexpression of survivin in the pancreatic beta cells during pregnancy is essential for beta cell mass expansion. Survivin deficiency in beta cells leads to defects in beta-cell proliferation, resulting in a decrease in beta cell mass expansion and glucose intolerance during pregnancy.

PI3K-C2α regulates proliferation and differentiation of pancreatic beta cells

B. Leibiger, T. Moede, P.-O. Berggren, I.B. Leibiger;
Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: PI3K-C2α generates PI(3,4)P₂ in beta cells and is involved in glucose-stimulated insulin release via a mechanism involving PKBa activation, TBC1D4 phosphorylation and regulation of glucokinase expression. We have recently shown that knock-down of PI3K-C2α in pancreatic beta cells, in contrast to most other cells, leads to increased proliferation and survival. The aim of this study was to evaluate the mechanism underlying the increased beta cell proliferation and survival after knock-down of PI3K-C2α.

Materials and methods: MIN6 cells, primary mouse and human beta cells were treated with control siRNA or siRNA against PI3K-C2α. Knock-down of protein levels of PI3K-C2α was verified by Western blotting (80% knock-down). Cell proliferation under different conditions was measured by BrdU- or EdU- incorporation. Protein expression and phosphorylation were evaluated by Western blot. PKBa activity was measured by Akt1/PKBa immunoprecipitation kinase assay. Apoptosis rate of MIN6 cells after treatment with either H₂O₂ or staurosporine was determined by triple staining with Hoechst 33342, propidium iodide (PI) and AlexaFluor488-annexinV, where AlexaFluor488-annexinV positive PI-negative stained cells were considered apoptotic.

Results: The area covered by BrdU-positive nuclei related to the area covered by all cells was increased 2.3 ± 0.12fold in PI3K-C2α siRNA-treated MIN6 cells compared to control siRNA-treated MIN6 cells. BrdU- and EdU-incorporation were also increased in mouse (1.88 ± 0.24fold) and human (1.92 ± 0.21fold) primary beta cells treated with PI3K-C2α siRNA compared to control siRNA-treated cells. Cells treated with PI3K-C2α siRNA were more resistant to apoptotic stimuli (48.4 ± 4.9% less apoptotic cells when treated with 20 μM H₂O₂ and 32 ± 2.9% less apoptotic cells when treated with 6 μM staurosporine). Knock-down of PI3K-C2α in MIN6 cells affected also cell size (cells were 37.9 ± 2.6% smaller), glucokinase protein expression (25 ± 3% less), first phase of glucose-stimulated insulin release (-25 ± 5.9 %) and abolished the insulin-stimulated activation of PKBa and downstream PKB target proteins (FoxO1, TCS2, TBC1D4). Basal PKBa activity did not change. The positive effect of PI3K-C2α knock-down on MIN6 cell proliferation was abolished by blocking PI3K class Ia (20 μM LY294002), by IR-blocking antibodies and by inhibiting PKBa (0.1 μM Akti-1/2). Knock-down of PKBa in MIN6 cells led to decreased proliferation (-33.9 ± 5.3%) and increased apoptosis, the latter both under normal culture conditions (+100 ± 9.9%) and when challenged with apoptotic stimuli H₂O₂ or staurosporine (+50 ± 5.2%).

Conclusion: PI3K-C2α and PKBa both contribute to the regulation of beta cell proliferation and differentiation. PI3K-C2α is a negative regulator of beta cell proliferation and maintains beta cell differentiation and function via a pathway involving signaling through insulin receptors, PI3K class Ia and PKBa.

MicroRNA profiling during expansion and differentiation of human islet-derived precursor cells reveals stage specific microRNA signature

G. Sebastiani^{1,2}, F.A. Grieco^{1,2}, A. Po³, E. Miele¹, L. Galleri^{1,2}, I. Spagnuolo^{1,2}, P. Marchetti⁴, E. Ferretti³, F. Dotta^{1,2};

¹Diabetes Unit, University of Siena, ²Umberto di Mario Research Foundation, Siena, ³University of Rome Sapienza, ⁴University of Pisa, Italy.

Background and aims: Generation of insulin producing cells from stem/progenitor cells is potentially crucial to develop a proper cell therapy for type 1 diabetes. MicroRNAs (miRs) are small endogenous RNAs representing important negative regulators of gene expression. We have previously obtained human pancreatic islet derived mesenchymal (hPIDM) cells that can be *in vitro* expanded and induced to re-acquire a pancreatic endocrine phenotype when cultured in appropriate conditions. In order to gain insights into the mechanisms regulating gene expression during beta cell regeneration and differentiation, we here performed an extended miR profiling in hPIDM cells during expansion and their differentiation into insulin producing cells in comparison with human native pancreatic islets.

Materials and methods: hPIDM cells, obtained from human pancreatic islets purified from 3 organ donors, were expanded in medium containing 10% FBS. For differentiation, hPIDM cells were cultured for 21 days in serum-free medium containing insulin, transferrin and Na-selenite. Real time PCR was used for gene expression analysis of 92 genes (associated to a mesenchymal or to a pancreatic endocrine phenotype). MiR profiling (762 human miRs) was performed using TaqMan array cards. Genes and miRs expression were evaluated at the following stages: primary human islets, hPIDM cells during expansion and after differentiation. In addition, for miRs of interest, a six points time course expression analysis was performed during the 21 days of differentiation.

Results: Gene expression analysis confirmed that, during expansion, hPIDM cells acquired mesenchymal-associated genes (e.g. vimentin, nestin) and lost islet-related genes (e.g. insulin, glucagon, somatostatin, etc.). Upon differentiation, hPIDM cells re-acquired islet-associated genes with a major reduction of mesenchymal-associated ones. MiR profiling showed a stage specific differential expression of several miRs, including some involved in stemness regulation or islet function and development. Specifically miR-302-367 cluster, involved in self-renewal and in stemness maintenance, were absent in native islets and appeared in proliferating hPIDM cells, which subsequently and progressively lost their expression during the first 10 days of pancreatic endocrine differentiation. We also found that miR-200 family miRs, reported as regulators of epithelial-mesenchymal transition, were expressed in native islets, strongly down-regulated during expansion and re-expressed upon pancreatic endocrine differentiation. As for islet-associated miR-375, this was highly expressed in native islets and showed an extreme down-regulation in proliferating hPIDM cells, which progressively re-acquired its expression

during their differentiation into an islet-like phenotype. Of note, during the first 10 days of such differentiation, miR-375 showed an increasing expression parallel to that of insulin gene.

Conclusion: We have identified a specific expression signature of stem- and differentiated islet-associated miRs during expansion and re-differentiation of hPIDM cells, indicating that these miRs may have a role in the regulation of human beta cell mass and islet regeneration phenomena.

Generation and characterisation of pancreas-specific Tcf7l2 null mice

G. da Silva Xavier, G. Sun, G.A. Rutter;
Cell Biology, Imperial College, London, UK.

Background and aims: Genome wide association studies (GWAS) generate vast quantities of data and identify potential genetic contributions to complex polygenic disorders such as type 2 diabetes (T2D) that would often have been difficult, if not impossible, to predict using a candidate gene approach. However, identifying the causal gene within a particular genetic locus, and understanding the mechanisms and tissues through which the implicated genetic variations act, has been challenging. A single nucleotide polymorphism (SNP) rs7903146 in the TCF7L2 gene was identified in GWA studies as strongly (odds ratio >1.3) associated with the development of T2D. Patients carrying risk alleles of rs7903146 display impaired insulin secretion and decreased sensitivity to the incretin glucagon-like peptide 1 (GLP-1). It has also been reported that islet TCF7L2 message levels are elevated in T2D patients compared to controls whilst TCF7L2 protein content is depressed. These changes were accompanied by down-regulation of GLP-1 and glucose-dependent insulintropic polypeptide (GIP) receptor expression. Our own and others' work has subsequently shown that Tcf7l2 silencing in isolated primary islets and clonal beta cells leads to increased apoptosis and impaired beta-cell function. In the present, study we sought to determine whether deletion of Tcf7l2 selectively in the pancreas in mice may be sufficient to impair glucose homeostasis in vivo.

Materials and methods: Pancreas-specific Tcf7l2 null mice (pTcf7l2 mice) were generated by crossing Tcf7l2-flox^d mice (GenOway) with Cre deleter animals in which Cre recombinase expression is driven by the Pdx1 promoter (a kind gift from Prof. D. Melton, Harvard University). Mice were genotyped by PCR using genomic DNA from ear biopsies, and gene expression in pancreatic islets of Langerhans was assessed by real-time quantitative PCR (qPCR). Glucose tolerance was assessed following intraperitoneal injection or oral administration of glucose (1g/kg). Insulin secretion was assessed in isolated islets during static incubations and assessed by radioimmunoassay.

Results: Tcf7l2 transcript levels were undetectable (Ct > 39) in islets from pTcf7l2 mice vs islets from littermate controls. pTcf7l2 mice displayed normal glucose tolerance and body weight at 8, 12 and 16 weeks, as measured by intraperitoneal glucose tolerance test, but had decreased oral glucose tolerance compared to control littermates (n=7–13 mice from 4 separate litters). Interestingly, Glp1r and insulin2 (Ins2) gene expression were significantly lower in pTcf7l2 islets (42 ± 0.08 % and 15.4 ± 4.6 % decrease, respectively) vs control islets. Islets from pTcf7l2 mice displayed impaired glucose and GLP-1 stimulated insulin secretion (54.6 ± 4.6 % and 44.3 ± 4.9 % lower than from control islets cultured at 16.7 mM glucose and 16.7 mM glucose plus 100 nM GLP-1, respectively), in keeping with published data on human islets, which may be due, at least in part, to the down-regulation of Glp1r expression.

Conclusion: Loss of Tcf7l2 gene expression selectively in the pancreas is sufficient to cause impaired tolerance to oral glucose, whilst responses to intraperitoneal glucose are normal. This likely reflects altered Glp1r expression in beta cells and an impaired response to circulating GLP-1.

Role of glial cell line-derived neurotrophic factor in endocrine pancreas formation

J. Muñoz, A. Leal Cerro, D.A. Cano;
Unidad de Gestión de Endocrinología, Instituto de Biomedicina de Sevilla (IBiS) Hospital Universitario Virgen del Rocío / CSIC / Universidad de Sevilla, Spain.

Background and aims: Recent studies have suggested that endocrine pancreas formation is regulated by signals from the neural crest cells that migrate and populate the gut with neural and glial cells during embryonic

development. Glial Cell Line-Derived Neurotrophic Factor (GDNF) is a neurotrophic factor that plays a critical role in the development and survival of the enteric nervous system. Both in vitro and in vivo experiments have shown that GDNF overproduction promotes beta cell survival and proliferation. To determine the functional role of GDNF in endocrine pancreas formation in mice we have decided: 1) to analyze the expression pattern of GDNF during pancreas development and 2) to genetically inactivate GDNF in pancreas.

Material and methods: GDNF expression was studied by semiquantitative PCR and by the use of a lacZ-based transgenic mouse throughout embryonic development and adulthood. Cre/lox recombination was used to conditionally eliminate GDNF in mouse pancreatic cells. The pancreata of the mutant mice was analyzed by immunohistochemistry and molecular biology techniques.

Results: GDNF expression was detected at embryonic day 10.5 (E10.5), soon after the pancreas evaginates for the foregut, and E12.5 along with progenitor markers such as Pdx-1 but not in differentiated glucagon producing cells. At E14.5, after the secondary transition, GDNF expression persisted in Pdx-1 expressing progenitor cells in the ducts. From E15.5 on, GDNF was expressed only in differentiating ducts albeit at much lower levels, and after birth became almost undetectable. GDNF was detected exclusively within pancreatic epithelial cells, with no expression in mesenchyme throughout the embryonic development. This is in sharp contrast to other regions of the gut where GDNF is expressed only in mesenchyme. GDNF was specifically inactivated in developing pancreatic epithelium using the Pdx-1-Cre transgenic mouse line. No differences in islet architecture and mass were observed between GDNF knockout mice and control mice, demonstrating the GDNF function is dispensable for islet formation. However, a profound loss of neural cells was found in the pancreata, including islets, of GDNF knockout mice, as determined by staining for the neural marker HuC/D. Our analysis of the embryonic pancreas indicates that migration of neural progenitor cells is compromised in pancreas-specific GDNF mutant mice.

Conclusion: GDNF is expressed in the pancreatic progenitor compartment during early embryonic development becoming restricted to ducts at later stages. The colocalization of GDNF and progenitor markers during embryonic development suggests a functional role for GDNF in embryonic pancreas development. However, our results show that GDNF is dispensable for pancreas formation. Our results indicate that the production of GDNF in embryonic pancreatic epithelium is necessary for the neural colonization of pancreas. We believe the pancreas-specific GDNF mutant mice might be a useful to analyse neural-islet interactions in endocrine pancreas.

Self-replication is not the only mechanism of maintenance of pancreatic beta cell mass after birth

K. Minami¹, K. Tamura¹, K. Iemoto¹, K. Nakamura¹, S. Seino^{1,2};
¹Molecular and Cellular Medicine, Kobe University Graduate School of Medicine, ²Division of Diabetes and Endocrinology, Kobe University Graduate School of Medicine, Japan.

Background and aims: Pancreatic beta cell mass is maintained throughout lifetime to control blood glucose levels. Although it has been shown that the major mechanism of the maintenance of beta cell mass after birth is self-replication of pre-existing beta cells, pancreatic beta-cells might also be generated from non-beta-cells. We address this issue by using the inducible Cre/loxP system to trace beta cells.

Materials and methods: We generated Ins2-CreERT2 knock-in mice, in which a fusion protein containing Cre-recombinase (Cre) and modified estrogen receptor is replaced with mouse insulin 2 gene. Unlike conventional transgenic mice expressing Cre driven by insulin promoter, expression of Cre in Ins2-CreERT2 knock-in mice reflects insulin expression with no position effect. We crossbred Ins2-CreERT2 knock-in mice with R26R-YFP mice to generate Ins2-CreERT2/R26R-YFP double knock-in mice, in which pancreatic beta cells can be labeled specifically and permanently upon injection of tamoxifen, and traced the beta-cells by pulse and chase experiment in several different conditions. For tracing beta-cells in adult pancreas, mice of 6 weeks of age were injected with tamoxifen to label the beta cells. For tracing in neonates, pregnant mothers of the mice were injected with a single dose of 4-hydroxytamoxifen on the day before they gave birth. For tracing beta cells after injury, the mice were injected with streptozotocin after tamoxifen treatment. In the chase periods, pancreata removed from the mice were processed for immunostaining. The frequency of labeling of the pancreatic beta cells

was calculated by dividing the number of YFP-positive cells by the number of insulin-positive cells.

Results: When beta cells were labeled in adults under physiological and untreated conditions, $25.8 \pm 3.75\%$ of insulin-positive cells were labeled with YFP and the frequency of the labeling (labeling index) was not altered throughout the 12-month experimental period. In addition, the labeling index was not changed after ablation of beta cells by streptozotocin treatment. In contrast, when tamoxifen was injected to pregnant mothers just before they gave birth, the labeling index in the neonates was decreased significantly around weaning, suggesting that beta cells might be generated from non-beta cells. In addition, small insulin-positive cell clusters, an indication of neogenic islets, containing no YFP-positive cells were detected in this period.

Conclusion: These results indicate that various mechanisms are involved in the maintenance of beta cells after birth and that the present system using knock-in mice is useful for investigation of beta cell fate.

Change in HDL cholesterol and risk of hospitalised coronary artery disease or stroke among patients with type 2 diabetes

S. Vupputuri¹, G.A. Nichols², A.G. Rosales²;

¹The Center for Health Research, Kaiser Permanente Georgia, Atlanta, ²The Center for Health Research, Kaiser Permanente Northwest, Portland, USA.

Background and aims: The burden of cardiovascular disease (CVD) is especially high among patients with diabetes. Low levels of high density lipoprotein cholesterol (HDL-C) are associated with CVD, but it remains unclear whether raising HDL-C reduces CVD risk. The aim of this study was to assess whether changes in HDL-C were associated with risk of hospitalization for coronary artery disease or stroke among a population-based sample of patients with type 2 diabetes.

Materials and methods: We conducted an observational cohort study of 30,067 members of Kaiser Permanente who had type 2 diabetes and two HDL-C measurements 6–24 months apart from 2001–2006. After calculating change in HDL-C, we followed patients for up to 7.5 years (through 2009) to determine whether change in HDL-C was associated with CVD hospitalizations. We examined HDL-C change continuously, and also stratified patients into categories of change: increased HDL-C by 6.5mg/dl, decreased HDL-C by 6.5mg/dl, or remained within ± 6.4 mg/dl. Cox regression models were used to assess the association of baseline HDL-C and change in HDL-C with CVD hospitalizations, adjusted for demographic and clinical risk factors as well as comorbidities and pharmaceutical use.

Results: Of the 30,067 study subjects, HDL-C levels remained within ± 6.4 mg/dl for 61.4% (n=18,449), increased by at least 6.5mg/dl for 21.6% (n=6,488), and decreased by at least 6.5mg/dl for 17.0% (n=5,130). Over a mean follow-up of 55.8 ± 23.8 months, 3,717 (12.4%) patients experienced a CVD hospitalization. After multivariable adjustment, each 5mg/dl increase in baseline HDL-C was significantly associated with 7% lower CVD hospitalization risk (HR 0.93, 95% CI 0.92–0.95, $p < 0.0001$) and each 5mg/dl increase in HDL-C change was associated with a 5% CVD risk reduction (HR 0.95, 95% CI 0.93–0.97, $p < 0.0001$). In categorical analysis, a 6.5mg/dl HDL-C or greater decline was associated with 15% increased CVD risk (HR 1.15, 95% CI 1.05–1.27, $p = 0.003$) while a 6.5mg/dl or greater increase was associated with a 10% CVD risk reduction (HR 0.90, 95% CI 0.83–0.98, $p = 0.016$) relative to individuals with stable HDL-C.

Conclusions: In our large, diverse, population-based sample of patients with diabetes, we found that declining HDL-C was positively and significantly associated with risk of CVD hospitalization while increasing HDL-C was significantly and inversely associated with risk of CVD hospitalization. Our study adds to the growing body of evidence suggesting that raising HDL-C levels may be an important strategy for CVD risk reduction and suggests that prevention of HDL-C declines may be equally important.

Table: Fully adjusted hazard ratios of hospitalized CVD associated with baseline HDL-C and change in HDL-C

	Hazard Ratio (95% Confidence Interval)	P value
Continuous Model		
Baseline HDL per 5mg/dl	0.93 (0.92 - 0.95)	<0.0001
HDL-C Change per 5mg/dl	0.95 (0.93 - 0.97)	<0.0001
Categorical Change Model		
HDL-C Remained ± 6.4 mg/dl	1.00	--
HDL-C Decreased < -6.5 mg/dl	1.15 (1.05 - 1.27)	0.003
HDL-C Increased ≥ 6.5 mg/dl	0.90 (0.83 - 0.98)	0.016

Glycaemic control and heart failure in 83,021 patients with type 2 diabetes

M. Lind¹, M. Olsson², A. Rosengren¹, A.-M. Svensson³, I. Bounias¹, S. Gudbjörnsdóttir¹

¹Institute of Medicine, University of Gothenburg, Uddevalla, ²Department of Mathematical Sciences, Chalmers University of Technology, Gothenburg, ³Center of Registers in Region Västra Götaland, Gothenburg, Sweden.

Background and aims: Intensive glycaemic control has shown no preventive effect in heart failure (HF) in patients with type 2 diabetes. Findings from observational studies are not consistent with respect to the relationship between glycaemic control and HF. The aim was therefore to study the association between glycaemic control and HF in a large study with long follow-up of patients with type 2 diabetes.

Materials and methods: We linked data from patients with type 2 diabetes from the Swedish National Diabetes Register, with the national hospital discharge and mortality registries. The diagnosis of HF is validated as correct in 90–95% of cases. Unadjusted and adjusted incidence rates were estimated by Poisson regression and relative risk by Cox regression.

Results: A total of 83,021 patients with type 2 diabetes, registered between 1998 and 2003 (mean age 65.8 years (SD 11.7) years), and initially free from HF were followed through December, 2009. During a median follow-up of 7.2 years, 10,969 patients (13.2 %) were hospitalized with a primary or secondary diagnosis of HF. The unadjusted incidence rates of HF per 1,000 person-years ranged from 13.8% (95% CI 12.9,14.8) for patients with HbA1c <6.0% (42.0 mmol/mol) to 25.8 % (23.5,28.4) for patients with HbA1c ≥10.0% (85.8 mmol/mol). Cox regression was performed adjusting for age, sex, diabetes duration, smoking, BMI, systolic and diastolic blood pressure, prior or intervening myocardial infarction, atrial fibrillation, heart valve surgery, ischaemic heart disease, use of beta blockers, angiotensin converting enzyme-inhibitors and angiotensin receptor blockers. The adjusted hazard ratio was 2.01 (95% CI 1.79–2.27) for patients with updated mean HbA1c>10.0% (85.8 mmol/mol), as compared with patients with HbA1c <6.0% (42.0 mmol/mol) (reference). The hazard ratio for each percentage unit (10.9 mmol/mol) increase in HbA1c was 1.16 (95% CI 1.14–1.18).

Conclusion: The incidence of HF in type 2 diabetes was high, with 13.2% hospitalized for HF during a mean follow-up period of 7.1 years in a population with a mean age of 65.8 years. Impaired glycaemic control is strongly and independently associated with hospitalization for HF.

Clinical Trial Registration Number: N7A

Trends in hospital admissions for major cardiovascular events and procedures among people with and without diabetes between 2004 and 2009 in England: a nationwide study

E.P. Vámos, C. Millett, M. Parsons, P. Aylin, A. Majeed, A. Bottle;
Department of Primary Care and Public Health, Imperial College London, UK.

Background and aims: Despite population reductions in cardiovascular disease (CVD) in recent decades, it is unclear whether this decline is present in both people with and without diabetes. We aimed to compare recent trends in hospital admission rates for angina, acute myocardial infarction (AMI), stroke, percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) among people with and without diabetes in England.

Materials and methods: We identified all patients aged >16 years with cardiovascular events in England between 2004 and 2009 using national hospital-activity data. Diabetes and non-diabetes specific rates were calculated for each year. To test for time trend, we fitted Poisson regression models.

Results: Over the study period, diabetes-related admission rates for angina, AMI and CABG decreased significantly in England by 5% (rate ratios 0.95 (95% CI 0.94–0.96)), 5% (0.95 (95% CI 0.93–0.97)) and 3% (0.97 (95% CI 0.95–0.98), $P<0.001$ for all) per year. The incidence of stroke did not significantly change in people with and without diabetes (rate ratio 0.99 (95% CI 0.99 (0.98–1.00) and 0.99 (95% CI 0.97–1.01) per year, respectively), while admission rates for PCI increased in both groups (1.02 (95% CI 1.01–1.03, $P<0.01$) and 1.03 (95% CI 1.01–1.05, $P<0.001$) per year, respectively). People with diabetes experienced similar proportional changes for all CVD outcomes as those without diabetes. The median length of hospital stay signifi-

cantly decreased for all admissions in both groups over the study period. Diabetes was associated with an approximate 3.5 to five-fold risk of CVD events. **Conclusion:** This is the first study we are aware of to identify recent diabetes-related admission rates for major CVD events using a national sample that covers the entire population of England. These national data show a considerable decline in hospital admission rates for angina, acute myocardial infarction and CABG, unchanged rates for stroke and an increase in PCI procedure rate among both people with and without diabetes in England. These findings emphasize the ongoing need for aggressive risk reduction and primary prevention of CVD.

Predicting the mortality of people with type 2 diabetes mellitus following a major complication: a study using Swedish National Diabetes Register data

P.J. Kelly¹, P.M. Clarke¹, A.J. Hayes¹, U.G. Gerdtham², P.M. Nilsson³, B. Eliasson⁴, J. Cederholm⁵, S. Gudbjörnsdóttir⁴

¹Sydney School of Public Health, University of Sydney, Camperdown, Australia, ²Department of Economics, Lund University, Sweden,

³Department of Clinical Sciences, Lund University, Sweden, ⁴Institute of Medicines, University of Gothenburg, Sweden, ⁵Department of Public Health and Caring Sciences, Uppsala University, Sweden.

Background and aims: The aim of this observational study was to predict the risk of mortality and life expectancy for diabetic patients following diabetes-related complications.

Materials and methods: This study comprised of people in Sweden with type 2 diabetes alive on or after 1 January 2001. Data were collected from three separate sources: 1) risk factor data from the Swedish National Diabetes Registry (NDR); 2) hospital records of inpatient episodes; and 3) Swedish death records. Data were confidentially linked at the individual patient level by the NDR. The cohort comprised of 22,751 patients who had one of the following complications of diabetes between January 2001 and December 2007: myocardial infarction, stroke, heart failure, amputation or renal failure. Logistic regression was used to estimate mortality within the first month post-complication and a Gompertz proportional hazards model was used to model mortality after the first month post-complication. Follow-up was ended at 31 December 2007. For both models, the following risk factors were examined: type of complication, sex, age at time of complication, duration of diabetes, smoking status, HbA1c, systolic blood pressure, ratio of total cholesterol to HDL, microalbuminuria, proteinuria and Chronic Kidney Disease (CKD) using eGFR.

Results: Besides age at the time of complication and the type of complication, factors increasing the immediate risk of mortality following a complication included: male (OR = 1.10; 95% CI: 1.01, 1.20); duration of diabetes per decade (OR = 1.15; 95% CI: 1.10, 1.21); HbA1c > 8% (OR = 1.27; 95% CI: 1.12, 1.45); smoking (OR = 1.66; 95% CI: 1.48, 2.05); body mass index <20 kg/m² (OR = 1.64; 95% CI: 1.27, 2.11); systolic blood pressure <110 mmHg (OR = 1.55; 95% CI: 1.14, 2.09); proteinuria (OR = 1.14; 95% CI: 1.01, 1.29). These same factors also increased the risk of mortality after the first month: male (HR = 1.14; 95% CI: 1.07, 1.21); duration of diabetes per decade (HR = 1.05; 95% CI: 1.02, 1.09); HbA1c > 8% (HR = 1.13; 95% CI: 1.03, 1.25); smoking (HR = 1.56; 95% CI: 1.41, 1.72); body mass index <20 kg/m² (HR = 1.58; 95% CI: 1.33, 1.89); systolic blood pressure <110 mmHg (HR = 1.55; 95% CI: 1.30, 1.84); proteinuria (HR = 1.33; 95% CI: 1.22, 1.45). CKD was also associated with increased risk of mortality after the first month: moderate decrease in GFR (HR = 1.19; 95% CI: 1.11, 1.28), severe decrease in GFR (HR = 1.41; 95% CI: 1.23, 1.63), and end-stage kidney failure (HR = 1.90; 95% CI: 1.49, 2.43).

Conclusion: In this large, nationwide, population-based study that included a range of risk factors, we have derived a two-part model that can be used to predict survival following five different types of diabetes-related complications. Several risk factors including smoking, BMI, and kidney function were shown to significantly impact on mortality following a major complication. This information is useful in understanding the prognosis of patients following major complications and are useful in modeling the potential benefits of altering risk factors such as smoking status.

53

Systolic and diastolic blood pressure levels associated with lowest risk in type 2 diabetes: a cohort study of 37,798 primary care patientsJ. Sundström^{1,2}, C.J. Östgren³, B. Svennblad², R. Sheikhi¹, J. Bodegård⁴, P.M. Nilsson⁵, G. Johansson⁶;¹Department of Medical Sciences, Uppsala University, ²Uppsala Clinical Research Center, Uppsala University, ³Department of Medical and Health Sciences, Linköping University, ⁴AstraZeneca Nordic, Södertälje, ⁵Department of Clinical Sciences, Lund University, Lund, ⁶Department of Public Health & Caring Sciences, Uppsala University, Sweden.**Background and aims:** Aggressive blood pressure treatment targets in type 2 diabetes guidelines have recently been questioned. We therefore aimed to investigate the systolic and diastolic blood pressure levels associated with the lowest risk of cardiovascular events in a large primary care-based sample of patients with diabetes.**Materials and methods:** We identified a cohort of 37,798 patients with type 2 diabetes aged 35 years or older (mean age 65 years) by in 2010 extracting data from electronic patient records for all patients who had a diagnosis of type 2 diabetes or had glucose lowering agents prescribed between 1999 and 2008 in 76 Swedish primary care centers. We followed the cohort for subsequent incidence of a combined endpoint of major cardiovascular events (myocardial infarction, stroke, heart failure, or cardiovascular death) by linking the patients to the Swedish National Cause of Death and Hospital Discharge registries. We investigated restricted cubic spline functions for annually updated systolic and diastolic blood pressures (in separate models) in Cox proportional hazards models, adjusting for age and sex.**Results:** During a median of 3.8 (range 0–10) years of follow-up, 8,994 patients (24%) had a major cardiovascular event (incidence rate 55/1000 person-years at risk). The associations of systolic and diastolic blood pressures with risk of major cardiovascular events were U-shaped (figure). The lowest risk was observed at a systolic blood pressure of 146 mm Hg and a diastolic blood pressure of 79 mm Hg.**Conclusion:** In a large primary care-based sample of patients with type 2 diabetes, associations of systolic and diastolic blood pressures with risk of major cardiovascular events were U-shaped. The blood pressure levels associated with the lowest risk were not consistently in agreement with treatment target levels recommended in current guidelines.

HbA_{1c} as predictor of morbidity and all-cause mortality in people with type 2 diabetes: a Danish population-based observational studyM.V. Skriver¹, H. Støvring², J.K. Kristensen¹, M. Charles¹, A. Sandbæk¹;¹Dept. of General Practice, ²Dept. of Biostatistics, Aarhus University, Denmark.**Background and aims:** The evidence for recommending individuals with type 2 diabetes to strive toward a HbA_{1c} level below a certain value is growing, but there is however sparse evidence from population-based follow-up studies. Since 2003 the Danish Department of Health have recommended offering intensive antidiabetic treatment aimed at reducing HbA_{1c} to less than 7% to all individuals with type 2 diabetes. Thus, the aim of this study is to investigate, in a population-based setting, whether individuals with type 2 diabetes and a HbA_{1c} level below 7% have a lower diabetes related morbidityand/or all-cause mortality than individuals with type 2 diabetes and a HbA_{1c} level above 7%.**Materials and methods:** Individuals with type 2 diabetes were identified with a dedicated validated algorithm, from public data files in Aarhus county, Denmark. The algorithm has a sensitivity of 96% and a positive predictive value of 89%. Individuals were identified in the years 2000 to 2006 and were required to have at least one HbA_{1c} measurement. In total 22,238 people were identified. HbA_{1c} level was defined as the average for each individual of all HbA_{1c} measurements in the year of the first registered HbA_{1c} measurement. Information of morbidity was obtained from the Danish Hospital Discharge Registry (which covers all hospitalisations in Denmark) and information of death and emigration was obtained from the Danish Civil Registration System (which comprises all Danes). Survival was estimated by the Kaplan-Meier method. Possible excess mortality and/or morbidity for individuals with HbA_{1c} above 7% compared with individuals with HbA_{1c} below 7% were estimated with 95% CIs using Cox proportional hazard models. Analysis was stratified on whether information of diabetes duration was observed or not. Adjustment was made for age, sex, prior cardiovascular disease and number of prior admissions of non-cardiovascular diseases. Further adjustment was made for diabetes duration when analysing the subgroup where this information was available. The proportionality assumption was tested using Schoenfeld residuals. Time since 1st of January the year after the first registered HbA_{1c} measurement was used as time scale. Each person was followed until death or morbidity outcome, emigration (censoring) or two years after inclusion, whichever came first. Analyses were performed using Stata version 10.1.**Results:** Please see the table for the specific hazard ratios. In general, a HbA_{1c} level above 7% increased mortality and diabetes related morbidity. Inclusion of diabetes duration slightly lowered the excess risk.**Conclusion:** In this population based study individuals with type 2 diabetes and a HbA_{1c} level below 7% had lower mortality and lower diabetes related morbidity than those with a level above 7%. This supports the recommended treatment target of a HbA_{1c} level below 7%Hazard ratios for individuals with HbA_{1c} ≥ 7%. Individuals with HbA_{1c} < 7% as reference group

Pioglitazone improves insulin sensitivity by modulating novel biomarkers: results from the ACTNOW study

D. Tripathy¹, W.E. Gall², K.-P. Adam³, D.C. Schwenke³, M. Banerji⁴, G.A. Bray⁵, T.A. Buchanan⁶, S.C. Clement⁷, R.R. Henry⁸, A.E. Kitabchi⁹, S. Mudaliar⁸, R.E. Ratner¹⁰, N. Musi¹, P.D. Reaven³, R.A. DeFronzo¹;
¹Medicine, UTHSCSA, San Antonio, ²Metabolon, Inc., Durham, ³Phoenix VA Health Care System, Phoenix, ⁴Suny Health Science Center at Brooklyn, ⁵Pennington Biomedical Research Center, Baton Rouge, ⁶University of Southern California Keck School of Medicine, Los Angeles, ⁷Division of Endocrinology & Metabolism, Georgetown University, Washington, ⁸VA San Diego Healthcare System, ⁹Division of Endocrinology, Diabetes and Metabolism, University of Tennessee, Memphis, ¹⁰Medstar Research Institute, Hyattsville, USA.

Background: ACT NOW is a randomized double-blind, placebo-controlled study to examine whether pioglitazone (PIO) can prevent/delay development of type 2 diabetes mellitus (T2DM). The aim of the study was to examine the effect of pioglitazone on novel biomarkers that could contribute to the metabolic effects of pioglitazone.

Methods: 602 IGT subjects (FPG =105, 2-h PG [OGTT]=168 mg%) were randomized to PIO (45 mg/day) or placebo (PLAC) and followed for 2.4 years. Indices of insulin secretion and insulin sensitivity were derived from the plasma glucose, insulin, and C peptide concentrations during the OGTT and in a subset from IVGTT before and at study end. Using mass spectrometry, targeted analysis was conducted in 431 individuals with IGT who completed the ACT NOW study. Selected from our previous euglycemic clamp metabolomics studies, we measured top-ranking insulin sensitivity metabolites, including plasma alpha-hydroxybutyrate (alpha-HB), linoleoyl-GPC, oleoyl-GPC, glycine, serine, betaine, decanoylcarnitine, and oleic acid, before and after treatment with pioglitazone/placebo.

Results: 50 PLAC-treated subjects developed diabetes versus 15 PIO-treated subjects (hazard ratio=0.28; 95% CI= 0.16, 0.49; p<0.0001). The improvement in Matsuda insulin sensitivity index in PIO-treated (3.9 ± 0.2 to 7.6 ± 0.3 mcg/ml; p<0.0001) subjects was ~2-fold greater than in PLAC-treated (3.9 ± 0.2 to 5.2 ± 0.3 mcg/ml, p<0.0001 PIO vs PLAC). There was no significant difference between groups in plasma metabolite concentrations at baseline. At study end pioglitazone-treated individuals had significantly lower alpha-HB (3.85 ± 0.1 vs 4.33 ± 0.1 mcg/ml, p=0.002), oleic acid (73 ± 1 vs 82 ± 2 mcg/ml, p=0.001) and higher glycine (15.9 ± 0.3 vs 13.7 ± 0.3 mcg/ml, p<0.005), serine (9.1 ± 0.4 vs 8.2 ± 0.1 mcg/ml, p<0.005), linoleoyl-GPC (13.0 ± 0.3 vs 11.2 ± 0.2 mcg/ml, p<0.005). At baseline matsuda index of insulin sensitivity correlated with alpha-HB (r=0.178, p<0.005), glycine (r=0.296, p<0.005), serine (r=0.123, p<0.005), oleoyl-GPC (r=0.267, p<0.005) and betaine (r=0.157, p=0.001). The improvement in Matsuda index of insulin sensitivity correlated with change in alpha-HB (r=0.112, p=0.02), glycine (r=0.275, p<0.005), serine (r=0.272, p<0.005) and oleoyl-GPC (r=0.144, p=0.04).

Conclusion: Pioglitazone modulates novel metabolites related to lipid metabolism and oxidative stress which may in part explain the beneficial effects of pioglitazone on insulin sensitivity.

Hyperglycaemia enhances the expression of the diabetogene ped/pea-15 through chromatin remodelling

P. Mirra¹, M. Ciccirelli², R. Teperino³, F. Fiory², L. Albano¹, I. Manzo¹, L. Carbonari¹, F. Beguinot¹, P. Ungaro²;
¹Dipartimento di Biologia e Patologia Molecolare, Università degli Studi di Napoli, Italy, ²IEOS, CNR, Napoli, Italy, ³Epigenetic Focus, Max-Planck Institute of Immunobiology and Epigenetics, Freiburg, Germany.

Background and aims: Both genes and environment contribute to the development of type 2 diabetes (T2D) and the molecular mechanisms of gene-environment interplay in T2D onset have recently received increased attention. Indeed, emerging evidence indicates that epigenetics plays an important role in the regulation of gene expression and environment may affect chromatin

structure, increasing thus the risk of diabetes in exposed individuals. PED/PEA-15 is a gene commonly over-expressed in T2D subjects and in their offsprings, healthy individuals with a high risk of developing diabetes. In addition, the over-expression of ped/pea-15 gene in mice impairs glucose tolerance and leads to diabetes when they are fed a high-fat diet. The aim of this study was to evaluate whether hyperglycaemia contributes to changes in ped/pea-15 expression and to investigate changes in chromatin structure due to hyperglycaemia and associated with ped/pea-15 expression.

Materials and methods: The rat skeletal muscle cell line L6 was cultured in DMEM supplemented with either 5.5 mM D-glucose (normal glucose, NG) or in 25 mM D-glucose (high glucose, HG). Real Time-Polymerase Chain Reaction (RT-PCR) and Chromatin Immunoprecipitation (ChIP) assays have been performed to evaluate ped/pea-15 expression and changes in chromatin structure at the ped/pea-15 promoter, respectively.

Results: L6 cells cultured in HG showed an increase of the ped/pea-15 mRNA levels up to twofold compared to NG cultured cells. We could exclude the osmotic stress as a cause of this result, since culturing L6 cells under osmotic stress conditions, such as in 20 mM mannitol for 2 weeks, had no effect on ped/pea-15 expression. Time-course experiments revealed an increase of ped/pea-15 mRNA levels already after a 4 hour exposure to HG. We used ChIP experiments to show that HG increased the binding of nuclear factor κB (NF-κB) p65 subunit and the activator protein 1 (AP-1) c-jun subunit to the ped/pea-15 promoter in L6 cells. Furthermore, the HG-induced recruitment of chromatin remodelling factors to the ped/pea-15 promoter was assayed with an antibody specific for the acetyl-histone H3 at lysine 9 and lysine 14, and other epigenetic marks are now under investigation. In addition, in our laboratory new treatments are going on to confirm the importance of NF-κB and AP-1 transcription factors in ped/pea-15 expression, such as treatment with the tumor necrosis factor alpha (TNF-alpha), which is known as a potent inflammatory mediator.

Conclusion: These results provide novel evidence that a close relationship exists between ped/pea-15 gene expression and acetylated histone at the ped/pea-15 promoter under hyperglycaemia conditions. In more detail, our results suggest that hyperglycaemia increases the activation of AP-1 and NF-κB and regulates chromatin remodelling, leading to an increase in ped/pea-15 expression. This may have a role in explaining how hyperglycaemia in turn exacerbate insulin resistance, contributing significantly to the pathogenesis of the disease.

The role of diacylglycerol concentrations in the development of lipid-mediated insulin resistance in human skeletal muscle

J. Szendroedi^{1,2}, T. Yoshimura³, E. Phielix¹, M. Marcucci³, D. Zhang³, S. Baudot¹, C. Fuehrer¹, C. Herder¹, P. Nowotny¹, G.I. Shulman³, M. Roden^{1,4};
¹German Diabetes Center, Duesseldorf, ²Department for Metabolic Diseases, Heinrich Heine University Hospital, Duesseldorf, Germany, ³Yale School of Medicine, New Haven, USA, ⁴Department for Metabolic Diseases, Heinrich Heine University Hospital, Duesseldorf, Germany.

Background and aims: Skeletal muscle is mainly determines insulin resistance in humans with or at risk of type 2 diabetes, but the underlying cellular mechanisms causing are still unclear. Possible mechanisms are alterations in adipocytokines linked to inflammation, mitochondrial function and intramuscular lipid metabolites [ceramides, diacylglycerols (DAGs)] and have been tested in animal studies, but not yet proven in humans.

Materials and methods: We examined 16 healthy humans (n=16, 30±5 years, BMI: 24±2 kg/m²) and measured circulating cytokines (n=6: TNFα, IL-6, sI-CAM, adiponectin, RBP-4, FGF-21), intramuscular DAG and ceramide contents, protein kinase C isoforms (PKC β, Δ, θ) expression and activities as well as mitochondrial function before and after a 4h infusion of lipid (Intralipid 20%) or glycerol infusion. Detailed mitochondrial function, including ADP-coupled glutamate and succinate oxidation (state 3), FCCP-induced maximal oxidative capacity (state u) as well as kinetics of NADH and FADH₂ dehydrogenases were examined in permeabilized muscle fibers with high-resolution respirometry. Thereafter, a hyperinsulinemic [40 mU/(m².min)]-euglycemic clamp was performed combined with [6,6-2H₂]glucose to assess muscle insulin sensitivity.

Results: Whole-body glucose disposal was ~66% lower during lipid infusion than during glycerol infusion (P<0.000001). Associated with lipid-induced insulin resistance, muscular DAG, but not ceramide, content increased ~2fold (P<0.005) at 2.5h and remained elevated (~1.4fold, P<0.05) at 4 h of lipid infusion. At 4 h, only the activity of PKCθ, but not other isoforms, was raised by 64% (P<0.005). On the other hand, plasma concentrations of all measured cytokines but FGF-21 were not affected despite the marked insulin resistance.

FGF-21 was ~3.5 fold higher at 4 h lipid as compared to glycerol experiments (863 ± 151 vs 248 ± 68 pg/ml, $p < 0.009$). Mitochondrial oxidative capacity and kinetics of respiratory chain complexes I/II also remained unchanged during the lipid infusion.

Conclusion: These results support the concept that DAG-induced activation of PKC θ plays a key role in causing lipid-induced insulin resistance in human skeletal muscle. On the other hand, neither circulating adipocytokines nor muscular ceramides contribute to acute lipid-induced muscle insulin resistance in humans.

Obesity is associated with elevated Hsp60 plasma levels that might contribute to the development of insulin resistance in insulin sensitive cell types

T. Märker¹, H. Sell¹, S. Famulla¹, P. Zilleßen¹, A. Glöde¹, J. Kriebel¹, M. Ouwens¹, J. Ruige², J. Eckel¹, M. Roden¹, C. Habich¹;

¹German Diabetes Center, Düsseldorf, Germany, ²Ghent University Hospital, Belgium.

Background and aims: Obesity is a strong risk factor for the development of insulin resistance and associated with increased circulating pro-inflammatory adipokines. It has been suggested that adipokines are important paracrine mediators of adipose tissue inflammation and endocrine mediators of the crosstalk between adipose tissue and other tissues such as skeletal muscle, contributing to insulin resistance. The signals initiating these processes are not well understood to date, but recent studies characterized stress protein heat shock protein 60 (Hsp60) as a potent inducer of inflammation processes in murine adipocytes. Thus, this study aimed at analysing the inflammatory and metabolic effects of Hsp60 on human adipocytes and skeletal muscle cells (SkMC). Moreover, human adipocytes were investigated as a putative source of circulating Hsp60 and Hsp60 plasma levels from lean and obese individuals were determined.

Materials and methods: Preadipocytes from human subcutaneous adipose tissue and myoblasts were differentiated in vitro. The release of pro-inflammatory mediators after Hsp60 treatment was measured by multiplexbeads assays. Insulin signaling, pro-inflammatory and cellular stress pathways were analyzed by Western blots. The uptake of 2-deoxy-glucose in SkMC was measured for 2 h after insulin (10^{-7} mol/l) administration for 30 min. Hsp60 release was determined by ELISA from adipocytes without and with stimulation by a mixture of cytokines (TNF α , IL-1 β , IFN γ , 1000 U/ml each). Hsp60 plasma levels were determined by ELISA in 18 lean (BMI: 23.4 ± 5.6 kg/m²) and 23 obese (BMI: 44.5 ± 5.6 kg/m²) men.

Results: Hsp60 release from human adipocytes was 2-fold increased after cytokine treatment (0.9 ± 0.3 ng/ml; $p < 0.05$) compared to control (0.4 ± 0.3 ng/ml). In human adipocytes and SkMC, Hsp60 inhibited insulin-stimulated phosphorylation of Akt. Furthermore, Hsp60 exposure decreased glucose uptake in SkMC (1.7 ± 0.1 -fold over basal; $p < 0.01$) compared to control (2.1 ± 0.1 -fold over basal). To elucidate the underlying mechanisms, stress signaling was investigated in both cell types. Hsp60 causes a 2- to 3-fold increase of phosphorylation of ERK1/2, JNK and NF κ B. Moreover, Hsp60 exposure led to increased secretion of TNF α (63.9 ± 49.2 pg/ml; $p < 0.001$), IL-8 (1.2 ± 0.9 ng/ml; $p < 0.01$) and RANTES (970.5 ± 351.0 pg/ml; $p < 0.01$) from human adipocytes, compared to medium control. Furthermore, Hsp60 induced a significant release of MCP-1 (1.2 ± 0.6 ng/ml; $p < 0.001$), IL-8 (1.7 ± 0.9 ng/ml; $p < 0.001$) and IL-6 (0.4 ± 0.3 ng/ml; $p < 0.001$) from SkMC after 24h. Hsp60 plasma levels were 1.6-fold higher in obese than in lean males ($p < 0.05$) and positively correlated with body mass index ($p = 0.04$; $r = 0.34$), plasma leptin ($p = 0.04$; $r = 0.34$) and QUICKI ($p = 0.04$; $r = 0.38$), indices of insulin resistance.

Conclusion: Human adipocytes release Hsp60, which in turn induces secretion of various pro-inflammatory adipocytokines. Hsp60 induces insulin resistance via inflammatory pathways in human adipocytes and SkMC. As circulating Hsp60 levels are elevated in obese humans, Hsp60 likely contributes to obesity-associated inflammation and insulin resistance.

Chronic mTOR inhibition induces muscle insulin resistance despite weight loss in rats

L. Bourgoïn¹, N. Deblon², C. Veyrat-Durebex², M. Peyrou¹, M. Vinciguerra¹, A. Caillon², C. Maeder¹, M. Fournier¹, X. Montet^{3,1}, F. Rohner-Jeanrenaud², M. Foti¹;

¹Department of Cell Physiology and Metabolism, Faculty of Medicine,

²Department of Internal Medicine, Division of Endocrinology, Diabetology and Nutrition, Faculty of Medicine, ³Department of Radiology, Faculty of Medicine, University of Geneva, Switzerland.

Background and aims: mTOR inhibitors are currently used as immunosuppressive therapies in transplanted patients and as promising anti-cancer agents. However, new-onset diabetes is a frequent complication occurring in patients treated with mTOR inhibitors such as rapamycin (Sirolimus).

Materials and methods: We investigated the mechanisms associated with the diabetogenic effects of chronic Sirolimus administration in rats fed either a standard or a high-fat diet. Rapamycin effects on glucose metabolism and insulin signaling were further evaluated in cultured myotubes.

Results: Sirolimus treatment (SIR) for 21 days promoted a decrease in cumulative food intake (-21.1 ± 7.5 %, $p < 0.001$) and concomitant weight loss (delta BW gain: $+35.5 \pm 3.8$ g for CTL vs -7.1 ± 2.1 g for SIR, $p < 0.001$). Compared to pair-fed rats, SIR also induced a specific fat mass loss measured by EchoMRI (-62.9 ± 12.4 %, $p < 0.01$) that was independent from changes in food intake. Despite these beneficial effects, Sirolimus-treated rats were glucose intolerant (AUC of GTT: 878.2 ± 24 for CTL vs 1179.3 ± 74 for SIR, $p < 0.01$), hyperinsulinemic (fasting insulinemia: 1.4 ± 0.2 ng/ml for CTL vs 3.5 ± 0.6 ng/ml for SIR, $p < 0.05$) and hyperglycemic (fasting glycemia: 4.6 ± 0.1 mM for CTL vs 6.4 ± 0.5 mM for SIR, $p < 0.05$), but not hyperlipidemic. Skeletal muscles

represented the major site of Sirolimus-induced insulin resistance as assessed by euglycemic-hyperinsulinemic clamps (GIR in mg/kg/min: 21.6 ± 1.1 for CTL vs 9.3 ± 0.7 for SIR, $p < 0.001$). In vitro, long-term rapamycin treatment of L6 myotubes inhibited insulin-induced glucose uptake (by $62.9 \pm 11.2\%$, $p < 0.001$) and glycogen synthesis (by $96.2 \pm 6.4\%$, $p < 0.001$). At the molecular level, both in vitro and in vivo analyses showed that rapamycin (Sirolimus) impairs muscle glucose metabolism by preventing full insulin-induced Akt activation and by altering the expression of glucose transporters. Finally, rats fed a high-fat (HF) diet and treated with Sirolimus displayed an exacerbate glucose intolerance (AUC of GTT: 1223.4 ± 89 for HF fed rats and 1789.0 ± 141 for HF fed rats + SIR, $p < 0.01$) although they were protected from diet-induced obesity.

Conclusion: Taken together, our data demonstrate that the diabetogenic effect of chronic rapamycin administration is due to an impaired insulin action on glucose metabolism in skeletal muscles.

Individualised diabetic education can contribute to decrease the incidence of diabetic foot and avoid amputation: results of a 9-year prospective study

X. Zhenghua, C. Dingyu, Y. Qiling, Z. Qian, X. Jin, H. Chunling, H. Ling, L. Wei, D. Laiming, Q. Qingxin, Y. Lin, H. Shuiqing;
Endocrinology, Guangzhou Medical University, China.

Background and aims: The annual morbidity of diabetic foot ulcers (DFU) is between 1.2% and 3.1% and 49.5% and 27.4% separately in elder or pre-elder patients. 33% of patients with DFU needed to be amputated in China. There are more of the changeable factors including patient education, optimizing glycaemic control, smoking cessation, and diligent foot care etc. There is some dispute about significance of diabetic education on prevention and prognosis of diabetic foot ulcers.

Materials and methods: 229 patients with high-risk diabetic foot (with diabetic neuropathy or Lower extremity vascular disease or with both) were randomly divided into individual education group ($n=125$)(IDE) and conventional educational group ($n=104$)(CDE). They were separately given the individual diabetic education and conventional diabetic education on the basis of the original therapeutic schedule. The difference of cumulative incidence, amputation rate, mortality, ABI and vibration threshold value were observed every year from January 1999 to December 2009.

Results: 1. The annual incidence of diabetic foot ulcer IDE group was lower than that in CDE group from the third year ($P < 0.05$). The cumulative incidence of diabetic foot ulcers in IDE Group at 9 years was 19.2%, RDE group was 39.4%. The relative risk decreased 51.3%. 2. By the end of ninth year, ABI were separately 0.75 ± 0.09 (IDE Group) 0.51 ± 0.10 (CDE group), (IDE vs CDE, $P < 0.001$). 3. The vibration threshold value was separately 16.9 ± 1.7 volts (IDE), 29.5 ± 1.4 volts (CDE) (IDE vs CDE, $P < 0.05$). 4. At the sixth year end, there was significant difference between the two groups whether or amputation rate of mortality ($P < 0.05$). At the end of ninth year, the relative risk of amputation in IDE group decreased 39.95%, $P < 0.01$, the relative risk of death decreased 40.52%, $P < 0.05$.

Conclusion: Individualized diabetic education may not only decrease the incidence of diabetic foot ulcer, but also retard the progress of diabetic foot and reduce amputation rate and mortality.

62

The effect of self-monitoring of blood glucose on metabolic control in type 2 diabetes patients

L. Czupryniak¹, E. Szymańska-Garbacz¹, M. Saryusz-Wolska¹, M. Pawłowski¹, J. Sojczyńska¹, J. Wójcik-Odyniec¹, E. Jakubczyk¹, A. Szyborska-Kajane², M. Wróbel², Z. Ruprecht³, G. Majcher-Witczak⁴, A. Trojak⁵, M.T. Małecki⁵, J. Loba¹, K. Strojek²;

¹Internal Medicine and Diabetology Dept, Medical University of Lodz,

²Silesian Medical University, Zabrze, ³Medical University of Bydgoszcz,

⁴Diabetes Care Centre, Kielce, ⁵Metabolic Diseases Dept, Collegium Medicum, Jagiellonian University, Cracow, Poland.

Background and aims: The role of self-monitoring of blood glucose (SMBG) in type 2 diabetes treatment remains controversial, and the effect of SMBG on the medication dosage adjustment in type 2 diabetes is unclear. We conducted a multi-centre cross-sectional study assessing the relationship between application of SMBG and the glycemic control.

Materials and methods: The study group comprised 564 patients with type 2 diabetes (mean age [\pm SD] 64.3 ± 9.9 years, diabetes duration 10.4 ± 8.4 years, BMI 31.3 ± 5.5 kg/m², 59.7% treated with insulin, HbA_{1c} $7.37 \pm 1.26\%$, fasting and postprandial blood glucose 128 ± 27 and 150 ± 34 mg/dl, respectively). The patients were asked to fill in a standardized questionnaire consisting of closed questions regarding their use of SMBG.

Results: Mean frequency of SMBG was 2.9 ± 1.3 /day and 18.1 ± 10.2 /week. The patients who performed SMBG 3 or more times/day as compared to SMBG < 3 times/day had longer duration of diabetes (11.5 ± 9.0 vs 9.2 ± 7.5 years, $p < 0.01$), higher HbA_{1c} (7.63 ± 1.33 vs $7.28 \pm 1.10\%$, $p < 0.01$), were taking insulin more times daily (3.1 ± 1.2 vs 2.4 ± 1.1 injections/day, $p < 0.001$) and were treated with higher daily insulin dose (56 ± 31 vs 44 ± 26 IU, $p < 0.001$). More frequent SMBG showed slight but significant positive correlation with HbA_{1c} ($r=0.144$, $p < 0.05$; see figure) and insulin daily dos-

age ($r=0.229$, $p<0.05$). However, multiple regression analysis showed that only BMI and not frequency of SMBG was an independent determinant of HbA_{1c} . Patients performed SMBG “to know their blood glucose” (76%), “per doctor’s order” (67%), and “to know what to eat” (53%). Antidiabetic medication dosing was modified according to SMBG results by 46% of subjects. Pre-meal elevated blood glucose resulted in food intake decrease in 51%, and increase in physical exercise in 55% of the studied subjects. **Conclusion:** SMBG does not seem to be associated with improved metabolic control in type 2 diabetes - probably the opposite is true i.e. patients with worse glucose control tend to perform SMBG more often. As only half of subjects change their behavior due to abnormally high results of SMBG, therefore patients with type 2 diabetes should be educated more effectively to utilize SMBG to modify their lifestyle.

63

Group follow-up compared to individual clinic follow-up after structured education for type 1 diabetes: the Irish DAFNE Study

S.F. Dinneen^{1,2}, M. O’Hara³, J. Newell^{3,4}, N. Coffey⁴, D. O’Shea^{5,6}, D. Smith⁷, H. Courtney⁸, C. McGurk⁹, M. O’Scannail⁶, C. Breen⁶, DAFNE Study Group; ¹Medicine, NUI Galway, ²Endocrinology and Diabetes Day Centre, University Hospital Galway, ³HRB Clinical Research Facility, NUI Galway, ⁴Mathematics, Statistics and Applied Mathematics, NUI Galway, ⁵Diabetes and Endocrinology, St. Vincent’s University Hospital, Dublin, ⁶Diabetes and Endocrinology, St. Columcille’s Hospital, Dublin, ⁷Diabetes, Beaumont Hospital, Dublin, Ireland, ⁸Regional Endocrinology and Diabetes Centre, Royal Victoria Hospital, Belfast, UK, ⁹Diabetes, St. Luke’s General Hospital, Kilkenny, Ireland.

Background and aims: To compare the effectiveness of an education-based strategy of group follow-up with a traditional individual clinic visit strategy after participation in the Dose Adjustment for Normal Eating (DAFNE) structured education programme for patients with type 1 diabetes.

Materials and methods: We cluster randomised 6 hospital diabetes clinics across Ireland. Participant eligibility included type 1 diabetes for more than 1 year and a HbA_{1c} below 13 percent. Group follow-up was delivered at 6 and 12 months post-DAFNE using a semi-structured curriculum with an emphasis on meeting the perceived needs of the group and goal setting. Control arm patients received individual clinic visits from a doctor, nurse and/or dietitian. Change in HbA_{1c} and rates of severe hypoglycaemia were assessed at 6, 12 and 18 months.

Results: Mean duration of diabetes among participants ($n = 437$) was 16 years; mean HbA_{1c} was 8.3 percent with over 29 percent having a HbA_{1c} below 7.5 percent and 24 percent reporting one or more episodes of severe hypoglycaemia in the previous year. At 18 months there was no clinically or statistically significant change in mean HbA_{1c} in either group and no between-group difference in mean HbA_{1c} over time (0.11%, 95% CI (-0.22 to 0.44), $p=0.41$). Among patients with baseline HbA_{1c} above 7.5 percent we found no significant difference between groups (0.1%, 95% CI (-0.31 to 0.51), $p=0.53$) but mean HbA_{1c} did improve over time (-0.16%, 95% CI (-0.27 to 0.06), $p<0.001$). Rates of severe hypoglycaemia decreased significantly over time (0.27 episodes per patient per year, $p<0.001$) but there was no difference between groups. Episodes of severe hypoglycaemia per patient were categorised as ‘increased’, ‘no change’ or ‘decreased’ and an analysis based on proportions was undertaken. This provided convincing evidence that, regardless of treat-

ment ($p=0.89$), those with no hypoglycaemic episodes at baseline tended not to worsen over the period of the study as 90% remained hypoglycaemia free (95% CI (84%, 94%)) while 10% (95% CI (6%, 16%)) reported an increase. Of those that had 1 or more hypoglycaemic episodes at baseline 90% reported a decrease (95% CI (78%, 97%)), 4% reported an increase (95% CI (0.005%, 13%)) while 6% reported no change (95% CI (1%, 17%)) with no evidence of a significant treatment effect ($p=0.28$).

Conclusion: In a relatively well controlled cohort of patients with type 1 diabetes DAFNE training was associated with no change in mean HbA_{1c} over 18 months but with significant improvement in rates of severe hypoglycaemia. The addition of group follow-up for 12 months following DAFNE training was not associated with improvement over and above that seen with one-to-one clinic visits. Our data do not support implementation of group-based care for individuals with type 1 diabetes.

Effectiveness of therapeutic-educational re-training in patients affected by type 1 diabetes treated with CSII (continuous subcutaneous insulin infusion)

A. Carlone, L. Cipolloni, G. Gillanti, C. Gnessi, G. Leto, R. Buzzetti; Clinical Sciences Department, Sapienza, University of Rome, Italy.

Background and aims: Treatment of type 1 diabetes (T1DM) using insulin pumps has certainly made a significant improvement in metabolic control and patients quality of life. However, it is not rare to see a gradual stabilization of the metabolic advantage gained at the beginning of therapy and the progressive deterioration of the glycometabolic situation in some cases. Considering that the role of medical nutrition therapy (MNT) and education of advanced Continuous Subcutaneous Insulin Infusion (CSII) function is not standardized after the initial phase of CSII installation, we performed an educational re-training to patient with long standing insulin pump to test its effectiveness in the metabolic control.

Materials and methods: We enrolled 23 T1DM patients treated with CSII at least for 12 months. The subjects were randomized into two homogeneous groups: a control group $n=11$ (mean age 34 ± 15) and treatment group $n=12$ (mean age of 39 ± 15) and they were followed for six months. Either groups were subjected to quarterly diabetes visits with blood tests and continuous glucose monitoring for 3 days. The treatment group, received in addition six educational weekly group meetings regarding the technical re-training on advanced features of the insulin pump, a healthy diet, the insulin/carbohydrate ratio, carbohydrate counting, insulin sensitivity, index and glycemic load.

Results: Baseline HbA_{1c} levels were similar in treatment group and control group (8.1% vs 8.3% $p=ns$), at sixth month HbA_{1c} levels in treatment group showed a significant reduction compared to control group (7.1% vs 8.3%, $p=0.03$ and $p=0.04$ vs baseline). Furthermore, patients in treatment group showed a significant lower glucose variability at sixth month measured by continuous glucose monitoring compared to control group ($p=0.004$). No significant differences between the two groups in terms of hypoglycemia and weight gain were observed.

Conclusion: Educational training made patients more aware of their disease and more autonomous in the management of everyday problems. Cycles of educational group meetings can be considered an effective therapeutic tool in the maintenance or improvement of metabolic control in patients on insulin pump therapy.

65

Effect of diabetes self-management education combined with self-monitoring of quantitative urine glucose on glycaemic control in non-insulin-treated type 2 diabetes

Z.L. Sun¹, J. Lu¹, R.F. Bu²

¹Department of Endocrinology, Zhongda Hospital, Institute of Diabetes, Medical School, Southeast University, Nanjing, ²Department of Endocrinology, Wuxi People’s Hospital, Affiliated Hospital of Nanjing Medical University, Wuxi, China.

Background and aims: To assess whether diabetes self-management education (DSME) combine with self monitoring of urine glucose (SMUG) or self monitoring of blood glucose (SMBG) is effective, convenient and safe for glycaemic control in non-insulin treated type 2 diabetes.

Materials and methods: This is a prospective, randomized, controlled pilot study. Adults with non-insulin treated type 2 diabetes were recruited from two clinical centers and randomized into three groups: SMBG by using a blood glucose meter (LifeScan OneTouch[®] Ultra Easy[™], n=38), SMUG by using a quantitative urine glucose meter (TANITA[®] UG - 201, n=35), and the control group without self-monitoring (n=35). All patients accepted 5 days standard diabetes education for diabetes knowledge and self-management skills, and were followed up for six months at four weekly intervals, during which identical diabetes care and laboratory measurements were provided.

Results: There was a significant decrease of glycated haemoglobin (HbA_{1c}) within each group (p<0.05). At end-point, mean changes (95% confidence interval) in HbA_{1c} from baseline were -1.9% (-2.5, -1.3) for SMUG group, -1.5% (-1.9, -1.1) for SMBG group and -1.0% (-1.9, -0.2) for the control group, and proportions of patients achieving HbA_{1c} ≤6.5% were 38.9%, 35.3% and 20.0% respectively. However, no significant differences between groups were found. The average monitoring frequency was significantly higher in SMUG group than in SMBG group (74.5±11.6 vs. 58.6±14.6 times per month, p<0.05). Overall hypoglycaemia incidences and scores of diabetes quality of life were similar between groups, although DQOL scores increased significantly only in SMUG and SMBG groups (p<0.05).

Conclusion: This pilot study suggests that DSME combined with SMUG has comparable efficacy with SMBG on glycaemic control while incorporated into diabetes education, life style interventions and pharmacological treatment. Furthermore, SMUG with a quantitative urine meter owes better compliance than SMBG, without influencing the quality of life or risk of hypoglycaemia. Supported by: Key Program of Jiangsu Natural Science Foundation (BK2010087)

were significantly decreased compared to professional group after providing education. The study subjects of professional group had significantly better DBP (mmHg, 81.8±13.1 vs 87.2±8.2, p<0.006) compared to peer leader group. No significant differences were found in SBP (mmHg, 132.6±11.7 vs 129.1±12.6, p=0.5) and BMI (kg/m², 25.0±2.8 vs 22.8±9.3, p=0.3) of the study subjects between peer leader and professional group.

Conclusion: These findings suggest that education with peer support may have improved desired glycemic achievement on diabetes management among type 2 diabetic persons.

Effectiveness of diabetes education on improving glycaemic achievement by professionals versus peers

F. Khan¹, F. Pathan², N. Huda³, F. Saleh⁴;

¹Dept of Specialty Business Unit, Sanofi-aventis Bangladesh Ltd, Dhaka,

²Dept of Endocrinology, BIRDEM, Dhaka, ³Dept of Nephrology, CMCH, Chittagong, Bangladesh, ⁴Dept of Community Nutrition, BIHS, Dhaka, Bangladesh.

Background and aims: Diabetes is a complex disorder that requires a life-long process of self-care, demanding life-long treatment and lifestyle changes. Diabetic patients should be made aware of the sign and symptoms, consequences of the disease. Studies related to education with peer support for improving glycaemic status among diabetes subjects are relatively rare in developing countries like Bangladesh. The aim of the study was to compare the effectiveness of diabetes education with professionals vs peer leaders for achieving target glycaemic status in type 2 diabetic subjects.

Materials and methods: A total of 133 type 2 diabetic subjects (HbA_{1c} >7%) were screened purposively from the OPD of BIRDEM (the tertiary hospital of Diabetic Association of Bangladesh) under a follow-up study. Sixty seven participants led by 4 professionals (diabetes educator) versus 66 participants led by 4 peer leaders. For both groups (4 professionals + 4 peer leaders) total 3 education classes, 4 hours/per class was conducted with a predesigned curriculum. Changes over after 12 weeks educational intervention as well as psychological support and related variables (FBG, HbA_{1c}, weight, SBP and DBP) were compared on 124 (n=59 for professional vs n=65 for peer leader) type 2 diabetic subjects (mean ±SD, age 53.4±10.4 yrs; M 64%, F 36%). Two women and two men were selected as peer leaders who had type 2 diabetes (within last 5 years), education level up to graduation, HbA_{1c} <7%, having in-depth knowledge of disease and good interaction capacity with others. Differences between baseline and follow-up data were calculated using paired t-test and unpaired t-test were used for group differences.

Results: Fasting blood glucose (mmol/L, 7.07±1.9 vs 5.3±2.1, p<0.001) and HbA_{1c} (%), 10.6±1.2 vs 8.04±1.1, p<0.04) level of the study subjects were significantly reduced among peer leader group after getting education intervention. SBP was also significantly reduced (mmHg, 140.7±17.5 vs 132.6±11.1, p<0.002) though no significant difference was found before and after value of DBP (mmHg, 85.1±9.2 vs 88.0±7.8), weight (kg, 68.7±11.1 vs 68.10±10.4) and BMI (kg/m², 25.2±3.05 vs 25.09±2.8) in this group. The level of HbA_{1c} (%), 9.51±1.7 vs 9.05±1.5, p<0.001) of the study subjects were significantly reduced after getting education intervention by professionals. However, after receiving education no significant difference was found in SBP (mmHg, 134.6±16.7 vs 129.4±13.7), DBP (mmHg, 82.6±10.6 vs 83.4±7.9), FBG (mmol/L, 7.9±3.2 vs 6.7±0.8) and BMI (kg/m², 24.7±5.9 vs 23.8±8.04) values of this group. Fasting blood glucose (mmol/L, 3.9±3.1 vs 6.8±1.7, p<0.0001) and HbA_{1c} (%), 8.04±1.1 vs 9.1±1.5, p<0.0001) level of the study subjects in peer leader group

Glucagon-like peptide-1 receptor activation increases myocardial blood flow but does not alter myocardial glucose uptake or metabolism in patients with type 2 diabetes

M. Gejl¹, C. Stecher², H.M. Søndergaard³, N. Møller⁴, H.E. Bøtker⁵, S.B. Hansen², A. Gjedde⁶, J. Rungby¹, B. Brock²;

¹Inst. of Pharmacology, Aarhus University, ²Aarhus University, ³Viborg Regional Hospital, ⁴Aarhus University Hospital, ⁵Skejby Hospital, Dept. of Cardiology, Aarhus, ⁶University of Copenhagen, Denmark.

Background and aims: Cardiovascular effects of glucose-lowering agents are of increasing interest. The incretin hormone glucagon-like peptide-1 (GLP-1) and GLP-1 receptor (GLP-1r) agonists currently emerging as antidiabetic medications have shown promising cardiovascular effects and are speculated to have cardioprotective potentials. Patients with type 2 diabetes mellitus (T2DM) have altered metabolism in the heart with reduced glycolysis and increased beta oxidation of free fatty acids. Thus, a mechanism of enhancing myocardial energetic efficiency by increasing glucose availability and utilization and thereby reducing beta oxidation and increasing cardioprotection may exist. Of interest, GLP-1 seems to increase myocardial glucose uptake (MGU) in dogs. Thus, our aim was to assess the effects of GLP-1r activation on glucose metabolism and blood flow in hearts of subjects with T2DM.

Materials and methods: We conducted a randomized, double-blinded, placebo-controlled cross-over study including eight type 2 diabetes patients, all males, insulin naive, and without coronary artery disease. Positron emission tomography was used to determine the effect of GLP-1 on myocardial blood flow (MBF) and myocardial glucose uptake (MGU) during a pituitary-pancreatic hyperglycemic clamp (plasma glucose 9.0 mmol/l) with ¹³N-ammonia and ¹⁸fluoro-deoxy-glucose (FDG) as tracers. We used a 3-compartment model to describe MGU and MBF. Since exenatide does not seem to have any acute hemodynamic effect on heart rate or blood pressure in humans (1; 2), we used this GLP-1r agonist.

Results: While GLP-1r activation did not affect MGU (0.13 ± 0.07 and 0.15 ± 0.05 micromol/g/min, P=0.66), GLP-1r activation increased MBF from 0.73 ± 0.094 to 0.85 ± 0.091 ml/g/min, p=0.0056. The efflux rate of FDG from cardiomyocytes to blood was 0.88 ± 0.3 min⁻¹ and 1.15 ± 0.2 min⁻¹ (P=0.53) and the amount of FDG metabolised in cardiac mitochondria was 0.04 ± 0.02 min⁻¹ and 0.04 ± 0.02 min⁻¹ (P=0.93), indicating that GLP-1r activation did not alter glucose uptake nor change the intracellular glucose phosphorylation rate. Except from changes in C-peptide levels, no differences in circulating hormones and metabolites (catecholamines, free fatty acids, insulin, growth hormone, cortisol and P-glucose) were found.

Conclusion: The phosphorylation rate of glucose in myocardial cells seems to be extremely low in patients with T2DM and is not altered by exenatide. While GLP-1r activation does not seem to enhance MGU, the myocardial muscle blood flow however increases acutely after infusion of exenatide. Surprisingly, this is not induced by increases in catecholamines, thus we speculate a direct action through the GLP-1r. In spite of increase in blood flow the MGU did not change pointing to a decrease in glucose extraction rate.

Exendin-4 directly improves endothelial dysfunction in obese rats through cAMP/AMPK-eNOS pathways

L.N. Han, Y.R. Yu, B. Wang;

Endocrinology and Metabolism, West China Hospital, Chengdu, China.

Background and aims: There is growing evidence to suggest that Glucagon-like peptide-1 (GLP-1) may play an important role in the cardiovascular system. Some human and animal studies indicated that infusion of GLP-1 has beneficial effects on endothelial function. The aim of this study was to determine whether GLP-1 per se, independent of hormonal changes, might improve endothelial dysfunction in aorta isolated from high-fat diet induced obese rats.

Materials and methods: Male wistar rats 5 weeks of age were randomized to receive a regular chow (Control, n=5) or a high-fat supplemented chow

(OB, n=10). The rats were sacrificed after 10 weeks feeding and thoracic aorta was dissected and cut into four rings of 3-mm length. The response to acetylcholine (ACh) and sodium nitroprusside (SNP) were examined in organ bath. In order to study the direct effects of exendin-4 (a GLP-1 agonist) on obese rats vascular function and investigate possible mechanisms of action of exendin-4, the aortic rings obtained from obese rats were sub-divided into four groups and incubated in organ bath with exendin-4 (2.5nM) in the presence or absence of the following specific inhibitors of candidate pathways: (1) 20μM AMPK inhibitor compound C (Ex-4+CC, n=10), (2) 200mM adenylate cyclase inhibitor Dideoxyadenosine (Ex-4+D, n=7), (3) 1mM NO synthase inhibitor L-NAME (Ex-4+L-NAME, n=10), and (4) vehicle (Ex-4, n=10). After 1 hour of incubation, the aortic rings were precontracted with norepinephrine (0.1μmol/L), then the rings were exposed to cumulative concentration of Acetylcholine (ACh, 10⁻⁹-10⁻⁵M) or sodium nitroprusside (SNP, 10⁻¹⁰-10⁻⁶M) to test the endothelial dependent (EDV) and independent vasodilation (EIV).

Results: Acetylcholine caused a concentration dependent vascular relaxation in all pre-constricted aortic rings. The maximum EDV value was (94.6±1.9)% in the control group and (53.4±5.8)% in the OB group (p < 0.05). The EIV values were comparable between two groups. Pre-incubation of obese rats vessels with exendin-4 significantly increased cumulative relaxation to ACh, the maximum EDV value increased from (53.4±5.8)% to (76.3±5.5)% (p < 0.05). The beneficial effect of exendin-4 on obese rats EDV was partly attenuated in the presence of AMPK inhibitor (Ex-4+CC: 52.1±3.6%, p < 0.05), adenylate cyclase inhibitor (Ex-4+D: 58.8±5.3%, p < 0.05), and NO synthase inhibitor (Ex-4+L-NAME: 58.1±6.6%, p < 0.05). SNP induced vessels relaxation had no statistical significance among four groups.

Conclusion: Endothelial function was impaired in obese rats. The current study demonstrated that exendin-4 directly mitigate impaired endothelial-dependent vasorelaxation of isolated obese rats aortas. The beneficial effect of exendin-4 appears to be mediated, at least in part via stimulation of cAMP/AMPK-related signal transduction pathway and enhancement of eNOS activity. The directly endothelial action of exendin-4 indicates potential therapeutic benefit beyond glycaemic control in obese diabetic patients.

Exendin-4 protects human coronary artery endothelial cells against lipoperoxidation

Ö. Erdogdu¹, L. Eriksson¹, Å. Sjöholm², T. Nyström², Q. Zhang¹;

¹Department of Clinical Science and Education, ²Karolinska Institutet, Department of Internal Medicine, Södersjukhuset, Stockholm, Sweden.

Background and aims: Inappropriate apoptosis of endothelial cells is an important mechanism behind endothelial dysfunction, which plays an important role in macrovascular complications in diabetes. We recently showed that the glucagon-like peptide-1 receptor is expressed in human coronary artery endothelial cells (HCAEC) and that GLP-1 improves endothelial dysfunction in type 2 diabetic patients with coronary artery disease. The aim of the present study was to investigate the role of the stable GLP-1 receptor agonist exendin-4, which has been approved for clinical use against type 2 diabetes, on apoptosis of HCAECs under hyperlipidemic conditions *in vitro*.

Materials and methods: HCAEC cells were cultured in the endothelial growth medium in the presence of 5 mM glucose. Phosphorylation and expression of endothelial nitric oxide synthase (eNOS), p-38 Map kinase and JNK were examined by Western blotting using anti-phospho-eNOS, p-38, JNK and anti-eNOS, p-38 and JNK antibodies, respectively. Alpha-tubulin examined in same blots acted as loading control. Caspase-3 activity and DNA fragmentation were evaluated using ELISA kit as a measure of apoptosis after 24 h-incubation with the reagents.

Results: Incubation of the cells with 0.125 mM palmitate provoked apoptosis, and this effect was significantly inhibited by exendin-4 or GLP-1 (7-36). In contrast, palmitate-induced apoptosis was not affected by the GLP-1 metabolite GLP-1(9-36). Incubation of HCAEC cells with palmitate alone for 24 h resulted in an increased eNOS, p-38 MAP kinase and JNK phosphorylation, which were neutralized by exendin-4. The protective effect of exendin-4 on apoptosis was prevented after treatment of the cells with the specific inhibitors for protein kinase A or for eNOS. In addition, the effects of exendin-4 on apoptosis and enzyme activation were completely blocked by the GLP-1 receptor antagonist exendin (9-39).

Conclusion: Our study reveals that exendin-4 and GLP-1(7-36) protect HCAECs from lipoperoxidation, an effect that is mediated through the GLP-1 receptor and involves PKA, eNOS, and p-38 MAP kinase, JNK dependent

pathways. These novel findings add yet other beneficial properties of exen-4, increasing its clinical utility in type 2 diabetic patients in whom endothelial dysfunction is a salient feature that adversely affect their survival. Elucidation of the mechanisms underlying these beneficial vascular effects of exen-4/GLP-1 may be exploited when intervening pharmacologically against vascular dysfunction in diabetes and may form the basis of improved incretin enhancers that hold the potential to prevent vascular lesions in diabetic patients.

70

Effects of SAR184841 (30 mg/kg/d) on microvascular reactivity in spontaneously hypertensive rats: comparison with irbesartan and rosiglitazone

P.J. Chamiot-Clerc, C. Duquenne, M.-A. Chabanaud, P. Briand, T. Pouyet, C. Canalis, M.-P. Pruniaux;
sanofi-aventis, Chilly-Mazarin, France.

Background and aims: Selective 11 β -hydroxysteroid dehydrogenase type 1 (11 β HSD1) inhibitors have received a major interest for their potential in treating diabetes and macrovascular complications but nothing has been reported yet about their effects on microvascular complications. The aim of this study was to evaluate the effects of chronic oral administration with SAR184841, a selective rodent and human 11 β HSD1 inhibitor, on microvascular reactivity in spontaneous hypertensive rats (SHR) by measuring post occlusive reactive hyperemia (PORH) using the technique of Laser Doppler flowmetry. The effects of SAR184841 were compared with those of the oral antidiabetic rosiglitazone (ROSI) and the antihypertensive drug irbesartan (IRBE).

Materials and methods: 12-week old male SHR (n=48) and their control Wistar Kyoto (WKY, n=12) were included in the study. SHR were treated orally during 21 days with Vehicle (VHC) (0.6% Methocel/Tween 80 in water (0.5 / 99.5, v/v), SAR184841 (30 mg/kg/day), ROSI (5 mg/kg/day) or IRBE (30 mg/kg/day). WKY were treated with VHC (10ml/kg/day). At the end of the treatment period, PORH was assessed in anaesthetized animals using a hyperaemia index measured following the occlusion of the femoral artery. Blood and organ collection were performed to measure insulinemia, biochemical markers and hepatic triglycerides.

Results: In SHR, the hyperaemia index was significantly lower than in WKY (0.20 ± 0.09 versus 0.77 ± 0.18 respectively, $p=0.006$). ROSI was not able to significantly improve microvascular function whereas IRBE and SAR184841 significantly improved the hyperaemia index compared to SHR VHC (0.78 ± 0.09 , $p=0.005$ and 0.72 ± 0.15 , $p=0.034$ versus 0.20 ± 0.09 respectively). Furthermore, both IRBE and SAR184841 restored microvascular function close to the one observed in WKY (0.77 ± 0.18). At the end of the experiment, non fasting insulin blood levels were not changed either between normotensive animals and SHR or among all SHR groups. Conversely, corticosterone levels were found significantly higher in SHR VHC compared to WKY (271 ± 13 and 209 ± 20 ng/mL respectively, $p=0.014$). None of the treatments studied were able to significantly modify corticosterone blood levels when compared to SHR VHC. Similarly adiponectin was found significantly higher in SHR VHC compared to WKY (63.4 ± 7.4 μ g/mL and 38.1 ± 6.2 μ g/mL respectively, $p=0.0096$) but none of the treatments modified these levels significantly. Hepatic TG levels were significantly increased in SHR VHC compared to WKY (13.1 ± 1.7 mg/g versus 3.5 ± 0.5 mg/g respectively, $p<0.001$) and decreased by ROSI treatment vs SHR VHC ($p=0.006$) whereas IRBE treatment did not modify liver TG levels. A clear tendency to decrease hepatic TG levels in SHR was observed with SAR184841 (7.7 ± 1.2 and 13.1 ± 1.7 mg/g respectively) although this effect was not significant ($p=0.055$).

Conclusion: SAR184841 (30 mg/kg/d) significantly improved microvascular reactivity in SHR. In this model, SAR184841 was shown to be equipotent to IRBE on microvascular function and to ROSI on metabolic parameters. These promising results emphasize the potential of 11 β HSD1 inhibitors for the treatment of diabetic microvascular complications.

Aspirin resistant subjects present a proinflammatory milieu with an increased oxidative stress: in these conditions, high glucose fails to influence platelet responses to agonists

I. Russo, C. Frascaroli, L. Mattiello, M. Viretto, C. Barale, G. Doronzo, L. Di Martino, M. Trovati, G. Anfossi;
Department of Clinical and Biological Sciences, University of Turin, Orbassano, Italy.

Background and aims: We previously demonstrated that: i) exposure of platelets from healthy subjects to "in vitro" high glucose attenuates the anti-aggregating effect exerted by aspirin incubation, owing to oxidative stress-mediated inhibition of the aspirin-induced increase of platelet nitric oxide; ii) exposure to "in vitro" high glucose of platelets from "in vivo" aspirin-treated non diabetic patients enhances platelet responses to agonists, but only in aspirin-sensitive patients. To clarify the biochemical mechanisms of this phenomenon, we aimed to clarify the differences between aspirin-sensitive and aspirin-resistant subjects potentially justifying the lack of high glucose effects in the last ones.

Materials and methods: Non-diabetic subjects (n=59, M/F: 33/26, age: 60.2 ± 1.1 years) taking 100 mg/day of aspirin owing to the presence of cardiovascular risk factors and/or previous cardiovascular events, were evaluated for aspirin sensitivity by Platelet Function Analyzer-100 (PFA-100). In aspirin sensitive and aspirin resistant subjects we evaluated: i) platelet aggregation (expressed as Maximal Aggregation, MA) in platelet-rich plasma (PRP) stimulated by sodium arachidonate (NaA, 1mmol/l), ADP (10 μ mol/l) and collagen (4 mg/l) in the presence or the absence of a 60-min preincubation with 25 mmol/l glucose; ii) serum levels of the stable thromboxane metabolite TXB₂; iii) urinary levels of 11-dehydro-TXB₂; iv) a circulating pattern of inflammatory and anti-inflammatory markers including: PCR, IL-1b, IL-1ra, IL-4, IL-6, IL-10, TNF-alpha; v) *in vivo* markers of oxidative stress: 8-OH-2'-deoxyguanosine (8-OH-dG) levels and superoxide dismutase (SOD) activity.

Results: Aspirin resistance was detected in 14 subjects (24%), who, in comparison to aspirin sensitive subjects, showed increased platelet responses to agonists, being MA (%) in response to NaA 14.8 ± 3.5 vs 7.6 ± 6.0 ($p<0.005$), in response to ADP 83.9 ± 7.8 vs 65.0 ± 4.2 ($p<0.04$) and in response to collagen 48.0 ± 10.1 vs 33.9 ± 3.9 ($p<0.02$). In aspirin-resistant subjects platelet exposure to high glucose did not modify aggregating response to agonists, that was reduced in aspirin-sensitive subjects ($p=0.01$ - 0.05 for the different agonists). Furthermore, aspirin resistant subjects showed: i) increased serum concentrations of TXB₂ (pg/ml): 5920.7 ± 1297.8 vs 450.3 ± 72.9 ($p<0.0001$); ii) increased urinary concentrations of 11-dehydro-TXB₂ (ng/mg creatinine): 5.1 ± 0.5 vs 3.5 ± 0.2 , ($p<0.001$); iii) decreased concentrations of anti-inflammatory cytokines (pg/ml) IL-4 (36.5 ± 5.0 vs 87.0 ± 9.3 , $p<0.004$) and IL-10 (27.2 ± 3.8 vs 55.3 ± 2.6 , $p<0.0001$); iv) increased plasma concentrations of 8-OH-dG (ng/ml) (84.8 ± 8.0 vs 31.3 ± 15.5 , $p<0.01$) and decreased plasma SOD activity (U/ml) (4.8 ± 0.14 vs 6.3 ± 0.16 , $p<0.0001$).

Conclusion: Aspirin resistant subjects present not only an incomplete inhibition of COX-1, but also a proinflammatory milieu and an increased oxidative stress, together with an insensitivity to the pro-aggregating effect of glucose. These results suggest that an elevated oxidative stress masks the glucose effects on platelets, that are mediated by the oxidative stress itself.

Determinants of the variability in the recovery rate of platelet cyclooxygenase activity during chronic therapy with low-dose aspirin in type 2 diabetes

F. Zaccardi, D. Pitocco, B. Rocca, F. Santilli, L. Mucci, G. Petrucci, E. Vitacolonna, S. Lattanzio, D. Mattoscio, R. Liani, N. Vazzana, F. Martini, G. Ghirlanda, G. Davi, C. Patrono;
Catholic University, Rome, Italy.

Background and aims: Aspirin is currently recommended for cardiovascular prevention in type 2 diabetes (T2DM). However, primary prevention trials failed to substantiate its efficacy in T2DM and incomplete platelet inhibition has been reported. Hyperglycemia has been often hypothesized to contribute to such an incomplete inhibition. We tested whether a faster recovery of platelet COX-1 activity and/or a suboptimal 24-hour glycemic control would account for an incomplete thromboxane (TX) A₂ inhibition by low-dose aspirin during the 24-hour dosing interval.

Materials and methods: One-hundred T2DM patients on chronic low-dose aspirin (100 mg daily) were studied. Serum TXB₂, an index of platelet COX-1 activity, was measured every 3 hours, between 12 and 24 hours after a witnessed aspirin administration, to characterize the kinetics of platelet COX-1 recovery (phase 1); 46 out of 100 patients underwent 24-hour continuous glucose monitoring (CGMS) as well. Thirty-three patients with the steepest COX-1 recovery slopes were subsequently randomized to receive aspirin 100 mg daily, 200 mg daily or 100 mg twice daily for 28 days (phase 2). On day 29, COX-1 recovery was reassessed over the 12 to 24 hour dosing interval.

Results: COX-1 activity displayed linear kinetics with large inter-individual variability in recovery slope. Multiple linear regression showed that mean platelet volume, higher BMI quartiles and age predicted serum TXB₂ recovery slope, independently of other variables. None of the CGMS variability indices, (mean 24h glycemic value, standard deviation, MAGE and CONGA1-5) as well as HbA1c and fasting glucose correlated with serum TXB₂ recovery slopes. A twice-daily aspirin regimen, but not a doubling of the dose, completely corrected the abnormal recovery slope of platelet COX-1 activity.

Conclusion: We conclude that inter-individual variability in the recovery rate of platelet COX-1 activity during the aspirin dosing interval most likely reflects abnormal megakaryopoiesis associated with T2DM while is not influenced by 24-hr glucose control or other glycemic indices; inadequate TX inhibition can be overcome by a twice daily regimen.

OP 13 GLP-1 receptor agonists

Adding insulin detemir (IDet) to liraglutide and metformin improves glycaemic control with sustained weight reduction and low hypoglycaemia rate: 52 week results

S.C. Bain¹, J.H. DeVries², J. Seufert³, D. D'Alessio⁴, H.W. Rodbard⁵, A.B. Thomsen⁶, R.E. Sondergaard⁶, J. Rosenstock⁷;

¹Department of Medicine, Abertawe Bro Morgannwg University NHS Trust, Swansea, UK, ²Academic Medical Centre, Amsterdam, Netherlands, ³University Hospital of Freiburg, Germany, ⁴University of Cincinnati, ⁵Endo-crine and Metabolic Associates, Rockville, USA, ⁶Novo Nordisk A/S, Copenhagen, Denmark, ⁷Dallas Diabetes and Endocrine Center, Medical City, USA.

Background and aims: To evaluate and compare efficacy and safety of metformin + liraglutide 1.8 mg + insulin detemir (Met+Lira+IDet) versus metformin + liraglutide 1.8 mg (Met+Lira) in a 26-week extension to the previous 12 week run-in followed by 26-week randomised main trial, 64 weeks in total.

Materials and methods: After the 12-week Met+Lira run-in, subjects with HbA_{1c} <7% entered an observational (O) arm and continued on Met+Lira for 52 weeks. Subjects with HbA_{1c} ≥7% were randomised 1:1 to Met+Lira (R) or Met+Lira+IDet for 52 weeks. IDet was titrated from an initial dose of 10U/day. At weeks 26 and 38 post-randomisation, Met+Lira (O or R) subjects with HbA_{1c} ≥8% could intensify therapy with IDet. Twenty-four Met+Lira subjects (7 of 498 observational and 17 of 161 randomised subjects who entered the main period) intensified with IDet during the extension; their last observation carried forward (LOCF) values before intensification were included in the analyses.

Results: 821 of 988 subjects completed the run-in; of these, 498 (61%) reached HbA_{1c} <7% and proceeded to the Met+Lira (O) arm. The remaining 323 (39%) subjects were randomised. Randomised subjects had a mean screening HbA_{1c} of 8.3%, which decreased to 7.6% following run-in. HbA_{1c} decreased a further -0.50% with Met+Lira+IDet vs. +0.01% with Met+Lira (R) by week 52 post-randomisation; estimated treatment difference (ETD) [95% CI]: -0.51% [-0.70; -0.31]; p<0.0001. By week 52, 52% of Met+Lira+IDet subjects reached HbA_{1c} <7% vs. 22% of Met+Lira (R) subjects; odds ratio [95% CI]: 3.94 [2.37; 6.55]; p<0.0001. All groups lost weight during run-in with a mean of -3.5 to -4.3 kg (Fig). From randomisation to week 52, weight did not increase (-0.05 kg) with Met+Lira+IDet and further decreased (-1.02 kg) with Met+Lira (R); ETD [95% CI]: 0.97 [0.04; 1.91]; p=0.0416. Rates of minor hypoglycaemia were low at 0.12, 0.03, and 0.23 events/subject-year for Met+Lira (O), Met+Lira (R), and Met+Lira+IDet, respectively. No major hypoglycaemic episode occurred in any group from randomisation to week 52.

Conclusion: Intensification of Met+Lira with IDet provided improved glycaemic control with low risk of hypoglycaemia and sustained weight loss for up to 52 weeks.

Mean change in body weight over time, no imputation.

Values after intensification are not included in this figure for the 24 Met+Lira subjects who intensified with IDet during the extension.

Four weeks treatment with liraglutide reduces insulin dose without loss of glycaemic control in type 1 diabetic patients with and without residual beta cell function

U. Kielgast¹, T. Krarup², J.J. Holst³, S. Madsbad¹;

¹Department of Endocrinology, Hvidovre Hospital, ²Department of Endocrinology, Bispebjerg Hospital, ³Department of Biomedical Sciences, The Panum Institute, Copenhagen, Denmark.

Background and aims: To investigate the effect of 4 weeks treatment with liraglutide on insulin dose and glycaemic control in type 1 diabetic patients with and without residual beta-cell function.

Materials and methods: Ten type 1 diabetic patients with residual beta-cell function (C-peptide positive) and nineteen without (C-peptide negative) were studied. All C-peptide positive patients were treated with liraglutide plus insulin, whereas C-peptide negative patients were randomised to liraglutide plus insulin or insulin monotherapy. Continuous glucose monitoring with identical food intake and physical activity was performed before (week 0) and during treatment (week 4). Differences in insulin dose, HbA_{1c}, time spent with blood glucose (BG) <3.9 mM, >10 mM and 3.9–9.9 mM and body weight were evaluated.

Results: Insulin dose decreased from 0.50±0.06 to 0.31±0.08 U/kg/day, p<0.001 in C-peptide positive patients and from 0.72±0.08 to 0.59±0.06 U/kg/day, p<0.01 in C-peptide negative patients treated with liraglutide, but did not change with insulin monotherapy. HbA_{1c} decreased in both liraglutide treated groups. The % reduction in daily insulin dose was positively correlated with beta-cell function at baseline and two patients discontinued insulin treatment. In C-peptide positive patients, time spent with BG <3.9 decreased from 3.0 to 1.0 hour, p=0.03. 18/19 patients treated with liraglutide lost weight during treatment (mean -2.3±0.3 kg, range: -0.5 to -5.1 kg, p<0.001). Transient gastrointestinal side-effects occurred in almost all patients treated with liraglutide.

Conclusion: Treatment with liraglutide in type 1 diabetic patients reduces insulin dose with improved or unaltered glycaemic control.

Efficacy and safety of exenatide once weekly versus liraglutide in subjects with type 2 diabetes (DURATION-6): a randomised, open-label study

J.B. Buse¹, M.A. Nauck², T. Forst³, W.H. Sheu⁴, B.J. Hoogwerf⁵, S.K. Shenouda², C.R. Heilmann⁵, M.K. Boardman⁵, M. Fineman⁶, L. Porter⁶, G. Schernthaner⁷;

¹Endocrinology, University of North Carolina School of Medicine, Chapel Hill, USA, ²Diabeteszentrum Bad Lauterberg, Germany, ³Institute for Clinical Research and Development, Mainz, Germany, ⁴Division of Endocrinology and Metabolism, Taichung Veterans General Hospital, Taiwan, ⁵Eli Lilly and Company, Indianapolis, USA, ⁶Amylin Pharmaceuticals, Inc., San Diego, USA, ⁷Rudolfstiftung Hospital, Vienna, Austria.

Background and aims: To compare exenatide once weekly (EQW) versus liraglutide once daily (Lira) on glycemic control, body weight and safety in type 2 diabetes patients treated with life style modification and oral antihyperglycemic medications (OAMs).

Materials and methods: 26-week, multicenter, open-label, randomized (stratified by sulfonylurea use, baseline HbA_{1c} (<9.0%; ≥9.0%) and country), 2-arm parallel study in 19 countries, comparing EQW (2 mg, once-weekly injection) versus Lira (1.8 mg, once-daily injection) in addition to patients' OAMs (metformin, sulfonylurea and/or pioglitazone). Non-inferiority was concluded if the upper limit of the confidence interval for the treatment difference of change from baseline HbA_{1c} (EQW - Lira) was <0.25%.

Results: Of the 912 randomized subjects, 911 subjects were included in the intent-to-treat analysis (450 Lira, 461 EQW). Baseline characteristics (mean [SD]): Age 57 (10) y; BMI 32.3 (5.5) kg/m²; HbA_{1c} 8.5 (1.0) %. Change in HbA_{1c} at endpoint was greater in subjects taking Lira (-1.48%, SE 0.05) than in those taking EQW (-1.28%, 0.05; treatment difference 0.21%, 95% CI (0.08, 0.34) using mixed model repeated measures analysis and the difference did not meet the non-inferiority criteria. More subjects taking Lira achieved HbA_{1c} <7% (n=271, 60.2%) than those taking EQW (n=241, 52.3%) p=0.008. Subjects taking Lira lost more weight (-3.58 kg, SE 0.18) than those taking EQW (-2.68 kg, SE 0.18; treatment difference 0.90 kg, 95% CI [0.40, 1.41]). There was no major hypoglycemia during the study. Minor hypoglycemia was experienced by 50 (10.8%) EQW-treated subjects and 40 (8.9%) Lira-treated subjects (p = 0.374 for treatment difference). Subjects taking Lira and EQW

had similar decreases in systolic and diastolic blood pressure (SBP; -3.5 and -2.5; DBP; -0.5 and -0.5, respectively). Changes in other cardiovascular biomarkers (lipids, high sensitivity C-reactive protein, brain natriuretic peptide) were similar between groups at endpoint. The most common adverse events were gastrointestinal side effects for both Lira-treated subjects (nausea n=92 [20.4%], diarrhea n=59 [13.1%], vomiting n=48 [10.7%]) and EQW-treated subjects (nausea n=43 [9.3%], diarrhea n= 28 [6.1%], vomiting n=17 [3.7%]). Among subjects taking Lira, 24 (5.3%) discontinued due to adverse events (nausea n=8 [1.8%], diarrhea n=3 [0.7%], vomiting n=4 [0.9%]) compared to 12 (2.6%) of subjects taking EQW (nausea n=1 [0.2%], diarrhea n=1 [0.2%], vomiting n=1 [0.2%]).

Conclusion: Both treatment groups demonstrated robust glycemic lowering with associated weight loss. HbA_{1c} lowering and weight loss were greater with daily injections of Lira while gastrointestinal side effects and withdrawals due to adverse events were lower with EQW. Compared to the 5 previous DURATION studies, the efficacy results for EQW in this study were of lower magnitude (range of LS mean HbA_{1c} response -1.5% to -1.9%).

Safety and efficacy of once monthly exenatide administration over 20 weeks in patients with type 2 diabetes

L. MacConell, J. Malloy, W. Huang, B. Cirincione, L. Shen, L. Porter; Amylin Pharmaceuticals, Inc., San Diego, USA.

Background and aims: Exenatide, a GLP-1 receptor agonist, improves glycaemic control and reduces body weight when administered twice daily or once weekly by subcutaneous (s.c.) injection in patients with type 2 diabetes (T2DM). A new formulation, exenatide suspension, utilizes the extended-release microspheres of exenatide once weekly (ExQW) with a triglyceride-based diluent that enables delivery of higher doses with less frequency. The aim of this trial was to investigate the safety and efficacy of monthly administration of exenatide suspension.

Materials and methods: The safety and efficacy of 3 exenatide once monthly (ExQM) suspension doses (5, 8, or 11 mg s.c.), with ExQW (2 mg s.c.) as a reference arm, were assessed in this randomized, open-label, controlled study with 121 patients (36% female, age 50±10 years, weight 97±19 kg, HbA_{1c} 8.5±1.2%, fasting plasma glucose [FPG] 10.3±2.5 mmol/L, diabetes duration 6±5 years, mean±SD) with T2DM treated with diet/exercise, metformin (MET), pioglitazone (PIO), or MET+PIO. Patients were treated for 20 weeks and received 5 monthly ExQM injections or 20 weekly ExQW injections. Primary analyses were performed at week 20.

Results: Patient retention was high (94%). Sustained plasma exenatide concentrations within the known therapeutic range were achieved with all doses of ExQM. Based on the longer dosing interval, greater peak-to-trough variability was observed with ExQM than ExQW; however, mean trough concentrations of exenatide remained within the therapeutic range across all 3 ExQM doses. The 2 highest ExQM doses achieved exenatide levels similar to ExQW. As seen with ExQW, ExQM concentrations approached non-detectable levels 8 weeks after last injection. HbA_{1c} and FPG were substantially reduced with all doses of ExQM, with improvements comparable to ExQW (Table). Weight loss was observed in all treatment groups. Results were consistent between Evaluable and Intent-to-Treat (ITT) Populations. ExQM was generally well-tolerated with no unique safety findings relative to ExQW. The most frequent adverse events (AE) were headache (17–27%) and nausea (17–23%) for ExQM, and headache (30%) and diarrhea (27%) for ExQW (ITT Population). No major or minor hypoglycaemia was observed. One AE of vomiting with ExQM led to withdrawal. There was no evidence of prolonged AE duration with ExQM or ExQW.

Conclusion: Monthly dosing with exenatide suspension was well-tolerated with robust improvements in glycaemic control in patients with T2DM, supporting further development of the monthly suspension formulation.

Treatment	N	Δ HbA _{1c} (%)	HbA _{1c} <7% at Week 20	Δ FPG (mmol/L)	Δ Weight (kg)
ExQW (2 mg)	29	-1.5 (0.2)	48%	-1.9 (0.5)	-1.4 (0.6)
ExQM (5 mg)	26	-1.3 (0.2)	50%	-1.4 (0.4)	-1.1 (0.8)
ExQM (8 mg)	28	-1.3 (0.3)	57%	-1.7 (0.6)	-0.4 (0.6)
ExQM (11 mg)	27	-1.5 (0.2)	70%	-2.7 (0.5)	-1.1 (0.7)

Long-term, injection-free treatment with ITCA 650, a continuous subcutaneous delivery of exenatide via DUROS[®] device, leads to stable glycaemic and weight control for 48 weeks in metformin-treated type 2 diabetesK. Luskey¹, J. Rosenstock², T. Alessi¹, R.R. Henry³;¹Intarcia Therapeutics, Hayward, ²Dallas Diabetes and Endocrine Center,³University of California at San Diego, La Jolla, USA.

Background and aims: Current therapy with exenatide requires frequent self-injections and is associated with significant nausea, leading to poor therapeutic compliance. An alternative form of exenatide delivery was evaluated in a phase 2 study with ITCA 650, a subcutaneous osmotic delivery system that provides for continuous delivery of exenatide at specified doses for 3 months.

Materials and methods: Subjects (n=155) treated with metformin only and having HbA_{1c} between 7% and 10% were enrolled in a 24-week study to evaluate ITCA 650. Initially subjects were randomized to three groups receiving either ITCA 650 at 20 or 40 mcg/day or exenatide injections at 10 mcg BID. At week 12, subjects were randomized such that subjects treated with ITCA 650 remained on the same dose or were dose escalated to 60 or 80 mcg/day and subjects treated with exenatide injections were treated with ITCA 650 at 40 or 60 mcg/day. At week 24, subjects were offered the option to continue treatment at their current dose of 20, 40, 60 or 80 mcg/day for an additional 24 weeks.

Results: ITCA 650 treatment resulted in significant reductions in HbA_{1c} and weight after 24 weeks. At week 24, 86 subjects (85% of eligible subjects) elected to continue treatment at their current dose. Changes in HbA_{1c} and weight observed over the 48-week treatment, as well as the proportion of subjects with HbA_{1c} <7%, are shown in the table below. The reductions in HbA_{1c} and weight at week 48 were maintained from those initially observed at week 24. Overall, 71% of the subjects had both a reduction in HbA_{1c} and no weight gain. In addition, desirable trends in lipids, blood pressure and heart rate were observed, especially at the higher doses. Changes observed at 60 mcg/day, the chronic dose selected for future Phase 3 studies based on activity and tolerability, were total cholesterol -11.3±31.8 mg/dL, triglycerides -7.4±110.3 mg/dL, LDL-C -10.1±28.3 mg/dL (p<0.05), HDL-C +0.1±7.2 mg/dL, systolic BP -1.7±8.1 mmHg, diastolic BP -7.8±12.5 mmHg and heart rate -1.1±11.4 bpm. Continuing treatment with ITCA 650 was very well tolerated with minimal side effects and a completion rate of 85%. Among all of the subjects, onset of nausea was reported in only one subject and vomiting was reported in another subject throughout the final 24 weeks of treatment. No clinically meaningful change in calcitonin was seen in any subject.

Conclusion: This extension study shows that long-term treatment with ITCA 650 is effective in controlling glycemic parameters and weight and can also lead to potential positive cardiovascular benefits through beneficial changes in lipids and blood pressure. In addition, tolerability is excellent with minimal GI side effects noted with long-term treatment that provides constant, continuous exposure to exenatide. Phase 3 will evaluate devices of 6-12 month duration.

Liraglutide promotes weight maintenance and additional weight loss in obese adults without diabetes after diet-induced weight loss: the SCALETM 56-week randomised studyV.C. Woo¹, P.A. Hollander², K.D. Niswender³, S. Klein⁴, L.J. Aronne⁵, C.B. Jensen⁶, T.D. Le Thi⁶, T. Wadden⁷;¹University of Manitoba, Winnipeg, Canada, ²Baylor University MedicalCenter, Dallas, ³Vanderbilt University School of Medicine, Nashville,⁴Washington University School of Medicine, St. Louis, ⁵Weill-CornellMedical Center, New York, USA, ⁶Novo Nordisk A/S, Søborg, Denmark,⁷Center for Weight and Eating Disorders, University of Pennsylvania School of Medicine, Philadelphia, USA.

Background and aims: Weight loss is difficult to achieve and sustain by lifestyle changes alone. Liraglutide is a once-daily human glucagon-like peptide-1 analogue approved for the treatment of type 2 diabetes mellitus. Here we present data from a randomised, phase 3, placebo-controlled, double-blind trial in obese adults without diabetes that tested the ability of liraglutide (3 mg) to maintain initial diet-induced weight loss and to promote further weight loss.

Materials and methods: Individuals (age ≥18 years, BMI ≥30 or ≥27 kg/m² with comorbidities) who lost ≥5% body weight during a 4-12 week run-in comprising low-calorie diet (1200-1400 kcal/d) and exercise counseling were randomised to receive s.c. liraglutide (N=212) or placebo (N=210) and a 500 kcal/d deficit diet + exercise counseling for 56 weeks. Of 511 individuals entering run-in, 422 (77%) were randomised 1:1 to each arm. Maintenance of run-in weight loss and additional weight loss were the primary endpoints evaluated.

Results: Mean run-in weight loss for all individuals who were randomised was 6.0% (6.3 kg). After 56 weeks of treatment, liraglutide provided statistically significant improvements in all measures of weight loss change from run-in compared to placebo treatment (Table) (p<0.0001 in all analyses). During treatment, net weight changes post-run-in were -6.1% vs 0.1% (-5.7 kg vs +0.2 kg) for liraglutide vs placebo, respectively. Significantly more liraglutide vs placebo recipients maintained run-in weight loss and lost additional run-in weight. More than twice as many participants on liraglutide lost ≥5% additional run-in weight compared to those on placebo. Completion rates, serious AEs and withdrawals due to AEs were similar for each group. More nausea and vomiting were reported during liraglutide vs placebo treatments, occurring mainly during dose-escalation; 64% of liraglutide nausea cases were mild, and most cases declined in frequency by 4-6 weeks. Psychiatric AEs were reported by 11% and 12% of subjects in each arm, respectively.

Conclusion: Liraglutide 3 mg was superior to placebo in maintaining diet-induced weight loss and in achieving additional clinically relevant weight loss in a majority of individuals while demonstrating safety and overall tolerability similar to placebo.

Islet autoantibody testing and prevention of diabetic ketoacidosis

A. Rewers¹, K. Barriga², G. Klingensmith², M. Rewers²;¹Department of Pediatrics, University of Colorado, Denver, ²The Barbara Davis Center for Childhood Diabetes, University of Colorado, Aurora, USA.

Background and aims: At diagnosis of type 1 diabetes (T1D), children may suffer potentially fatal ketoacidosis (DKA). The rates in Colorado have recently increased from <30% to >40% despite community education efforts. Screening for pre-diabetes and early treatment could prevent DKA.

Methods: Healthy infants with immediate family history of T1D (n=1,120) or without, but high-risk HLA-DR/DQ genotypes (n=1422), have been followed for up to 16 years. Autoantibodies to insulin, GAD65, IA-2, and ZnT8 have been assessed annually. Persistent autoantibodies have developed in 181 children and T1D in 71. DKA rate at diagnosis was compared in this prospectively followed group (pre-T1D; age 8.4±3.9y; 48%F; 11% minorities) with that in 1101 children diagnosed during the same period in the community (8.3±3.8y; 46%F; 25% minorities).

Results: During the study period, 3 children died at diagnosis of diabetes in the community vs. none in the pre-T1D group. DKA affected 411/1101 (37%) of the community controls and 5/71 (7%) of pre-T1D children (p<0.001). Of the 5 DKA cases in among pre-T1D children, one was 10 mo old and three were not seen by the study for 5–11 years prior to diagnosis. Four additional children were lost to follow-up for 2–11 yrs, yet avoided DKA. Thus DKA developed in 2/64 (3%) of the active study participants and 3/7 (43%) of those who have dropped out. The median HbA_{1c} at diagnosis in these groups was 6.6% (interquartile range 6.2–8.8%) and 12.4% (10.1–12.8%), respectively, compared with 11.2% (9.7–13.4) in the community cases.

Conclusion: Annual screening of high-risk children for islet autoantibodies and counseling of parents of children with pre-T1D can prevent most of the morbidity associated with T1D onset. The benefit is lost with a longer interruption of the follow-up.

Haemoglobin A_{1c} as an indicator of type 1 diabetes in pediatric and adolescent youth

K. Vehik¹, D. Schatz², D. Boulware¹, D. Cuthbertson¹, C. Beam¹, H. Rodriguez¹, M. Rewers³, L. Legault⁴, J. Krischer¹, DPT-1, TEDDY, TRIGR, TrialNet;¹University of South Florida, Tampa, ²University of Florida, Gainesville,³University of Colorado, Aurora, USA, ⁴McGill University, Montreal, Canada.

Background and aims: HbA_{1c} testing has been recommended by the 2009 International Expert Committee to be used for diagnostic purposes for diabetes. The current recommended thresholds are ≥6.5% for diagnosis of diabetes and ≥5.7% (ADA) for high-risk for progression to diabetes. The aim of this study is to evaluate the sensitivity and specificity of HbA_{1c} as a marker for type 1 diabetes (T1D) and/or impaired glucose tolerance (IGT) in high-risk children and adolescents as compared to the ADA OGTT criteria for diabetes and determine if differences exist by age.

Materials and methods: The study population consisted of youth <21 years of age from the prospective DPT1, TEDDY, TRIGR and TrialNet studies that had an HbA_{1c} within 90 days of a diagnostic 2-hour plasma glucose measure by OGTT to determine sensitivity and specificity. Asymptomatic T1D cases were included in the TEDDY and TRIGR studies since OGTTs were not routinely done. An OGTT ≥200mg/dl or FPG ≥126mg/dl defined diabetes and OGTT 140–199mg/dl defined IGT. ROC analysis was used to assess diagnostic accuracy of the HbA_{1c} test vs. the OGTT (AUC=0.5, poor diagnostic; AUC=1.0, excellent diagnostic).

Results: There were 587 youth from the DPT1, 884 from TrialNet, 102 from TEDDY and 426 from TRIGR included in the analysis. Seventy-five percent of youth were between 5–15 years of age. On applying a threshold of ≥6.5% for T1D diagnosis, the sensitivity was very poor and specificity was excellent (Sensitivity/Specificity: DPT1-24%/98%, TrialNet-28%/99%, TEDDY-34%/98%, TRIGR-39%/100%). ROC analyses suggested that HbA_{1c} was not a good indicator of T1D (0.90 required for diagnostic tests) in the DPT1 (AUC=0.72), TrialNet (0.85), TRIGR (0.60) and TEDDY (0.80) studies. The threshold of ≥5.7% as an indicator of T1D was poor with a higher

sensitivity and lower specificity vs. ≥6.5% threshold (DPT1- 73%/54%, TrialNet- 66%/91%, TEDDY-68%/93%, TRIGR- 46%/89%). HbA_{1c} of 5.7% was also a poor indicator of IGT; sensitivity (8–33%) and specificity were variable (64–95%) across the studies. No difference in HbA_{1c} performance in youth younger vs. older than 10 was noted.

Conclusion: HbA_{1c} ≥6.5% is a specific but not sensitive indicator of T1D in high-risk subjects <21 years of age. Asymptomatic high-risk children with HbA_{1c} ≥6.5% may be diagnosed with T1D without performing an OGTT.

Urinary C-peptide creatinine ratio is a practical outpatient tool in identifying MODY from type 1 diabetes in children with diabetes

R.E.J. Besser¹, M.H. Shepherd¹, T.J. McDonald^{1,2}, B.M. Shields¹, B.A. Knight¹, S. Hammersley¹, S. Ellard³, A.T. Hattersley¹;¹Peninsula NIHR Clinical Research Facility, Peninsula Medical School,²Department of Clinical Biochemistry, Royal Devon & Exeter NHSFoundation Trust, ³Department of Molecular Genetics, Royal Devon & Exeter NHS Foundation Trust, Exeter, UK.

Background: The young-onset hyperglycaemia seen in patients with maturity onset diabetes of the young (MODY) is frequently misdiagnosed as Type 1 diabetes (T1D), and inappropriately treated with insulin. Measurement of blood C-peptide can aid in the discrimination of diabetes subtypes but has practical limitations. Urinary C-peptide creatinine ratio (UCPCR) is stable at room temperature for 72 hours in boric acid preservative, offering the potential to be a non-invasive alternative to differentiate MODY from T1D in the outpatient setting.

Aims: To assess whether UCPCR can discriminate MODY from Type 1 diabetes in children with diabetes.

Materials and methods: We measured 2 hour postprandial UCPCR in patients <18years with T1D (n=96) and genetically confirmed MODY (n=29; HNF1A/4A n=10, GCK n=19). Samples were collected at home and posted directly to the laboratory for analysis

Results: T1D were similar to MODY patients for age (median(interquartile range) 12.9(10.4–15.4) v 14.6(12.1–16.1)y, p=0.19) and diabetes duration (3.6 (1.2–7.4) v 2.6 (1.5–4.8)y, p=0.28). UCPCR was lower in T1D than MODY: (median (IQR) 0.05(<0.02–0.67) v 3.41 (1.94–4.66)nmol/mmol; p<0.0001). Receiver Operating Characteristic Curves showed excellent discrimination (area under curve 0.95) and identified a cut-off UCPCR ≥1.4nmol/mmol for discriminating MODY from T1D with 100% sensitivity and 85% specificity. 14/95 (15%) T1D patients had UCPCR ≥1.4nmol/mmol and all were diagnosed within 2.5 years of diagnosis.

Conclusion: In children with diabetes, a single post meal UCPCR which may be posted gives excellent discrimination of T1D from MODY and is a useful adjunct to select patients for diagnostic genetic testing.

Centre differences in metabolic control in 1133 children with T1DM below 11 years: insulin regimen or centres' recipe?

J.-J.E. Robert¹, H.B. Mortensen², A. Neu³, P.R. Njolstad⁴, M. Phillip⁵, E.J. Schoenle⁶, T. Urakami⁷, M. Vanelli⁸, K. Lange⁹, C.E. de Beaufort¹⁰, Hvidoere Study Group;¹Hôpital Necker-Enfants Malades, Paris, France, ²Pediatric Department,Glostrup University Hospital, Denmark, ³Klinik für Kinder- undJugendmedizin, Universität Tübingen, Germany, ⁴Department of Pediatrics,Haukeland University Hospital, Bergen, Norway, ⁵National Center of

Childhood Diabetes, Schneiders Children Medical Center, Petah Tikva,

Israel, ⁶University Childrens Hospital, Zurich, Switzerland, ⁷Departmentof Pediatrics, Nihon University School of Medicine, Tokyo, Japan, ⁸ClinicaPediatrica Centro di Diabetologia, University of Parma, Italy, ⁹MedizinischePsychologie, Medizinische Hochschule, Hannover, Germany, ¹⁰DECCP,

Clinique Pédiatrique /CHL. Luxembourg.

Background: The Hvidoere Study Group (HSG) has demonstrated persisting center differences in metabolic control in adolescents in 4 continents. These differences appear to be not attributable to specific insulin regimens but seem to be influenced by centers effectiveness in implementing treatment regimens. To evaluate this in prepubertal children, HSG performed a cross sectional study in children <11 years with T1DM.

Methodology: All children, <11 y with a diabetes duration ≥ 1 y, were invited to participate. CRF's included information on clinical characteristics, treatment, DKA (hospital admission needed), hypoglycaemia (loss of consciousness/seizures), language difficulties and co morbidities. HbA_{1c} was measured centrally by ¹⁸Tosoh liquid chromatography (DCCCT aligned, range 4.4–6.3%).

Results: In total 1133 children from 18 centers participated ([female]: 47.7 %; mean age 8.0 ± 2.1 y; mean diabetes duration 3.8 ± 2.1 y). The grand mean HbA_{1c} was 8.0 ± 1.0 % without significant impact of diabetes duration, age or gender. Language difficulties had an adverse effect ($p = 0.036$) on HbA_{1c}. Significant ($p < .000$) center differences were demonstrated with mean HbA_{1c} varying between 7.3 ± 0.8 and 9.0 ± 1.1 %. Different insulin regimen were used (CSII: 32.8 %, Basal bolus 16.9 %; Conventional : free mix : 36.5 %; premix : 6.3 %; freemix+ (mainly 1 center : extra insulin for snacks/meals), 7.5 %). Significantly lower HbA_{1c} was observed in freemix+ (7.3 ± 0.8 %) and higher in the premix group (8.5 ± 1.7 %). Significant center differences ($p < .000$) in blood glucose measurement (BGM) frequency were reported (2.5 to $8.3 \times$ /day) with a higher frequency in CSII treated and younger children. A significant ($r = -.170$, $p < .000$) inverse correlation was seen with HbA_{1c} and BGM frequency.

Conclusion: In summary, center differences in metabolic outcome are already present in children <11 years, unrelated to diabetes duration, age, or gender, and despite generally lower HbA_{1c} values. BGM frequencies differ between centers and do have a weak effect on the HbA_{1c} level. Although treatment regimen has some effect, the centers effectiveness (recipe) using a specific treatment strategy remains the key factor for the outcome, confirming previous observations.

Sensor augmented pump therapy from onset of type 1 diabetes: late follow-up results of the Pediatric ONSET Study

O. Kordonouri¹, R. Hartmann¹, E. Pankowska², B. Rami³, T. Kapellen⁴, R. Coutant⁵, K. Lange⁶, T. Danne¹

¹Children's Hospital auf der Bult, Hannover, Germany, ²Medical University of Warsaw, Poland, ³Medical University of Vienna, Austria, ⁴Universitätskinderklinik und Poliklinik für Kinder und Jugendliche, Leipzig, Germany, ⁵Dept. de Pédiatrie Centre Hospitalier Universitaire, Angers, France, ⁶Medizinische Hochschule Hannover, Germany.

Background and aims: In the European multicentric randomised Pediatric Onset Study evaluating sensor-augmented pump therapy throughout the first year of type 1 diabetes (T1D), we found that children and adolescents with frequent use of sensors had significantly lower HbA_{1c} values at 12 months of treatment than those with less frequent or without sensor use. Aim of the present follow-up study was to evaluate the metabolic control and beta-cell function one year after the end of the intervention.

Materials and methods: 131 of 154 study patients (85.5% follow-up compliance) were re-examined 24 months after T1D onset (49.6% boys, age at onset 8.9 ± 4.3 years). 62 patients had been randomised to the primary group applying a sensor-augmented pump system (Paradigm REAL-Time, Medtronic MiniMed Inc) during the 1st year of T1D, whereas 69 patients belonged to the control group performing conventional insulin pump therapy (CSII) with self-monitoring blood glucose only. Groups were not significantly different concerning age or gender distribution. Additionally to the clinical assessment, HbA_{1c} as well as fasting blood glucose and C-peptide values were centrally measured.

Results: At 24 months, i.e. one year after the end of the interventional study, 50.0% of the patients used the sensor-augmented pump system, 48.3% conventional CSII and 1.7% multiple daily injections. HbA_{1c} was 7.6 ± 1.3 % in the primary group and 7.7 ± 1.2 % in the control group ($p = .493$). Frequent sensor use during the first year of T1D was associated with lower HbA_{1c} values at 24 months as compared with irregular or even no sensor use (7.4 ± 1.0 % vs 7.7 ± 1.3 %), however, this difference did not reach statistical significance ($p = .236$). Although fasting C-peptide was not clearly different between the primary and control group (0.13 ± 0.17 vs 0.09 ± 0.10 nmol/L, $p = .121$), patients with initially frequent sensor use had significantly less C-peptide loss within 24 months (C-peptide reduction 0.02 ± 0.18 vs 0.07 ± 0.11 nmol/L, $p = .046$). There was no difference between the groups regarding the daily insulin requirement.

Conclusion: Sensor-augmented pump therapy from onset of T1D may lead to better long-term glycaemic control and help to preserve endogenous beta-cell function, if patients comply with frequent use of continuous glucose monitoring.

Health-related quality of life among 11- to 17-year olds with early onset type 1 diabetes compared to peers of the representative German health survey KiGGS

A. Stahl¹, K. Straßburger¹, K. Castillo¹, C. Bächle¹, K. Lange², T. Meissner³, C. Graf⁴, A. Icks⁵, R.W. Holl⁶, G. Giani¹, J. Rosenbauer¹

¹German Diabetes Centre, Düsseldorf, ²Hannover Medical School,

³University Hospital, Düsseldorf, ⁴German Sport University, Köln,

⁵Heinrich-Heine University, Düsseldorf, ⁶University of Ulm, Germany.

Background and aims: Health-related quality of life (HRQoL) is a potentially relevant determinant of the long-term course of type 1 diabetes (T1DM) among children and adolescents with early onset. Despite the increasing incidence of T1DM among children younger than 5 years, a population-based study on psychosocial factors in this patient-group was not available for Germany until now. The presented analyses aimed to compare HRQoL of 11- to 17-year olds with early onset of T1DM and at least 10 years diabetes duration with representative, normative data for the population of children and adolescents in Germany. In addition, risk factors for poor HRQoL were analysed.

Materials and methods: Inclusion criteria for the nationwide questionnaire survey conducted in Germany 2009–2011 were onset of T1DM in the age 0–4 years during 1993–1999. HRQoL was assessed by means of the generic 24-item KINDL-R self-report questionnaire (scale 0–100, higher values indicate better HRQoL). Representative, normative data came from the first KiGGS-study conducted in Germany 2003–2006. Analyses were performed with regression models (SAS 9.2, SURVEYREG procedure) including the parameters age, sex, migration background, region, socio-economic status, family arrangement, kind of school, BMI, hospitalisation and HbA_{1c} concentration (stated values mean (SD)).

Results: Survey participants were 629 11- to 17-year olds with T1DM (54% boys, age 15.3 (1.66) years, diabetes duration 12.5 (1.6) years, HbA_{1c} 8.3 (1.4) %). The reference group consisted of 6813 peers (51% boys, age 14.6 (2.0) years, HbA_{1c} 4.9 (0.4) %). Total HRQoL did not significantly differ between children and adolescents with T1DM (73.1 (12.2)) and the reference group (72.6 (10.3), $p = 0.092$) after adjustment for confounders. The sub-scale scores for physical and emotional well-being and friends did not significantly differ between the two groups. Well-being in the family was decreased (78.6 (18.2) versus 81.9 (15.7), $p = 0.003$), but both functioning at school (69.5 (17.8) versus 66.1 (17.2), $p < 0.001$) and self-esteem (63.3 (18.9) versus 58.3 (18.4), $p < 0.001$) were significantly increased among children and adolescents with T1DM. In the T1DM cohort, higher HbA_{1c} was associated with lower total HRQoL (change in HRQoL per 1% increase in HbA_{1c}: -1.8 , $p < 0.001$) and lower scores in the dimensions physical well-being (-2.1 , $p = 0.001$), emotional well-being (-1.0 , $p = 0.039$), self-esteem (-2.3 , $p < 0.001$), family (-2.8 , $p < 0.001$), and school (-3.2 , $p < 0.001$). Being adolescent (14–17 years) was associated with lower scores in the dimensions family (-3.9 , $p = 0.016$) and school (-4.6 , $p = 0.004$). Boys reported compared to girls higher total HRQoL (2.8 , $p = 0.004$), physical well-being (7.8 , $p < 0.001$), and self-esteem (6.5 , $p < 0.001$).

Conclusion: HRQoL among 11- to 17-year olds with early onset and long-lasting T1DM is not worse than among peers. In fact, T1DM is a potential resource for improved self-esteem in this patient-group (especially among boys). The results further underline the close relationship between metabolic control and HRQoL among children and adolescents with T1DM. Age and gender influence the HRQoL to some extent.

85

Gestational diabetes identified by the IADPSG- and WHO-criteria in a multiethnic population in Oslo, Norway: the Stork Groruddalen Research Program

K. Mørkrid^{1,2}, A. Jenum^{1,2}, L. Sletner^{1,2}, S. Vangen³, K.I. Birkeland¹;

¹Department of Endocrinology, Oslo University Hospital, Aker, ²Institute of Clinical Medicine, University of Oslo, ³Oslo University Hospital, Rikshospitalet, Norway.

Background and aims: New criteria for gestational diabetes (GDM) with glucose threshold levels set to avert adverse fetal outcomes, has been suggested by the International Association of Diabetes and Pregnancy Study Group (IADPSG). The new criteria differ from the previous WHO criteria, mainly based on glucose threshold levels to identify women at risk of future diabetes. The aim of this study was to compare the prevalence rates and disparity in risk factors for GDM identified by the two criteria.

Materials and methods: Population-based cohort study of 823 (74% of the invited) healthy pregnant women attending three primary antenatal clinics in Eastern Oslo. 18 had abortion/preterm delivery, 33 drop-outs and 13 did not complete OGTT, leaving 759 with OGTT data. Fasting blood samples, anthropometrics and demographics were collected at visit 1 (V1), gestational week (GW) 15±5 and visit 2 (V2), GW 28±2. A 75-g OGTT was performed at V2, with venous blood samples analyzed on site (HemoCue, Angelholm, plasma calibrated). GDM by WHO: fasting plasma glucose (FPG) ≥7.0 mmol/l or 2-h PG ≥7.8 mmol/l, and IADPSG: FPG ≥5.1 mmol/l or 2-h PG ≥8.5 mmol/l. Insulin resistance was calculated using the homeostasis model assessment (HOMA2). Ethnic origin: Scandinavia (includes Western Europe, USA), Eastern Europe, South Asia, East Asia, Middle East, Somalia and Others. Simple descriptive, ANOVA (Bonferroni corrected), chi-square tests and logistic regression analyses were performed using PASW 18.

Result: GDM prevalence rates were 13% (WHO) and 32% (IADPSG). In total 9% were identified by both, 4% by only the WHO-criteria and 22% by only the IADPSG-criteria. Compared to Scandinavians all ethnic minority groups were shorter and had lower education ($p < 0.02$), South Asians were younger ($p < 0.001$) and together with Middle Easterners less likely to be para 0 and more likely to have 1° relatives with diabetes ($p < 0.03$), South Asians, Middle Easterners and Others were more insulin resistant at V1 ($p < 0.001$). GDM by the WHO-criteria was associated with age (OR=1.1, 95% CI: 1.1-1.2), parity ≥1 (OR 2.4, 95% CI: 1.4-4.0), 1° relatives with diabetes (OR 2.3, 95% CI: 1.4-3.8) and body height (cm) (OR 0.9, 95% CI: 0.88-0.96) after adjusting for ethnicity, age, BMI, body height, parity, education level and 1° relatives with diabetes. Adjusted for the same factors, GDM by the IADPSG-criteria was associated with prepregnant BMI (OR 1.1, 95% CI: 1.05-1.13) and South Asian origin (OR 2.5, 95% CI: 1.5-4.0).

Conclusion: The GDM prevalence by the WHO-criteria was high in all groups. The GDM prevalence increased 240% when applying the IADPSG-criteria. Before endorsing the IADPSG-criteria, the impact of diagnosing nearly 1/3 of all pregnant women should be considered.

Study sample divided into ethnic origin							
	Scandi- navia	Eastern Europe	South Asia	East Asia	Middle East	Somalia	Others

Gestational diabetes mellitus is a risk factor for future cardiovascular disease

E. Schwarcz¹, H. Fadl², I. Östlund², A. Magnusson³, S. Montgomery³, U. Hanson⁴;

¹Dept of Internal Medicine, University Hospital Örebro, ²Dept of Obstetrics and Gynaecology, University Hospital Örebro, ³Clinical Epidemiology and Biostatistics Unit, University Hospital Örebro, ⁴Dept of Women's and Children's Health, Uppsala University, Sweden.

Background and aims: Women with gestational diabetes mellitus (GDM) have an increased risk of developing type 2 diabetes mellitus later in life. Less is known about whether these women also have an increased cardiovascular disease risk. The aim of this study was to examine GDM as a risk for subsequent cardiovascular morbidity and mortality using Swedish register data.

Materials and methods: A case-control study using the data from Swedish National Health and quality registers from 1991 to 2008. Cases defined as a woman diagnosed with a first cardiovascular event (Ischemic heart disease, stroke or peripheral vascular disease using the ICD classification) and who gave birth to at least one child during the study period ($n = 4653$). Each case was matched by age with 5 controls who did not have cardiovascular disease and also gave birth to a child during the study period ($n = 22790$). Binary logistic regression was used to calculate odds ratios with 95% confidence intervals (OR with 95% CI) with adjustment for potential confounding factors including smoking, chronic hypertensive disease and overweight (BMI>25).

Results: A history of GDM during pregnancy (3.5% among cases and 1.8% among controls) was associated with statistically significantly raised risk of a cardiovascular event, with unadjusted and adjusted odds ratios of 1.98 (1.64 - 2.37) and 1.80 (1.49-2.18), respectively. The unadjusted OR for overweight was 1.42 (1.33-1.52), for chronic hypertensive disease 4.86 (2.72-6.34) and for smoking 2.08 (1.95-2.22).

Conclusion: Women with a history of GDM not only have an increased risk of type 2 diabetes mellitus but GDM is also a notable risk for subsequent cardiovascular disease. This emphasizes the need for appropriate long-term follow-up of these women post pregnancy to identify their cardiovascular risk profile, possibly reducing their risk for cardiovascular events through appropriate interventions.

87

Volatile organic compounds (VOCs) analysis in breath gas during 75g OGTT in women with suspected gestational diabetes mellitusJ.M. Maier¹, M. Hummel^{1,2}, S. Halbritter³, M. Fedrigo³, V. Höllriegel³, A.-G. Ziegler^{1,2}, W. Szymczak³,¹Forschergruppe Diabetes e.V., ²Institute of Diabetes Research, ³Department of Medical Radiation Physics and Diagnostics, Helmholtz Center Munich, Neuherberg, Germany.

Background and aims: Breath analysis in real time by using proton transfer reaction mass spectrometry (PTR-MS) is an innovative technology that can identify signatures and pathways that may be relevant for the pathogenesis of metabolic disorders. Furthermore, it can potentially be used as a non-invasive clinical diagnostic tool. In women with gestational diabetes mellitus (GDM), this technique has not been used and established yet. The aim of this study was to explore the applicability of the technology and the diagnostic potential of PTR-MS in woman suspect for GDM. We also describe metabolic products in expired air and assign them to metabolic pathways.

Materials and methods: We performed a 75g-OGTT in 53 consecutive pregnant women (median 28th gestational week). Parallel to OGTT we investigated in 6 minutes scanning the patient's exhaled air using the PTR-MS in real time. GDM was diagnosed in 8 patients (following the Carpenter criteria) and impaired glucose tolerance (IGT) in 13 patients. Thirty-two patients had normal glucose tolerance and formed the control group. Statistical analysis was performed by MANOVA and permutation analysis.

Results: We selected 17 volatile organic compounds (VOCs) in the exhaled air. Although there were fast and slow kinetics of the VOCs, all characteristic changes occurred within the first 45 minutes of the OGTT. Using the 17s VOC profiles we were able to accurately discriminate patients with GDM from patients with IGT, and from controls ($p=0.009$). Furthermore we were able to identify two distinct groups within the control group, one consisting of nine women, and one of the remaining 23 patients. Interestingly, the group of nine control women had significantly higher levels of fasting glucose (median 77 mg/dl vs. 71 mg/dl) and stimulated glucose (median 172 mg/dl vs. 147 mg/dl) than the remaining controls as well as higher triglyceride (TG) levels (median TG 211 mg/dl vs. 147 mg/dl). The correlation between VOCs profiles and metabolic status was a 'many masses', not a 'single mass' phenomenon. Nevertheless, two compounds could be identified which contributed most to the discrimination between patients and controls; these were related to the methionine and acetone metabolism.

Conclusion: Our data indicate that PTR-MS breath gas analyses are strongly correlated with glucose metabolisms during pregnancy and with diagnosis of gestational diabetes. Women with marginal values of glucose tolerance can be identified as distinct group that shows alterations of VOC signatures indicating pathology. Pathways utilizing methionine are potentially relevant for developing gestational diabetes.

88

Osteocalcin- and ctx-associated hyperinsulinaemia rather than osteopontin-mediated insulin resistance play a key role in gestational diabetes mellitusY. Winhofer¹, F.W. Kiefer¹, A. Handisurya², A. Tura³, G. Pacini³, A. Luger¹, T.M. Stulnig¹, A. Kautzky-Willer¹;¹Department of Internal Medicine 3, Division of Endocrinology and Metabolism, Medical University of Vienna, ²Department of Internal Medicine 3, Division of Nephrology, Medical University of Vienna, Austria, ³Metabolic Unit, ISIB, CNR, Padova, Italy.

Background and aims: Reciprocal and regulatory interaction between bone and glucose metabolism might emerge early in the development of type 2 diabetes. Recently osteocalcin was found to enhance insulin secretion and insulin sensitivity in experimental animals. Furthermore, we could show increased serum concentrations of osteocalcin in women with gestational diabetes compared to women with normal glucose tolerance during pregnancy and a relation to hyperinsulinemia. The C-terminal cross-linking telopeptide of Type-I collagen (CTX, crosslaps) and osteopontin, two further hormones which were initially detected in bone metabolism, have recently been associated with glucose metabolism and obesity-induced inflammation and insulin resistance. However a distinct role in gestational diabetes, a model to study early changes in the development of type 2 diabetes, has not been investigated yet. Therefore we aimed to investigate serum concentrations of osteopontin

and CTX as well as parameters of insulin sensitivity and secretion in women with gestational diabetes and healthy controls.

Materials and methods: An oral glucose tolerance test for the assessment of insulin sensitivity and secretion as well as blood sampling for the measurement of CTX, osteopontin, high-sensitive CRP and serum lipids were performed between 24th and 28th gestational weeks in 26 women with gestational diabetes (GDM) and 52 women with normal glucose tolerance during pregnancy (NGT), well matched for age and BMI.

Results: CTX was significantly higher in GDM compared to NGT (0.44 ± 0.20 vs. 0.28 ± 0.12 , $p<.0001$) and positively correlated with parameters of insulin secretion (Total Insulin Secretion, AUC of insulin and C-Peptide, Disposition- and Adaptation Index), while it showed an inverse correlation with hepatic insulin extraction and HDL-cholesterol. Furthermore, CTX was significantly inversely correlated with insulin sensitivity derived from OGTT (OGIS: $R=-0.3$, $p=0.003$). In contrast, osteopontin was significantly decreased in GDM compared to NGT (1.15 ± 0.88 vs. 1.51 ± 0.79 ; $p<0.04$), and did not show any relation to insulin secretion or sensitivity, but was significantly correlated with high-sensitive CRP ($R=0.3$, $p<0.03$).

Conclusion: Our findings support the idea of a tight regulation between bone and glucose metabolism, and suggest, that osteocalcin- and CTX-associated hyperinsulinemia rather than osteopontin-mediated insulin resistance contribute to glucose intolerance in women with gestational diabetes. However, osteopontin may play a role in inflammatory changes (hsCRP) related to early disturbances of glucose metabolism.

Maternal serum pregnancy associated plasma protein-A as predictor of gestational diabetes mellitusF. Jebunnesa¹, R. Karim², N. Sultana³, S. Hayat⁴, L. Ali¹;¹Dept of Biochemistry & Cell Biology, Bangladesh Institute of Health Sciences (BIHS), Dhaka, ²Dept of Biochemistry and Molecular Biology, Rajshahi University, ³Dept of Biochemistry & Cell Biology, BIRDEM, Dhaka, ⁴Dept of Gynecology and Obstetrics, BIRDEM, Dhaka, Bangladesh.

Background and aims: Pregnancy associated plasma protein-A (PAPP-A) has been shown to be a predictor for several pregnancy related complications including miscarriage, PIH and SGA. However, the predictive value of the protein has not been specifically investigated for gestational diabetes mellitus (GDM) which is a major complication of pregnancy and early prediction of which can largely contribute to the achievement of better maternal and fetal outcome. In the above context, we have tested the hypothesis that PAPP-A in early pregnancy can predict the development of GDM at the later stages.

Materials and methods: A group of 198 pregnant mothers, attending the OPD of our hospital, were enrolled in the study at 8-12 weeks of pregnancy and they were followed till delivery. A total of 102 (52%) women were found to develop GDM. From among the non-GDM cases a group of 96 women (the non-GDM group), matched for age and gestational age with the GDM group, were selected under a nested Case-Control design. GDM was diagnosed following the WHO Study Group Guidelines. Serum PAPP-A and serum insulin were measured by chemiluminescent ELISA techniques. Predictive value of early pregnancy PAPP-A in the development of GDM at later stages were explored by calculating the sensitivity, specificity, PPV and NPV using the McNamara test. Insulin secretory capacity (HOMA%B) and Insulin sensitivity (HOMA%S) were calculated by homeostatic model assessment and association of PAPP-A with GDM as well as with HOMA%B and HOMA%S were explored by univariate analysis and logistic /multiple regression as appropriate.

Results: PAPP-A (MOM) levels [median (range)] were markedly lower in GDM [$0.90(0.70-3.70)$] compared to the non-GDM [$6.40(2.6-10)$] groups ($p<0.001$). In Pearson's correlation analysis PAPP-A (MOM) had a significant positive correlation with HOMA%B. At optimum cut-off value of 5th percentile (2.6 mIU/m, calculated from an ROC curve) PAPP-A showed 99% sensitivity, 92% specificity, 93% PPV and 98% NPV in predicting the future development of GDM. On Logistic regression analysis PAPP-A showed significant association with insulin secretion ($p<0.001$) and insulin sensitivity ($p<0.001$) on adjusting the effects of the confounders.

Conclusion: Early pregnancy PAPP-A can be clinically useful in predicting the future development of GDM in later stages of gestation and it seems to have an association with insulin secretory defect and insulin resistance in this disorder.

Vascular endothelial growth factor and brain derived neurotrophic factor in gestational diabetes mellitusJ.M. Brix¹, C. Hoebaus², E. Kratz¹, G.-H. Scherthaner², G. Scherthaner¹;¹Medicine I, Rudolfstiftung Hospital, ²Angiology, Medicine II, Medical University of Vienna, Austria.

Background and aims: Gestational diabetes mellitus (GDM) is a translational state of increased insulin resistance and accelerated atherosclerosis. Vascular endothelial growth factor (VEGF) and brain derived neurotrophic factor (BDNF) are potent mediators of angiogenesis and vasculogenesis. Therefore we were interested in VEGF and BDNF in patients with GDM compared to normal pregnancy (NGDM) and non-pregnant healthy controls (CO).

Materials and methods: We performed a cross-sectional and a longitudinal study, in which 45 patients with GDM (BMI 30.0 ± 5.3 kg/m², mean age 34 ± 5 years) as well as 16 pregnant women without GDM (NGDM, BMI 28.2 ± 4.4 kg/m², mean age 31 ± 5 years) were included and compared with 29 non-pregnant healthy controls (CO, BMI 24.1 ± 4.5 kg/m², mean age 32 ± 5 years). An oral glucose tolerance test (75g) and HOMA insulin resistance were assessed at 28 weeks of gestation as well as 8 weeks postpartum. Blood samples for VEGF and BDNF were obtained at the same time points and were determined by an ELISA.

Results: VEGF and BDNF levels were significantly lower in GDM patients compared to CO (1.6 ± 0.3 vs 2.5 ± 0.3 ; $p=0.013$; 22.1 ± 5.4 vs 26.4 ± 8.8 ng/ml; $p<0.001$). In addition, NGDM patients also had significantly lower VEGF and BDNF levels than CO (1.6 ± 0.2 vs 2.5 ± 0.3 ; $p=0.002$; 18.0 ± 6.9 vs 26.4 ± 8.8 ng/ml; $p<0.001$). Patients with GDM differed from NGDM only in BDNF significantly intrapartum (22.1 ± 5.4 vs 18.0 ± 6.9 ng/ml; $p=0.044$). We obtained a significant increase of VEGF and BDNF levels in GDM (2.6 ± 0.2 ; $p<0.001$; 27.7 ± 4.9 ng/ml; $p<0.001$) and NGDM (2.7 ± 0.1 ; $p<0.001$; 27.8 ± 0.8 ng/ml; $p=0.001$) patients postpartum. After pregnancy VEGF levels were significantly higher in the GDM group compared to CO (2.6 ± 0.2 vs 2.5 ± 0.3 ; $p=0.015$).

Conclusion: This is the first study demonstrating significantly lower VEGF and BDNF in pregnant women compared to healthy CO. These lower values of vascular growth factors may indicate that pregnancy per se is a protecting condition. BDNF and VEGF significantly increased postpartum in both GDM and non-GDM. The significant higher VEGF levels in GDM vs CO might be a contributing factor to the well-known increased cardiovascular risk of those patients.

Glyoxalase-I overexpression attenuates early renal impairment in diabetic ratsO. Brouwers¹, P.M.G. Niessen¹, T. Miyata², J. Østergaard³, A. Flyvbjerg³, C.J. Peutz-Kootstra⁴, M. Brownlee⁵, C.D.A. Stehouwer¹, C.G. Schalkwijk¹;¹Department of Internal Medicine, Maastricht University, Netherlands,²Centre of Translational and Advanced Research, Tohoku University, Sendai, Japan,³Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Denmark,⁴Department of Pathology, Maastricht University Medical Center, Netherlands, ⁵International Center for Diabetic Complications Research, Albert Einstein College of Medicine, New York, USA.

Background and aims: In diabetes, intracellular glycation and elevated levels of advanced glycation endproducts (AGE) and AGE-precursor methylglyoxal (MGO) are associated with development of microvascular complications. In this study we used rats transgenically overexpressing the MGO-detoxifying enzyme glyoxalase-I (GLO-I) to determine the impact of intracellular glycation on the development of nephropathy in diabetes.

Materials and methods: Wild-type ($n=13$) and GLO-I transgenic rats ($n=18$) were made diabetic by streptozotocin (STZ) injection, sacrificed after 12 or 24 weeks and compared with controls ($n=14$). The levels of the AGEs, N^ε-(1-carboxymethyl)lysine (CML) and N^ε-(5-hydro-5-methyl-4-imidazolonyl)-L-ornithine (MG-H1) were measured with tandem mass-spectrometry and immunohistochemical stainings. Kidneys were isolated, weighted and analyzed for structural alterations, collagen content and glomerular volume. The early urinary nephropathy markers, albumin, osteopontin, lipocalin-2 and kidney injury molecule-1 (KIM-1), were measured by ELISA-based techniques.

Results: Diabetes resulted in accumulation of plasma AGEs, which was decreased by overexpression of GLO-I. In addition, immunohistochemical analysis showed increased presence of CML and MG-H1 in the mesangial matrix and peritubular capillaries of the diabetic rats, which could not be prevented by GLO-I overexpression. Diabetes resulted in renomegaly and increased glomerular volume after both timepoints, which were decreased, but not significantly improved by GLO-I overexpression. Histological analysis of the kidney did not show any collagen deposition fibrotic or inflammatory differences in glomerular, tubulointerstitial or capillary tissue between the three groups after 24 weeks of diabetes. After 24 weeks of diabetes, creatinine clearance was elevated, without improvement by GLO-I overexpression. Early urinary nephropathy markers, i.e. albumin, osteopontin, lipocalin-2 and KIM-1, were increased after 12 weeks of diabetes and further increased after 24 weeks of diabetes. The increase of albumin, osteopontin and KIM-1 after 24 weeks of diabetes was significantly attenuated by GLO-I overexpression. Finally, these biomarkers of nephropathy strongly correlated with plasma AGE levels.

Conclusion: Overexpression of GLO-I attenuates the development of early diabetic nephropathy, which is not dependent on structural changes of the kidney, suggesting effects due to an improvement in vascular/endothelial function. Inhibition of intracellular glycation by activation of GLO-I or quenching of MGO may provide a novel approach to prevent diabetic nephropathy.

SDF-1/CXCR4-mediated crosstalk attenuates albuminuria in experimental diabetic nephropathyL.-H. Chen¹, S.L. Advani¹, K. Thai¹, M.M. Sood², I.W. Gibson²,K.A. Connelly¹, R.E. Gilbert¹, A. Advani¹;¹Keenan Research Centre of the Li Ka Shing Knowledge Institute, St.Michael's Hospital, Toronto, ²Health Sciences Centre, University of Manitoba, Winnipeg, Canada.

Background and aims: The stromal cell-derived factor-1 (SDF-1)/CXCR4 signaling pathway exemplifies a podocyte-endothelial crosstalk system essential for renal vascular development. Within the renal glomerulus, while the homeostatic chemokine SDF-1 is abundantly expressed by podocytes, its cognate receptor, CXCR4, is present on the surface of endothelial cells where it may signal through the PI3K/Akt/eNOS pathway. In the context of recent evidence indicating that high glucose concentrations directly augment the

activity of hypoxia inducible factor-1 α (HIF-1 α), the major upstream regulator of CXCR4 expression, we investigated the role of SDF-1/CXCR4 signaling in human and experimental diabetic nephropathy.

Materials and methods: Gene and protein expression were determined in rat and human kidneys. CXCR4-antagonism was achieved by administering the bicyclam, AMD3100, to streptozotocin-diabetic rats and eNOS knockout mice.

Results: Immunostaining rat kidney sections confirmed podocytic expression of SDF-1, with CXCR4 protein restricted to endothelial cells of glomerular and peritubular capillaries. Real-time PCR of kidney homogenates from rats after 4 weeks of streptozotocin-induced diabetes revealed upregulation of both HIF-1 α and CXCR4 mRNA (HIF-1 α (AU), control 1.04 ± 0.09 , diabetes 1.68 ± 0.11 ; CXCR4 (AU), control 1.00 ± 0.04 , diabetes 1.70 ± 0.14 , each $p < 0.001$). CXCR4 mRNA was similarly increased in biopsies from patients with diabetic nephropathy (DN) relative to time-zero live kidney donor tissue (control) (CXCR4 (AU), control 1.09 ± 0.16 , DN 4.14 ± 0.79 , $p < 0.01$). Treatment of diabetic rats with the CXCR4 antagonist, AMD3100, augmented albuminuria (albumin excretion rate (AER) ($\mu\text{g}/24\text{h}$), vehicle 177.8 ± 1.2 , AMD3100 331.1 ± 1.2 , $p < 0.05$) without affecting body weight, blood glucose or blood pressure. In contrast, AMD3100-treatment had no effect on the heavy albuminuria that occurred in streptozotocin-diabetic eNOS knockout mice (AER ($\mu\text{g}/24\text{h}$), vehicle 302.0 ± 1.2 , AMD3100 281.8 ± 1.2 , $p = 0.81$).

Conclusion: These observations indicate that high-glucose mediated upregulation of CXCR4 serves to attenuate albuminuria development in diabetic nephropathy. Since podocytes are the primary source of CXCR4-ligand (SDF-1) within the renal glomerulus and since the albuminuric effects of CXCR4-blockade are abrogated by deficiency of an ostensibly endothelial-specific gene (eNOS), the SDF-1/CXCR4 signaling pathway defines a podocyte-endothelial crosstalk system that is altered in diabetic nephropathy. Therapeutic augmentation of CXCR4-signaling may represent a novel therapeutic strategy to slow the progression of renal injury in diabetes.

Effect of CB2 receptor deletion in streptozotocin-induced diabetic mice

F. Barutta, A. Corbelli, S. Pinach, M.P. Rastaldi, P. Cavallo Perin, G. Gruden; Internal medicine, University of Turin, Italy.

Background and aim: Diabetic nephropathy (DN) is characterised by increased glomerular permeability to proteins and excessive extracellular matrix accumulation in the mesangium, resulting eventually in glomerulosclerosis and progressive renal impairment. Endocannabinoids (EC), anandamide and 2-arachidonoylglycerol, bind to two receptors, named CB1 and CB2. In experimental diabetes the CB1 is overexpressed by podocytes and CB1 blockade ameliorates albuminuria. The CB2 is predominantly expressed by immune cells; however, we have previously reported preliminary data showing that the CB2 is also present on glomerular podocytes and that a CB2 agonist reduces albuminuria in diabetic mice. To further explore the role of CB2 in DN, herein we studied functional and structural abnormalities of DN in diabetic mice knockout for the CB2 receptor.

Materials and methods: Both wild type (CB2^{+/+}) and CB2 knockout (CB2^{-/-}) mice were made diabetic by intraperitoneal (IP) injection of streptozotocin at a dose of 55 mg/kg delivered in 3 consecutive days. Control mice were injected with citrate buffer alone. 16 weeks after the induction of diabetes, mice were individually placed in metabolic cages for urine collections and blood samples taken for blood glucose and glycated haemoglobin measurements. Then, mice were sacrificed, kidneys removed, weighed, and analysed. Urinary albumin excretion was measured by enzyme-linked immunosorbent assay. Expression of slit-diaphragm proteins (nephrin and podocin) was assessed by both immunofluorescence and immunoblotting. Fibronectin, CTGF, collagen I and TGF- β 1 mRNA levels were quantitated by real-time PCR on total renal cortex. Markers of inflammation (MCP-1, CCR2, F4/80 and GR1) were analysed by real time PCR or immunohistochemistry. Histological damage was assessed by both PAS staining and electron microscopy.

Results: Diabetes was associated with reduced body weight and elevations in both plasma glucose and glycated haemoglobin levels, but no differences were seen between CB2^{+/+} and CB2^{-/-} mice. Albuminuria was significantly increased in the wild type diabetic animals as compared to the controls and further enhanced by CB2 receptor deletion. In the diabetic mice the increase in albuminuria was paralleled a significant reduction in both nephrin and podocin protein expression and this effect was further exacerbated in diabetic mice lacking CB2 receptors. Histological assessment by PAS staining showed that the degree of mesangial expansion was greater in diabetic mice CB2^{-/-}

than in wild type mice as confirmed by electron microscopy. Consistently, diabetes-induced overexpression of fibronectin, CTGF, collagen I, and TGF- β 1 mRNA levels was significantly increased by CB2 deletion. Finally, lack of CB2 receptor induced a strong CCR2 upregulation in both control and diabetic mice and significantly enhanced monocyte infiltration in diabetic mice.

Conclusion: These findings demonstrate that in experimental diabetes CB2 deletion worsens both functional and structural abnormalities of DN. This strengthens the argument of a protective role of signalling through the CB2 receptor in this complication.

Effects of intrarenal tonic activation of angiotensin II and adenosine receptors on renal haemodynamics of control and diabetic rats

D. Patinha^{1,2}, A. Fasching², A. Albino-Teixeira¹, M. Morato^{1,3}, F. Palm²;

¹Institute of Pharmacology and Therapeutics, FMUP and IBMC, University of Porto, Portugal, ²Department of Medical Cell Biology, Uppsala University, Sweden, ³Laboratory of Pharmacology, Department of Drug Sciences, FFUP, REQUIMTE, University of Porto, Portugal.

Background and aims: Diabetic nephropathy (DN) is characterized by enhanced renal renin-angiotensin system (RAS) activity and renal vascular dysfunction. Both angiotensin II and adenosine influence renal vascular tone. Adenosine restrains renin release from juxtaglomerular cells and therefore may be an important modulator in DN. This study aimed at evaluating the effects of *in vivo* intrarenal blockade of angiotensin II AT₁ and AT₂ receptors and adenosine A₁ and A₂ receptors on renal hemodynamic in a model of DN.

Materials and methods: On day 14 after diabetes induction, streptozotocin-induced (50 mg/kg; iv; diabetic) or vehicle (controls) male Sprague-Dawley rats (≈ 340 g) were anaesthetized and prepared for surgery. The left kidney was immobilized and a lumbar catheter was advanced about 1 mm into the left renal artery to allow kidney specific delivery of vasoactive substances. The angiotensin II AT₁ receptor antagonist candesartan ($4.2 \mu\text{g}/\text{kg}$) and the adenosine A₁ receptor antagonist 8-Cyclopentyl-1,3-dipropylxanthine (DPCPX; $140 \mu\text{g}/\text{kg}$) were infused in the renal artery after a baseline period, in separate groups. An additional group received the combination of candesartan and DPCPX. The infusion was made in a step wise manner during 10 min to minimize leakage to the systemic circulation. In some animals, an additional experimental period was done subsequent to the infusion of angiotensin II AT₁-receptor antagonist PD-123,319 ($0.5 \text{ mg}/\text{kg}$) or adenosine A₂-receptor antagonist 3,7-dimethyl-1-propargylxanthine (DMPX; $0.5 \text{ mg}/\text{kg}$). GFR was measured by ³H-inulin clearance and renal blood flow (RBF) was measured by a transonic flow probe placed around the left renal artery. Statistical differences were evaluated by ANOVA followed by Tukey's test for multiple comparisons or Student's paired *t*-test, as appropriated.

Results: Baseline RBF was similar in all groups, averaging $8 \pm 0.1 \text{ ml}/\text{min}/\text{kidney}$. Intrarenal treatment of both diabetic and control animals with candesartan, DPCPX or candesartan+DPCPX increased RBF in approximately 30 % ($p < 0.05$). Baseline GFR and filtration fraction (FF) were higher in diabetic animals compared to controls (averaging 4 ± 0.2 vs $2 \pm 0.1 \text{ ml}/\text{min}$, 42 ± 2 vs $20 \pm 2 \%$, respectively, $p < 0.05$). In control animals, treatment with DPCPX or candesartan+DPCPX increased GFR when compared to baseline (1.8 ± 0.21 vs 1.5 ± 0.2 and 2.1 ± 0.3 vs $1.6 \pm 0.2 \text{ mL}/\text{min}$, $p < 0.05$, respectively). In diabetic animals, candesartan infusion reduced GFR (3.0 ± 0.3 vs $3.8 \pm 0.3 \text{ mL}/\text{min}$, $p < 0.05$) when compared to baseline. Baseline FF was reduced after the infusion of candesartan, DPCPX or candesartan+DPCPX in approximately 25 % ($p < 0.05$) in diabetic animals. Infusion of PD-123,319 after candesartan or DMPX after DPCPX, had no additional effect in these parameters.

Conclusion: Tonic activation of angiotensin II AT₁ and adenosine A₁ receptors in the afferent arteriole is the main regulator of renal vasoactivity in control animals. Interestingly, in diabetic animals the efferent arteriole seems to have a pivotal role. Our study also suggests that tonic activation of angiotensin II AT₂ and adenosine A₂ receptor does not participate in the process.

High NEFA level related with microalbuminuria and uncoupling of VEGF-NO axis in obese rats

X. Sun, Y. Yu;

Department of Endocrinology and Metabolism, West China Hospital, Sichuan University, Chengdu, China.

Background and aims: Obesity is associated with microalbuminuria (MAU), which is not only an early manifestation of kidney damage, but also an independent risk factor for ischemic cardiovascular disease. High NEFA level is a common feature of obesity and can cause impaired endothelium-dependent vasodilatation (EDV). It is known that the beneficial effects of vascular endothelial growth factor (VEGF) are mediated in part by ability to stimulate endothelial nitric oxide (NO) production, and thus maintain glomerular endothelial cells function. However, endothelial dysfunction may cause the uncoupling of VEGF with NO, resulting in increased levels of VEGF and excessive endothelial cell proliferation. The aim of this study was to determine whether increased NEFA release from excessive visceral fat accumulation is related to increased urine albumin excretion and reduced circulating NEFA level by fenofibrate has renal protective effects by improving endothelial dysfunction and regulating VEGF-NO axis in diet-induced obese rats.

Materials and methods: Male Wistar rats 8 weeks in age were randomly divided into three groups. The rats in the control group, obesity group and fenofibrate group were fed with normal diet (330 kcal 100 g⁻¹), high-fat diet (493 kcal 100 g⁻¹), and high-fat diet plus fenofibrate (100mg/kg/d), respectively. Blood samples for NEFA, triglyceride (TG) measurements and urinary samples for albumin measurements were collected. Endothelial function was determined by comparing the vasorelaxation response of thoracic aorta segment to acetylcholine (to determine EDV), with that of sodium nitroprusside (to determine endothelium-independent vasodilatation) in organ bath. Renal cortex tissues were collected for CD31 immunohistochemistry. Glomerular NO and VEGF expression were measured by griess reaction and western blot, respectively.

Results: At the end of 24 weeks, body weight increased 32.8% in obese rats compared to control group. The serum NEFA and TG levels increased significantly in obese rats (NEFA, 1.38±0.34 vs. 0.36±0.12; TG, 1.53±0.58 vs. 0.52±0.20, P<0.01). Fenofibrate intervention decreased serum NEFA and TG levels by 43.4% and 48% respectively, accompanied by reduced ratio of perirenal fat to body weight (PF/BW) and visceral fat to body weight (VF/BW). Urinary albumin/creatinine ratio (ACR) increased in obese rats (56.09±22.64 vs. 19.52±7.30 mg/g, P<0.01), which was decreased 62.6% after fenofibrate intervention. Severe EDV impairment was observed in obese rats, which was partly improved by fenofibrate (EDV increased 43.3%, P<0.05). CD31 expression in glomeruli increased in obese rats (P<0.05), indicating that increased endothelial cell proliferation. Obese rats showed increased glomerular VEGF expression (P<0.05) and reduced NO level (0.30±0.09 vs. 0.53±0.08 umol/g protein, P<0.05). And this uncoupling of VEGF-NO axis were partly improved by fenofibrate (P<0.05). Correlation analysis showed ACR had a positive correlation with NEFA, PF/BW and VF/BW (r=0.751, 0.783, 0.712, respectively, P<0.01) and had a negative correlation with EDV (r=-0.781, P<0.01).

Conclusion: Elevated circulating NEFA level may cause increased MAU in obese rats by impairment of EDV and increased MAU could be improved by reducing circulating NEFA level. The mechanism may be related to NEFA-induced uncoupling of VEGF-NO axis and the abnormal proliferation of endothelial cells.

P2X₇ deficiency attenuates renal disease induced by high-fat dietA. Solini¹, S. Menini², C. Rossi¹, C. Iacobini², E. Santini¹, C. Blasetti Fantauzzi², A. Salvati¹, G. Pugliese²;¹Dept of Internal Medicine, University of Pisa, ²Dept of Clinical and Molecular Medicine, La Sapienza University, Rome, Italy.

Background and aims: Renal disease associated with type 2 diabetes and the metabolic syndrome is characterized by a distinct inflammatory phenotype. The purinergic system plays a relevant role in the inflammatory and immune response to injurious stimuli, particularly through the P2X₇ receptor, which is expressed in resident and non-resident kidney cells, such as mesangial cells and macrophages. In addition to stimulating the release of pro-inflammatory cytokines, it has been shown to promote mesangial cell apoptosis and ma-

trix production, these effects being opposed by the P2Y receptors, and to be upregulated in glomeruli from animal models of diabetes, hypertension and glomerulonephritis. This study was aimed at verifying the hypothesis that P2X₇ promotes the development of lipid-induced renal disease through the induction of renal tissue inflammation and consequent dysregulated glomerular remodeling.

Materials and methods: P2X₇ knockout (KO) mice and coeval wild type (WT) controls were fed a high-fat diet (HFD, 60% saturated fat) or a normal-fat diet (NFD, 4% saturated fat) for 4 months. Glomerular lesions were evaluated by measuring mean glomerular area, mean mesangial area, and fractional mesangial area by morphometrical analysis. Glomerular protein expression and distribution and total kidney gene expression were assessed by immunohistochemistry and RT-PCR, respectively. Renal signalling events were evaluated by Western blot analysis.

Results: Body weights were significantly higher in KO vs. WT mice and increased in both genotypes upon HFD. HFD-induced glomerular lesions were attenuated in KO vs. WT mice. This was confirmed by morphometrical analysis, showing significantly lower values (P<0.001) in KO vs. WT mice of mean glomerular area (3,165±183 vs. 3,453±212 μm²), mean mesangial area (605.3±60.3 vs. 780.8±80.8 μm²), and fractional mesangial area (19.2±2.0 vs. 22.7±2.6 %). This was associated with significantly reduced glomerular expression of the extracellular matrix proteins fibronectin and collagen IV, the macrophage marker F4/80 and the advanced lipoxidation endproducts 4-hydroxy-2-nonenal (HNE)-adducts as well as with decreased kidney mRNA levels of collagen IV, F4/80 and the pro-inflammatory cytokine monocyte chemoattractant protein-1 (MCP-1). Phosphorylation of ERK1/2-mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K) were up-regulated upon HFD in WT and KO mice, respectively.

Conclusion: These data show that P2X₇ plays an important role in HFD-induced renal disease by modulating glomerular cell apoptosis and matrix accumulation and renal tissue inflammation.

Low-pass whole-genome sequencing, deep exome sequencing and dense array genotyping for determining genetic variants associated with type 2 diabetes

R.D. Pearson¹, H.M. Kang², B.F. Voight³, K.J. Gaulton¹, C. Fuchsberger², J.R. Maguire³, Genetics of Type-2 Diabetes (Go-T2D) Consortium;

¹Wellcome Trust Centre for Human Genetics, University of Oxford, UK,

²Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, ³Medical Population Genetics, Broad Institute of Harvard and MIT, Cambridge, USA.

Background and aims: Type 2 diabetes (T2D) is a complex disorder of incompletely known genetic etiology. Although lower-frequency and rare variants likely contribute to T2D susceptibility, these variants have not yet been thoroughly investigated on a large scale. In addition, association between small insertions and deletions (indels) and T2D has not previously been assessed on a genome-wide scale. In this study, we are attempting to identify additional variants contributing to T2D susceptibility in 1,325 T2D cases and 1,325 controls of Finnish, Swedish, and UK origin.

Materials and methods: We are using several approaches to target lower frequency and indel variants, including low-pass (4x) whole-genome sequencing, deep exome sequencing, array genotyping of 2.5 million SNPs, and genotype imputation using sequence data generated both within this project and from the 1000 Genomes project. Analysis of data from each approach, both independently and jointly, will help elucidate the genetic architecture of T2D across a wider allele frequency spectrum of both SNPs and indels, as well as the most effective approaches to achieve this end.

Results: Preliminary analysis of data from a first-term data freeze representing 179 low-pass genomes identified 11.3 million SNPs, 40% of which are not present in public databases. Among novel, rare variants are several unique to cases that create or delete a stop codon (nonsense) in genes at loci involved in monogenic (PAX4-W91*, WFS1-E752*) and polygenic (TSPAN8-*238R) forms of T2D. In addition, several novel nonsense variants unique to cases implicate previously unreported genes (e.g. GPR37-R68*); case allele frequency = 5%, uncorrected $P = .025$). Variants were tested for T2D association after imputation into 4,100 case and 5,200 control samples with genome-wide array data from the DGI, FUSION and WTCCC studies. Patterns of association in common variants were consistent with previous results imputing HapMap data into the same samples, including three established T2D loci with $P < 5 \times 10^{-8}$, suggesting that variants identified in low-pass sequencing can be effectively tested in larger sample sets to maximize risk allele discovery potential.

Conclusion: Data collection is ongoing with all data generation expected to be complete by autumn 2011, which will greatly enhance statistical power for discovery both directly and via imputation. This project represents the first opportunity to gain broad insight into the contribution to type 2 diabetes of different types of variant across the allele frequency spectrum.

98

Genome-wide association analysis of rare variants with type 2 diabetes

R. Mägi¹, J. Chen¹, K.J. Gaulton¹, J. Asimit², E. Zeggini², M.I. McCarthy^{1,3}, I. Prokopenko^{1,3}, A.P. Morris¹;

¹Wellcome Trust Centre for Human Genetics, Oxford, ²Wellcome Trust Sanger Institute, Cambridge, ³Oxford Centre for Diabetes Endocrinology and Metabolism, UK.

Background and aims: Genome-wide association studies (GWAS) of common variants have been extremely successful in identifying novel loci contributing effects to type 2 diabetes (T2D) susceptibility. However, despite this success, the joint effects of these common variants account for no more than 15% of the heritability of the disease. The aim of this study, therefore, was to assess the evidence for association of T2D with rare genetic variation, defined here to have minor allele frequency (MAF) less than 1%, which is typically poorly captured by GWAS genotyping products.

Materials and methods: We performed imputation in 1,926 T2D cases and 2,942 controls of European descent from the UK, genotyped using the Affymetrix GeneChip 500K Mapping Array Set as part of the Wellcome Trust

Case Control Consortium. Imputation was undertaken using IMPUTEv2 and the European reference panel from the August 2010 release of the 1000 Genomes Project. We tested for association of T2D with accumulations of minor alleles at rare variants (imputed and directly typed) within genes, incorporating 50kb up- and down-stream to allow for additional functional elements and regulatory regions. The analysis was performed using GRANVIL, which models disease status as a function of the proportion of rare variants at which an individual carries at least one minor allele in a logistic regression framework.

Results: The strongest signal of association of rare variation with T2D was observed for BMP2 ($p = 1.0 \times 10^{-6}$, genome-wide significant correcting for 30,000 genes). Common variants within this gene have previously been demonstrated to be associated with developmental and metabolic traits including height and body mass index. The gene contained 36 rare variants (mean MAF = 4.3×10^{-3}), with odds ratio of 1.26 (1.15–1.38) per minor allele. Strong evidence of association of rare variation with T2D ($p < 10^{-3}$) was also observed for IGFL4 ($p = 2.4 \times 10^{-6}$) and CLK3 ($p = 6.4 \times 10^{-6}$). IGFL4 belongs to a family of signalling molecules that play crucial roles in cellular energy metabolism and in growth and development. The gene contained 12 rare variants (mean MAF = 4.4×10^{-3}), with odds ratio of 1.85 (1.43–2.38) per minor allele. CLK3 contained 22 rare variants (mean MAF = 3.1×10^{-3}), with odds ratio 0.65 (0.54–0.79) per minor allele, hence demonstrating a protective effect against T2D.

Conclusion: Our analysis has demonstrated strong evidence of association of T2D with rare variation in three genes. These signals of association warrant follow-up in independent cohorts, and parallel efforts are underway in the DIAGRAM Consortium. Our results highlight the potential for the identification of rare variant associations using existing GWAS genotyping data, supplemented with imputation from high-density reference panels, without the need for costly re-sequencing experiments.

99

Large-scale replication using “MetaboChip” array identifies additional genetic loci influencing glycaemic traits

I. Prokopenko^{1,2}, V. Lagou^{1,2}, R.A. Scott³, E. Wheeler⁴, R. Welch^{5,6}, J. Luan³, R. Mägi¹, T.M. Teslovich^{5,6}, C. Langenberg³, I. Barroso^{4,7}, MAGIC investigators;

¹WTCHG, University of Oxford, ²OCDEM, University of Oxford, ³MRC Epidemiology Unit, Cambridge, ⁴Wellcome Trust Sanger Institute, Cambridge, UK, ⁵Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, ⁶Bioinformatics Graduate Program, The University of Michigan Medical School, Ann Arbor, USA, ⁷University of Cambridge Metabolic Research Labs, Cambridge, UK.

Background and aims: The Meta-Analyses of Glucose and Insulin-related traits Consortium (MAGIC) has previously performed the largest published meta-analysis of genome-wide association studies (GWAS) for glycaemic traits to date, bringing the number of established loci for fasting glucose (FG) to 16 and fasting insulin (FI) to 2. The “MetaboChip”, a custom iSELECT array of 217,697 SNPs, was developed to support large-scale follow-up of putative associations for cardio-metabolic traits and fine-mapping of established loci. It contains >65,000 top-ranked, independent SNPs selected from the stage 1 MAGIC discovery meta-analyses (up to 46,186 non-diabetic Europeans), including ~5k/1k selected for FG/FI ($10^{-75} < P < 0.02$).

Materials and methods: To identify additional loci for FG/FI, we combined SNPs selected for replication in the MetaboChip in 24/21 independent cohorts (53,149/42,252 individuals) with MetaboChip data with the non-overlapping MAGIC GWAS discovery cohorts and an additional 15/13 GWAS (25,618/23,130 individuals) using a fixed effects meta-analysis. The combined meta-analysis included a total of up to 120,845/99,610 individuals. Association analyses in each cohort were performed using an additive genetic model.

Results: We identified 15 novel genome-wide significant ($P < 5 \times 10^{-8}$) loci for FG, nine of which have been previously associated with other metabolic traits: SNPs in or near CDKN2A/2B, FOXA2, GRB10 (type 2 diabetes [T2D]), CENTD2/ARAP1 (T2D, proinsulin), PDX1 (MODY), PCSK1 (obesity, proinsulin), GIPR (2h glucose), LIN28B (age at menarche, height) and PPP1R3B (LDL-cholesterol and C-reactive protein). The remaining 6 novel loci were located in or near genes encoding for transcriptional repressors (14q31, 20q12), tRNA synthetase (14q32), nucleotide phosphodiesterase (10q24), purinoreceptors (12q24) and proinflammatory signaling kinase (9q31). We discovered 4 novel loci for FI at a genome-wide level of significance, including variants in or near FTO (BMI), TCF7L2 (T2D, FG, HbA1C), PPP1R3B and at 4q24 (in gene encoding for myelopoiesis-related protein). A further 7 loci attained “suggestive” evidence of association ($P < 5 \times 10^{-7}$) with FI. These loci

included LYPLAL1 (WHR, fat distribution, fatty liver), CENTD2/ARAP1, ARL15 (T2D, adiponectin).

Conclusion: Replication using the MetaboChip array has allowed us to extend the number of genetic loci for FG to 31. For FI, only 6 genome-wide significant and another 7 loci just below have been identified, a number that remains small compared to other traits. Identification of FI loci previously associated with lipids and fat distribution highlights a potential link to hepatic insulin resistance. The overlap between the novel FG/FI loci and established loci for T2D, metabolic and anthropometric traits reinforces the complex relationships that exist between these phenotypes. The MetaboChip provides an efficient opportunity to widen our knowledge about the genetics of fasting glycaemic traits.

100

Genome-wide association meta-analysis identifies novel genetic loci for birth weight in Europeans

M. Horikoshi¹, H. Yaghoobkar², D.O. Mook-Kanamori³, U. Sovio^{4,5}, N.J. Timpson⁶, I. Prokopenko¹, R.M. Freathy², EGG consortium investigators; ¹WTCHG, University of Oxford, ²Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, UK, ³Department of Epidemiology, Erasmus Medical Center, Rotterdam, Netherlands, ⁴Department of Epidemiology and Public Health, Imperial College London, ⁵Department of Medical Statistics, London School of Hygiene and Tropical Medicine, ⁶MRC Centre for Causal Analyses in Translational Epidemiology, Bristol, UK.

Background and aims: Reduced birth weight (BW) is associated with a higher risk of type 2 diabetes (T2D), but the mechanisms responsible are unclear. The fetal insulin hypothesis proposes that common genetic variants influencing insulin secretion or action explain part of this association because fetal insulin is a key fetal growth factor. BW may be influenced directly by fetal genotype and indirectly by maternal genotype through the intra-uterine environment and interaction of the fetal-maternal genotypes. Despite these challenging aspects involved in identification of BW susceptibility genes, previous genome-wide association (GWA) meta-analysis successfully identified variants in ADCY5 and near CCNL1 robustly associated with BW. Here we extend this effort by increasing the discovery sample.

Materials and methods: The discovery GWA meta-analysis of BW was performed in 18 studies (26,864 individuals) and one SNP at each of 17 associated loci ($p < 10^{-5}$) was selected for follow up in replication studies. We genotyped these variants in up to 37,120 participants from 18 cohorts of European descent. For analysis we considered singletons born at ≥ 37 weeks' gestation. We tested the association of each SNP using standardized Z-score of birth weight estimated in each study, assuming an additive genetic model and adjusting for sex and gestational age where available. We combined the results from replication and discovery studies (up to 63,941 individuals) using inverse-variance fixed-effects meta-analysis. We used a threshold of $p < 5 \times 10^{-8}$ to define the loci as genome-wide significant.

Results: SNPs in six loci were associated with BW at $p < 5 \times 10^{-8}$ or close to this threshold. The first two loci map near the CCNL1 gene ($p = 2.9 \times 10^{-28}$) and in ADCY5 ($p = 3.5 \times 10^{-15}$), which were both identified in the previous study. The next two identified signals map, respectively, to chromosome 12q15 ($p = 2.9 \times 10^{-19}$) and to the known susceptibility locus for T2D at CDKAL1 ($p = 8.8 \times 10^{-17}$). Two more independent signals on chromosome 4 were associated with BW. The former maps to chromosome 4p15 ($p = 1.1 \times 10^{-8}$) and the latter to chromosome 4q28 ($p = 8.8 \times 10^{-8}$). Of the six BW loci, three signals (12q15, 4p15 and 4q28) were in LD with known loci influencing adult height.

Conclusion: In our replication of expanded GWAS meta-analysis for birth weight, we confirmed 2 previously identified signals (in ADCY5 and near CCNL1) and discovered 4 novel BW genome-wide significant loci. These 6 signals include 3 known loci influencing adult height and 2 known T2D susceptibility loci (ADCY5 and CDKAL1). The alleles at the loci associated with an increased risk of T2D were also associated with lower BW. This is consistent with the fetal insulin hypothesis, which proposes that common genetic variants influencing insulin secretion play a key role in both low BW and later life chronic diseases. Identification of signals in LD with adult height loci suggests the impact of these loci in both pre- and post-natal growth.

101

Identification of novel type 2 diabetes susceptibility loci by large-scale replication using the “MetaboChip”

A.P. Morris¹, T.M. Teslovich², T. Ferreira¹, A. Mahajan¹, B.F. Voight³, D. Saleheen⁴, DIAGRAM Consortium;

¹University of Oxford, UK, ²University of Michigan, Ann Arbor, ³Broad Institute of MIT, Cambridge, USA, ⁴University of Cambridge, UK.

Background and aims: There are now more than 40 established loci influencing susceptibility to type 2 diabetes (T2D), most identified through genome-wide association studies. However, replication efforts have focussed on only the strongest signals of association, and have failed to fully exploit large-scale discovery meta-analyses. The “MetaboChip”, a custom iSELECT array containing ~195,000 SNPs, was designed to support large-scale follow-up of putative associations for T2D and other metabolic and cardiovascular traits, as well as fine-mapping of established loci.

Materials and methods: We performed meta-analysis of MetaboChip SNPs for 21,556 cases and 55,753 controls across 25 cohorts of European descent and 1,178 cases and 2,472 controls from a cohort of Pakistani descent. We subsequently combined these results with the unpublished DIAGRAMv3 meta-analysis (12,057 cases and 56,071 controls of European descent). Association analyses in each cohort were performed assuming additive allelic effects and the results combined via fixed-effects meta-analysis. These analyses were undertaken in males and females separately, and in both sexes combined.

Results: We began by considering 4,747 high quality, statistically independent SNPs which capture $>95\%$ of the ~5,000 strongest autosomal associations from the DIAGRAMv3 meta-analysis. At these SNPs, we compared patterns of replication between the DIAGRAMv3 and European descent MetaboChip sex-combined meta-analyses. After excluding SNPs at established loci, there was highly significant concordance in the direction of allelic effects (3,066 [65.3%] of 4,696 SNPs, binomial test $p = 8.8 \times 10^{-94}$). As expected, the directional consistency with the Pakistani descent cohort was weaker, but still highly significant (2,320 [53.3%] of 4,352 SNPs, binomial test $p = 6.8 \times 10^{-6}$). Combined meta-analysis of all samples at all MetaboChip SNPs revealed 11 novel loci exceeding genome-wide significance, the strongest signals mapping to ZMIZ1 ($p = 7.8 \times 10^{-11}$), GOLGA7 ($p = 1.6 \times 10^{-10}$) and PPFIBP1 ($p = 3.5 \times 10^{-10}$). Sex-differentiated meta-analyses highlighted a further 4 novel loci exceeding genome-wide significance, the strongest signal mapping to CCND2 ($p = 5.9 \times 10^{-10}$) where the association was markedly stronger in males ($p = 7.7 \times 10^{-10}$) than in females ($p = 0.032$). There was also evidence of heterogeneity in allelic effects between the sexes in already established T2D loci mapping to KCNQ1 (male $p = 6.8 \times 10^{-15}$, female $p = 0.0060$), DGKB (male $p = 4.6 \times 10^{-13}$, female $p = 0.0042$), and BCL11A (male $p = 1.1 \times 10^{-9}$, female $p = 0.013$).

Conclusion: The concordance of risk alleles between DIAGRAMv3 and MetaboChip meta-analyses, both within and between ethnic groups, is consistent with a long tail of common variants with modest effect on T2D susceptibility across populations. Further MetaboChip genotyping thus offers great promise for further discovery of T2D loci through inter- and intra-ethnic mapping studies, whilst sex-differentiated analyses may provide additional insights into the underlying genetic architecture of the disease.

102

Selection of extreme cases and controls as a strategy for efficient whole genome sequencing leads to enriched detection of most known type 2 diabetes susceptibility loci

A. Mahajan¹, J. Perry^{1,2}, K.J. Gaulton¹, R.D. Pearson¹, N. Robertson¹, N.W. Rayner^{1,3}, Y. Chen¹, T.D. Spector⁴, A.P. Morris¹, I. Prokopenko^{1,3}, M.I. McCarthy^{1,3}, GoT2D investigators;

¹Wellcome Trust Centre for Human Genetics, University of Oxford, ²Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, ³Ocdem, University of Oxford, ⁴Department of Twin Research and Genetic Epidemiology, King's College London, UK.

Background and aims: Sequencing-based studies allow exploration of the role of low frequency variants in common disease susceptibility. However, given the current extremely high cost of whole genome and exome sequencing, such studies naturally have to focus on the most informative subjects. Type 2 diabetes (T2D) patients with positive family history and early age of onset are likely to be enriched for low frequency loci with medium penetrance: selection for relatively lean cases should further enrich for effects on beta-cell function. By analogy, the most informative controls are likely to be those who remain normoglycemic at advanced age, particularly in the face

of obesity. The Genetics of T2D (GoT2D) study adopted this sample selection strategy to perform low-pass whole genome, deep exome sequencing and high-density array genotyping of 2650 individuals from the UK, Sweden and Finland.

Materials and methods: To establish whether these enrichment effects are visible with known (common) T2D-susceptibility loci, we examined the selected UK GoT2D samples. Cases ($n=337$) from the Warren 2 collection were selected for first degree family history of T2D, younger age of diagnosis (mean=50.4[SD=8.3] years) and lower BMI (26.5[2.6] kg/m²). Euglycemic controls ($n=351$) were chosen from the TwinsUK cohort to be older (61.4[10.0] years) with higher BMI (30.7[5.9] kg/m²) than cases. Cases and controls were also matched on principal components. These samples were genotyped on the 2.5M Illumina OmniChip (1,670,266 polymorphic SNPs passing QC). We compared signal effect size to those previously-reported by the DIAGRAM consortium using the ratio between the two effect size estimates.

Results: Among the studied loci, TCF7L2 (OR [95%CI], 2.1 [1.6-2.7]), DUSP9 (1.7 [1.2-2.5]), and ADCY5 (1.5 [1.2-2.0]) showed the largest effect sizes with the TCF7L2 association reaching genome-wide significance ($P=1.3 \times 10^{-9}$) despite the modest sample size. On average, the point estimate of per-allele risk was ~7% higher for the selected samples. Furthermore, 8 loci (DUSP9, TCF7L2, ADCY5, CDC123/CAMK1D, RBMS1, CENTD2, HHEX/IDE, GCK), all acting through presumed beta-cell effects, showed the most marked increases (20-58%).

Conclusion: Analysis of subjects selected from extremes of the liability distributions achieved the desired effect of enhancing effect size estimates for known common variants. Focusing sequencing efforts in such samples should aid discovery of novel low frequency associations.

103

Hydrogen peroxide is a nutrient-activated secondary signal in beta cells

A.K. Arata, R. Shah, C.J. Rhodes;

The Kovler Diabetes Center, Department of Medicine, University of Chicago, USA.

Background and aims: The islet β -cell is thought to be susceptible to damaging reactive oxygen species (ROS) due to low expression of endogenous antioxidant proteins such as superoxide dismutases (SOD1 and SOD2) that convert superoxide into H₂O₂ and glutathione peroxidase (GPX1) and catalase (CAT) which dispose of H₂O₂ to water. ROS are commonly produced from nutrient metabolism in the mitochondria and are able to diffuse into the cytosol to act as secondary signals. Certain proteins, such as kinases, may be activated by ROS due to redox changes of cysteine residues and disulfide bonding. Here we determine glucose-produced H₂O₂ as a secondary signal of action on mTOR.

Materials and methods: Wistar rat islets were used for all experiments. Quantitative PCR measured mRNA, immunoblot measured relative protein expression, and enzyme activities were determined by specific assays. H₂O₂ was measured in islet cell lysates by Amplex Red fluorogenic activity. Adenoviral-mediated expression of CAT was used to rapidly dispose of H₂O₂. Phosphorylation activation of mammalian target of rapamycin (mTOR) and mTOR substrates - p70S6 kinase 1 & 2 (p70S6K), eukaryotic translation initiation factor 4E-binding protein 1 (4E-BP1) and protein kinase B (Akt) - was assessed with phospho-specific antibodies.

Results: The mRNA, protein, and activity of the major antioxidant enzymes in isolated rat islets relative to hepatocytes was measured. Islet mRNA levels for SOD1 were 89%, SOD2 55% and GPX1 96% lower than that in liver, with catalase mRNA undetectable in islets. However, protein levels for SOD1 were 40%, and SOD2 equivalent, to that in the liver. GPX1 activity was only 19% of liver, with no catalase activity present in islets. As such, β -cells can efficiently produce H₂O₂ from superoxide generated from oxidative metabolism but cannot efficiently dispose of H₂O₂. Glucose stimulation (16.7mM) of islets rapidly increased islet H₂O₂ 4-fold within 2 min. that was sustained over a 90-min. incubation. Adenoviral-mediated expression of CAT decreases H₂O₂ by >90% ($p=0.04$). The mTOR was used as a model nutrient-activated kinase to test if glucose-induced H₂O₂ is a metabolic signal to activate this enzyme. Two protein complexes contain mTOR - complex 1 (mTORC1) and 2 (mTORC2). Phosphorylation activation of mTORC1-specific substrates p70S6K and 4E-BP1 was examined in parallel to the specific mTORC2 substrate Akt. mTORC1 substrates are phosphorylated within the first 5 min. of glucose (16.7mM) stimulation and maintained over an hour, while insulin-like growth factor 1 (IGF-1) treatment only transiently phosphorylates mTORC1 substrates at 15 min. Activation of mTORC2 by IGF-1 occurs quickly and is sustained, but is only slight with glucose alone. These data indicate glucose specifically activates mTORC1. Furthermore, ablating H₂O₂ production by CAT expression significantly decreased glucose activation of mTORC1 by 36% ($p=0.03$) in islet β -cells, whereas mTORC2 remained unaffected.

Conclusion: The antioxidant system of the islet β -cell is coordinated to generate H₂O₂ in response to glucose oxidative metabolism. H₂O₂ is a candidate secondary signal for nutrient activation of mTORC1, but not mTORC2 in β -cells. The N-terminus of mTOR contains conserved cysteines that are ideal targets for oxidation by H₂O₂, and we are currently conducting site-directed mutagenesis on mTOR to pursue this idea.

Expression and roles of NOX family NAD(P)H oxidases in pancreatic islets of Nox-specific knockout mice

N. Li¹, B. Li², T. Brun¹, C. Deffert², X.-J. Ma², K.-H. Krause², P. Maechler¹;

¹Department of Cell Physiology and Metabolism, ²Department of Pathology and Immunology, University of Geneva, Switzerland.

Background and aims: Elevated production of reactive oxygen species (ROS) has been proposed to contribute to pancreatic beta-cell impairment in diabetes. Expression of phagocyte-like Nox family NAD(P)H oxidases, a potential source of ROS, has been reported in pancreatic beta-cells. However, their role remains poorly characterized due to lack of specific inhibitors and

reliable antibodies. Here, functional analysis of Noxs in islets was carried out using Nox isoform-specific knockout mice.

Materials and methods: Expression of NAD(P)H oxidase components in C57BL/6J mouse and human islets was analyzed by RT-PCR. Next, islets isolated from wild-type (WT) mice and mice knocked out for specific Nox isoforms (koNox-1, -2 and -4) were used to study putative correlation between glucose-stimulated insulin secretion (measured by RIA) and Nox-derived superoxide generation (measured by NBT). Additionally, Nox-2 was knocked down in WT islets (siNox-2). Sub-cellular localization of NOX-2 in human islets was investigated (immuno-staining and internalization of rhodamine-conjugate dextran). KoNox-2 islet morphology, beta-cell area and insulin contents were measured (immuno-staining), calcium response was tested using fura-2-AM, and glucose homeostasis was examined by ipGTT. Additionally, specificity of the NOX inhibitor DPI was challenged on WT and koNox-1, -2 and -4 islets. The study has been carried out along the “Principles of laboratory animal care”.

Results: Both mouse and human pancreatic islets expressed membrane-associated NOX-2 and -4, NOX-2 being the predominant isoform. Nox-1 and cytosolic components, such as p22^{phox}, p40^{phox}, p47^{phox}, p67^{phox}, Noxo-1, Noxa-1 were expressed in mouse islets. Expression of Nox-2 was further confirmed in sorted beta-cells of mouse islets. A negative correlation ($r=-0.96$, $p<0.05$) was found between glucose-induced insulin secretion and Nox-derived superoxide generation comparing WT and koNox-1, -2 and -4 islets. Compared to WT, koNox-2 islets stimulated with 22.8 mM glucose exhibited potentiated insulin release (+119%, $p<0.05$) associated with lower superoxide production (-37%, $p<0.05$), confirmed with *in vitro* knockdown of Nox-2 (si-Nox-2). In human islets, NOX-2 co-localized with both insulin granules and endosomes/lysosomes. No differences in cytosolic calcium, islet organisation, beta-cell area and insulin contents and glucose homeostasis were observed. The NOX inhibitor DPI exhibited a general inhibitory effect on insulin secretion in WT and all koNox islets, showing lack of specificity of this inhibitor.

Conclusion: NOX-2 is the most abundant NAD(P)H oxidase in human and mouse islets. NOX-2 is found in insulin granules and endosomes/lysosomes of human beta-cells. Nox knockouts represent a valuable experimental model for the study of NAD(P)H oxidases, the use of non-specific NOX inhibitors being misleading. NAD(P)H oxidases positively contribute to glucose-induced ROS generation and negatively regulate insulin secretion.

FoxO feedback control of basal IRS-2 expression in pancreatic beta cells is distinct from that in hepatocytes

S. Tsunekawa¹, D. Demozay¹, I. Briaud², J. McCuaig¹, D. Accili³, R. Stein⁴, C.J. Rhodes¹;

¹Department of Medicine, the University of Chicago, ²Theriac Pharmaceutical Corp., Seattle, ³Naomi Berrie Diabetes Center and Department of Medicine, Columbia University, New York, ⁴Department of Molecular Physiology & Biophysics, and Cell Biology & Development, Vanderbilt University, Nashville, USA.

Background and aims: Appropriate regulation of IRS-2 expression in pancreatic beta-cells is essential to adequately compensate for insulin resistance. In liver, basal IRS-2 expression is controlled via a temporal negative feedback of SREBP1 to antagonize FoxO1/FoxO3a at an insulin response element (IRE) on the IRS-2 promoter. It was examined if a similar mechanism controlled IRS-2 expression in beta-cells.

Materials and methods: IRS-2 mRNA and protein expression as well as IRS-2 gene promoter activity, were examined in isolated rat islets ± various inhibitors and adenoviral gene manipulation. Specific transcription factor association with the IRE on the IRS-2 promoter was examined by chromatin immunoprecipitation (ChIP) assay and their nuclear translocation by immunofluorescence. A direct *in vivo* effect of insulin on control of IRS-2 expression in liver and pancreatic islets was also examined.

Results: In IRS-2 promoter-reporter assays conducted in isolated islets, removal of the IRE decreased basal IRS-2 promoter activity in beta-cells by < 80%. Activation of IRS-signaling in isolated rat islets by insulin/IGF-1 (used as an experimental *in vitro* tool) or downstream constitutive activation of protein kinase-B (PKB) significantly decreased IRS-2 expression. In contrast, inhibition of phosphoinositide 3-kinase (PI3K) or PKB significantly increased IRS-2 levels in beta-cells. ChIP assays indicated that transcription factors FoxO1 and FoxO3a associated to the IRE on the IRS-2 promoter in beta-cells in a PI3K/PKB dependent manner, whereas others like SREBP1, TFE3 and ARNT did not. However, only FoxO3a, not FoxO1, was capable of

driving IRS-2 promoter activity via the IRE in beta-cells. In *in vivo* studies insulin was able to suppress IRS-2 expression via activation of SREBP1 in the liver, but this mechanism did not occur in pancreatic islets from the same animal.

Conclusion: The molecular mechanism for feedback control of IRS-signaling to decrease IRS-2 expression in liver and beta-cells are quite distinct with a predominant role played by FoxO3a in beta-cells.

106

PRL-induced improvement of beta cell function: Is Cx36 a player?

H. Pontes, A. Charollais, D. Caille, P. Meda;
PHYME department, Faculty of Medicine, University of Geneva, Switzerland.

Background and aims: Pregnancy is the only physiological state in which pancreatic β-cell mass and function are naturally enhanced. The increase in plasmatic prolactin (PRL) that occurs during this period is thought to mediate these beneficial effects. It was already reported that insulin secretion is influenced by connexin 36 (Cx36), a membrane protein which forms gap junctions for the β-cell-to-cell exchange of cytosolic molecules. Therefore, the objective of this work is to investigate whether the beneficial effects of PRL on β-cells are mediated by Cx36, and whether this phenomenon can be used as a novel therapeutic approach to treat diabetes.

Materials and methods: PRL effects were evaluated on the mouse β-cell line (MIN6). MIN6 cells were exposed to PRL (500 ng/mL) for 24–48h, and the following parameters were evaluated: Cx36 expression (at the transcriptional and translational levels, as evaluated by RT-PCR and Western Blotting (WB), respectively), insulin release (by RIA) and cell-to-cell coupling (by fluorescent dye microinjection). The *in vitro* situation was correlated to an *in vivo* approach where 18th days pregnant C57BL6 mice and OFA rats (with physiologically increased PRL levels) were compared to non-pregnant animals, with regard to Cx36 localization and expression, both at mRNA and protein levels.

Results: PRL exposure slightly increased Cx36 mRNA expression. However, the protein levels, evaluated by WB, did not change. Strikingly, the number of Cx36-formed gap junctional plaques showed a 3-fold increase ($p < 0.05$) and the cell-to-cell coupling index (that correlates the coupling incidence of Lucifer Yellow with the area of dye spread) was also increased 2.7 times, indicating an increase in Cx36 function after PRL exposure. Consistent with this effect, PRL exposure also increased *in vitro* the number of insulin immunopositive cells and both basal and glucose-dependent insulin release. The increase in Cx36 plaques with PRL was also observed *in vivo*. In pregnant mice and rats, Cx36 increased 2- ($p < 0.05$) and 1.2-fold ($p < 0.01$), respectively, when compared to non-pregnant animals, as evaluated by immunostaining of β-cells in islet sections. Dye coupling of β-cells was also increased 2-fold in islets isolated from pregnant rats ($p < 0.05$).

Conclusion: The results suggest that Cx36 is one of the players mediating the beneficial effects of PRL on β-cell function, due to its influence on insulin secretion. The influence of this protein is being investigated in MIN6 cells and mice null for Cx36.

Cocaine- and amphetamine-regulated transcript (CART) is expressed in human islets and adipose tissue and stimulates insulin secretion and modulates insulin action

N. Wierup¹, E. Banke², H. Bennet¹, M. Fex¹, L. Shcherbina¹, E. Degerman², M. Riva¹;

¹Lund University Diabetes Centre, Malmö, ²Lund University Diabetes Centre, Sweden.

Background and aims: CART is an anorexigenic peptide expressed in brain areas controlling appetite. CART is also expressed in islet cells and CART KO mice exhibit impaired glucose tolerance due to islet dysfunction. Furthermore, CART is upregulated in islets of Type 2 diabetic (T2D) patients and rodent models of T2D and CART regulates islet hormone secretion in rodents. In this study we examined the effect of CART on insulin secretion in human islets and the impact of viral overexpression of CART on insulin secretion in clonal beta cells. Furthermore, CART-expression was examined in human and rodent white adipose tissue (WAT) and the effect of CART on lipolysis and glucose uptake was assessed in primary rat adipocytes.

Materials and methods: Human islets were cultured in 2.8, 8.3 and 16.7 mM glucose for 1 h with or without the addition of 10nM CART 55-102. Human CART was overexpressed in INS-1 (832/13) cells using adenoviral vectors. Insulin secretion was measured using ELISA. CART-expression in human and rodent white adipose tissue (WAT) was assessed by qPCR, and immunocytochemistry. Glycerol release and glucose uptake was examined in primary rat adipocytes.

Results: CART caused a 1.5-fold increase in glucose-stimulated insulin secretion (GSIS) in human islets, but had no effect at basal glucose levels. Viral overexpression of CART in INS-1 832/13 cells provoked enhanced GSIS and GSIS potentiated by cAMP secretagogues (IBMX, forskolin, and GIP). On the other hand, overexpression of CART had no effect when 35mM KCl was present. The effect on GSIS was blocked by H89 (Protein kinase A inhibitor), but not by U73122 (Phospholipase C inhibitor). The effect of CART-overexpression under elevated cAMP-levels was blocked by both H89 and U73122. CART mRNA and protein expression was evident in human, rat and mouse WAT. In primary rat adipocytes, CART potentiated isoprenaline-induced lipolysis and activation of hormone sensitive lipase (HSL). Furthermore, CART potentiated the inhibitory effect of insulin on lipolysis. Without isoprenaline, CART reduced insulin-induced activation of PKB and subsequent glucose uptake.

Conclusion: We conclude that 1) CART stimulates insulin secretion in humans. 2) Overexpression of CART enhance GSIS via protein kinase A and phospholipase C-dependent pathways in INS-1 832/13 cells. 3) CART is a novel constituent of human and rodent WAT. 4) CART modulates the action of insulin and isoprenaline on lipolysis and glucose uptake. Together these data suggests that CART is an important regulator of glucose metabolism in humans.

domain as evidenced by PM-IRRAS and ATR. Using the hGH reporter gene assay in PC12 cells, we found that transiently expressed wild-type VAMP2 but not mutant VAMP2 reconstituted KCl-evoked secretion after knock-down of endogenous VAMP2. Analysis of single fusion events by evanescent wave microscopy in clonal INS1-E beta-cells using VAMP2-phluorin as reporter revealed again a large decrease in stimulated secretion when comparing mutant VAMP2 versus the wild-type.

Conclusion: Collectively our results demonstrate an unprecedented dynamics of the transmembrane domain of VAMP2 never observed previously for any other transmembrane domain. Our mutational analysis suggests that these characteristics may play an important role during insulin exocytosis most likely by disturbing the membrane bilayers and thus promoting their fusion.

Structural dynamics and functions of the transmembrane domain of VAMP2 during exocytosis

B. Hastoy¹, A. Milochau¹, Z. Fezoua¹, B. Desbat¹, R. Oda¹, D. Perrais², P. Scotti¹, J. Lang¹;

¹UMR CNRS 5248, Université de Bordeaux - Institut Européen de Chimie et Biologie, Pessac, ²CNRS UMR 5297, Université de Bordeaux - Institut interdisciplinaire de Neurosciences, Bordeaux, France.

Background and aims: The regulated secretion of insulin by exocytosis from pancreatic beta-cells exerts a major role in glucose homeostasis. A set of highly conserved transmembrane or membrane-attached proteins, the so-called SNARE proteins, forms a complex that plays a central role during exocytosis and has been described as the minimal machinery for membrane fusion. In insulin exocytosis, the SNARE complex is composed of the plasma membrane proteins syntaxin 1 and SNAP25 as well as VAMP2 localized on the vesicle membrane. Whereas structure and function of the cytosolic domains of the SNARE proteins have been studied extensively, the structure and the potential role of their transmembrane domains in exocytosis are still poorly understood. We have therefore performed a structure-function analysis of the transmembrane domain of VAMP2.

Materials and methods: Structural analysis by Polarization Modulation Infrared Reflection Absorption Spectroscopy (PM-IRRAS) and Attenuated Total Reflectance (ATR) infrared spectroscopy was performed on peptides synthesized in-house or full-length recombinant proteins incorporated in lipid model bilayers. Phylogenetic analysis was conducted with Vector NTI. To study the effect of wild-type or mutant VAMP2 in cells, we have established a system based on silencing endogenous expression of VAMP2 (using a specific shRNA), re-expression of wild type or mutant shRNA resistant VAMP2 and a reporter gene assay. Secretion assays were performed in cells co-transfected either with cDNA encoding human-growth hormone or a pH-sensitive GFP attached to VAMP2 as reporter. Mutagenesis was performed by standard protocols. INS-1E or PC12 cells were cultured under standard conditions. Sub-cellular localisation was assessed by confocal immunomicroscopy.

Results: We observed that the transmembrane domain of the SNARE protein VAMP2 is able to switch reversibly from alpha-helices to beta-sheets in lipid bilayers depending on the peptide/lipid ratio (relative protein concentration). These structural changes may disturb the lipid organization during fusion where the local concentration of SNAREs is expected to be augmented. Phylogenetic analysis of VAMP transmembrane domains revealed the conservation of two small amino acids 3 residues apart, thus facing the same side of a helix and suggesting space constraints in this region. Their mutation to larger residues retarded structural conversion of the VAMP2 transmembrane

OP 19 Insulin therapy

Splitting high dose of insulin and injecting it in two sites improves blood glucose control

M. Saryusz-Wolska, E. Szymańska-Garbacz, M. Pawłowski, J. Loba, L. Czupryniak;

Internal Medicine & Diabetology Dept, Medical University of Lodz, Poland.

Background and aims: Increasing number of severely insulin resistant type 2 diabetes patients require extremely high doses of insulin (>2 IU/kg body weight) to control their blood glucose. As the greater the volume of injected insulin preparation, the poorer the absorption of the drug; therefore simple increasing the dose may fail to achieve the expected blood glucose control improvement. As U500 insulin preparation is not available in many countries, we conducted a prospective randomized study to assess the effect of a split-dose insulin on a long term metabolic control of type 2 diabetes.

Materials and methods: 31 type 2 diabetes patients (17 men, mean [±SD] age 54.3±6.1 years, BMI 34.3±5.2 kg/m², diabetes duration 11±4 years) were enrolled into the study. The main inclusion criteria were 1) being treated with multiple insulin dose regimen; 2) the need to inject >60 IU of insulin as a single dose at least once daily, and 3) concomitant poor metabolic control (HbA_{1c} >8%). The subjects with severe insulin resistance secondary to known cause i.e. infections, steroid use etc. were excluded from the study. 16 subjects were randomized into two-sites (TS) group i.e. they split each high (>60 IU) dose of insulin in two equal parts and gave them in two different symmetrical locations (i.e. on both sides of umbilicus or in both thighs etc.), while the other 15 patients (one-site group; OS) maintained their usual (all dose injected in one site) insulin dosage regimen. All other treatment procedures including repeated education and concomitant medications were similar in both groups. Hemoglobin A_{1c}, plasma lipids, hypoglycemia occurrence as well as patients' satisfaction were assessed with VAS scale (range 0-100) every three months for a 12-month period.

Results: Baseline HbA_{1c} was in TS and OS groups 10.3±1.8 and 10.0±1.6%, and mean daily insulin doses were 254±52 and 240±30 IU, respectively. HbA_{1c} value decreased after 3-month treatment period to 9.1±1.3% (p<0.05 vs baseline) in TS group and remained stable in OS group (9.7±1.5%). After 6 months HbA_{1c} values in TS and OS groups were 8.6±1.4 and 9.9±1.8%, and after 12 months - 8.8±1.4 (p<0.05 vs baseline) and 10.4±1.7%, respectively. Fasting plasma triglycerides at baseline improved in TS group (236±49 at baseline and 192±28 mg/dl after 12 months; p<0.01) while they remained stable in OS group (252±43 at baseline and 241±62 mg/dl after 12 months). No major events of hypoglycemia occurred in any subject during the study period. Mean treatment satisfaction score increased from 53±18 to 72±23 (p<0.05) in TS group, and it was unchanged in OS group (55±20 at baseline and 58±27 after 12 months).

Conclusion: In severely insulin resistant and poorly controlled type 2 diabetes subjects, in case of U500 insulin preparation unavailability, splitting high dose of insulin and injecting it in two sites may lead to a significant improvement of metabolic control of the disease and the increase in the patients' treatment satisfaction, without enhancing the risk of hypoglycemia.

110

Metabolic control and hypoglycaemia during the first year of insulin treatment in patients with type 2 diabetes mellitus: a systematic review and meta-analysis of different insulin regimens

A.E. Pontiroli, L. Miele, A. Morabito;

Cattedra di Medicina Interna, Università degli Studi di Milano, Italy.

Intensive insulin treatment in type 2 diabetes mellitus (T2DM) is accompanied by hypoglycemia. Aim was to define metabolic control and hypoglycemia during the first year of treatment as a function of treatment modalities. We considered 72 RCTs (22466 patients, lasting 12-52 weeks, published as full papers during years 1991-2009); we analyzed treatment duration, insulin regimen (basal, biphasic, prandial), glycemic target (aim), insulin doses, HbA_{1c} and its changes, hypoglycemia frequency. Estimates of insulin regimens on final HbA_{1c} (standardized mean difference, SMD) and hypoglycemia (Odds Ratio, OR), were calculated using Der Simonian and Laird models. From 1991 to 2009, aim (r=-.26, p=0.0015), basal (r=-.382, p=0.0001), and final (r=-.498, p=0.001) HbA_{1c} decreased. Final HbA_{1c} correlated with aim (r=.343, p=0.0001), regimen (r=.177, p=0.0293), dose (r=-.183, p=0.0279), that at step-

wise regression analysis, were predictors of final HbA_{1c} (r = .591, F = 24.14). Hypoglycemia frequency correlated with duration (r=.54, p=0.0001), aim (r=-.216, p=0.0213), dose (r=-.337, p=0.0003), that at stepwise regression, were predictors of hypoglycemia (r=.626, F=21.69). At meta-analysis (Table), basal vs biphasic, basal vs prandial, glargine and detemir vs comparators had less effect on HbA_{1c} and on hypoglycemia; within basal and within prandial regimens, new vs old analogs had more effect on HbA_{1c} and less on hypoglycemia; prandial was more effective than biphasic on HbA_{1c} with similar effects on hypoglycemia. In conclusion, hypoglycemia is a predictable effect of intensive insulin treatment in T2DM; regimens and analogs should be tailored to patients.

Table: meta-analysis of different insulin regimens and insulin analogs

Regimen (number of studies)	HbA _{1c} (SMD, 95% C.I.)	Hypoglycemia (OR, 95% C.I.)
Basal vs biphasic (14)	-0.24 (-0.10/-0.39) *	0.63 (0.49/0.81) *
Basal vs prandial (8)	-0.57 (-0.35/-0.78) *	0.37 (0.24/0.58) *
Biphasic vs prandial (9)	-0.65 (-0.25/-1.05) *	1.00 (0.54/1.86)
Within basal (new vs old analogs) (11)	0.06 (-0.07/0.19)	0.71 (0.59-0.85) *
Within prandial (new vs old analogs) (10)	0.21 (0.03/0.40) *	0.81 (0.63/1.03)
Glargine vs comparators (22)	-0.14 (-0.02/-0.15) *	0.74 (0.63/0.86) *
Detemir vs comparators (10)	-0.15 (-0.04/-0.25) *	0.56 (0.40/0.78) *

* statistically significant

Buccal spray insulin: a new tool to treat subjects with impaired glucose tolerance

A. Palermo¹, N. Napoli¹, E. Maddaloni¹, A. Lauria¹, S. Manfrini¹, A. Maurizi¹, M. Altomare², S. Leotta², P. Pozzilli¹;

¹University Campus Bio Medico, Roma, ²Ospedale Sandro Pertini, Roma, Italy.

Background and aims: In patients with impaired glucose tolerance (IGT), upon implementation of life style changes and metformin, a third returns to normal glucose tolerance, a third continues with IGT and the rest goes on to develop clinical type 2 diabetes. An increased risk for cardiovascular disease occurs in the latter two groups even though there is no progression to diabetes. A previous proof of concept study demonstrated that treatment with 12 puffs of buccal spray insulin was followed by a significant 29.6% decrease in mean plasma glucose at two-hours and a 26.8% decrease at three-hours. Primary endpoint of this study is the reduction of HbA_{1c} of 0.3 % at 6 month treatment between experimental vs control group. Secondary endpoints include the evaluation of production of antibodies against insulins (IA), changes in body weight, number of hypoglycaemic events.

Materials and methods: We have designed a randomized controlled trial in patients with IGT comparing buccal spray insulin (12 puffs per meal) plus physical exercise and diet (treatment group A, n=16, HbA_{1c} at entry 6.2% ± 0.4) vs. physical exercise and diet only (control group B, n=16, HbA_{1c} at entry 6.0% ± 0.3). HbA_{1c} levels, metabolic parameters and insulin antibodies were measured at baseline and every 3 months up to 6 months. Primary endpoint is the reduction of HbA_{1c} of 0.3% at 6 month treatment between the experimental and the control group. Secondary endpoints include the evaluation of antibodies against insulin (IA), changes in body weight and number of hypoglycaemic events.

Results: Subjects treated with buccal spray insulin achieved a significant reduction of HbA_{1c} compared to the control group (Δ HbA_{1c} 0' - 6 months -0.3% vs +0.09% p= 0.002). There was no significant difference in body weight and no hypoglycaemic or other adverse events were observed during the study period in both groups. No generation of IA was observed in subjects with IGT treated with buccal spray insulin.

Conclusion: These preliminary results indicate that buccal spray insulin is an effective treatment compared to diet + physical exercise in patients with IGT in reducing HbA_{1c} without adverse effects. A larger trial is required to demonstrate the long term effects of this therapy.

112

Insulin degludec does not compromise efficacy or safety when given in a flexible once-daily dosing regimen compared to insulin glargine once daily at the same time each day in type 2 diabetesS.L. Atkin¹, S. C. Bain², S. Gough³, M.V. Shestakova⁴, I. Raz^{5,6}, L. Blonde⁷, L. Meneghini⁸, K. Begtrup⁹, T. Johansen⁹, K.I. Birkeland^{10,11}¹Michael White Diabetes Centre, Hull York Medical School, Hull, ²Abertawe Bro Morgannwg University Health Board, Singleton Hospital, Swansea,³Oxford Centre for Diabetes, Endocrinology and Metabolism, UK,⁴Endocrinology Research Center, Moscow, Russian Federation, ⁵Hebrew University of Jerusalem, ⁶Hadassah University Hospital, Jerusalem, Israel,⁷Ochsner Diabetes Research Unit, Ochsner Medical Center, New Orleans,⁸Miller School of Medicine, University of Miami, USA, ⁹Novo Nordisk A/S, Søborg, Denmark, ¹⁰Faculty of Medicine, University of Oslo, ¹¹Oslo University Hospital, Norway.

Background and aims: Insulin degludec (IDeg) is a new-generation, ultra-long-acting basal insulin that forms soluble multi-hexamers upon s.c. injection, resulting in a flat and stable glucose-lowering effect. This ultra-long and stable action profile may offer the opportunity to vary the time of administration from day to day thus allowing patients to adapt injection timing to suit their daily activities. The primary objective of this registration trial was to evaluate non-inferiority of IDeg dosed once-daily in a flexible regimen (IDeg Flex) as compared to insulin glargine (IGlar) dosed every day at the same time each day.

Materials and methods: In this 26-week, open-label, treat-to-target trial, people with type 2 diabetes were randomised to IDeg Flex (n=229) and instructed to alternate the timing of insulin administration to morning and evening, in effect creating 8–40 h intervals between doses, or IGlar (n=230) given daily, at the same time each day according to label. Insulin was added to existing OAD therapy (if any) and titrated to FPG <5 mmol/l (90 mg/dl). Mean baseline characteristics such as age (56.2 vs. 56.7 yrs), HbA_{1c} (8.5 vs. 8.4%), FPG (9.0 vs. 9.0 mmol/l), diabetes duration (10.8 vs. 10.8 yrs), and BMI (29.3 vs. 30.0 kg/m²) were comparable between IDeg Flex and IGlar groups, respectively.

Results: For both groups, 88% of participants completed the trial. At 26 weeks, IDeg Flex and IGlar reduced HbA_{1c} by 1.28 and 1.26 %-points, respectively (estimated treatment difference (ETD) IDeg Flex-IGlar: 0.04 %-points [95% CI: -0.12; 0.20]; non-inferiority was confirmed as the upper 95% CI limit was <0.4). Mean FPG at Week 26 was significantly lower for IDeg Flex (5.8 mmol/l) than IGlar (6.2 mmol/l) (ETD: -0.42 mmol/l [-0.82; -0.02] p=0.04). At 26 weeks, mean daily insulin doses were similar between groups. Rates of confirmed hypoglycaemia (PG <3.1 mmol/l (56 mg/dl) or severe) were similar for IDeg Flex and IGlar (3.6 vs. 3.5 episodes/patient-yr; estimated rate ratio (ERR) IDeg Flex/IGlar: 1.03 [0.75; 1.40], p=NS) as were rates of nocturnal confirmed hypoglycaemia (0.6 vs. 0.8 episodes/patient-yr; ERR: 0.77 [0.44; 1.35], p=NS). Rates of adverse events were similar between groups. Severe hypoglycaemia was rare (2 episodes/group).

Conclusion: By using extreme dosing intervals of between 8 and 40 hours, this trial shows that IDeg can be dosed flexibly at any time of day so that injection times can be changed from day to day without compromising glycaemic control or safety compared to the commonly used basal insulin, IGlar, dosed at the same time each day according to label. The larger reduction in FPG with IDeg Flex, observed at similar rates of nocturnal hypoglycaemia to IGlar, may be related to the stable action profile of IDeg.

Clinical Trial Registration Number: NCT01006291

Factors associated with weight gain in type 2 diabetic patients starting on insulin: the CREDIT studyB. Balkau¹, P.D. Home², E. Wang³, M. Marre⁴¹INSERM CESP U1018, Villejuif, France, ²INSERM CESP U1018, Newcastle University, UK, ³sanofi-aventis, Villejuif, ⁴INSERM U695, Paris, France.

Background and aims: Moderate weight gain is usual after starting insulin therapy. The identification of factors associated with weight gain may help to target prevention strategies for weight gain.

Materials and methods: In the 314-center, 12 country, non-interventional CREDIT study, data was available on the change in weight, one year after insulin initiation in 2442 type 2 diabetic patients. Factors associated with a weight gain ≥ 1.6 kg (the median), both at baseline and at follow-up, were compared.

Results: Fifty-two percent of participants began insulin treatment with basal insulin alone, 23% pre-mix insulin, and 25% other insulins; these percentages were 41, 27 and 30% at one year. Patients who gained weight had a higher HbA_{1c} at baseline, a lower BMI, fewer took concomitant glucose-lowering medications, fewer started basal insulin, but more were on a multiple injection regimen (Table). Higher insulin dose at one year was also associated with weight gain, and those who gained weight still had a slightly higher HbA_{1c}. There were differences between the countries in weight gain (P < 0.001), ranging from 34% of people in Croatia gaining > 1.6 kg to 72% in Portugal. Age, sex, smoking status, lipid profile, presence of micro-or macro-vascular disease and prior treatment for diabetes were not associated with weight gain.

Conclusion: In real-life clinical practice, factors others than those traditionally associated with weight gain on starting insulin are significant, and could be used to target those at particular risk. Patient characteristics associated with a one year weight gain ≥ 1.6 kg after insulin initiation:

Measures	Weight gain < 1.6 kg	Weight gain ≥ 1.6 kg	P
At insulin initiation			
HbA _{1c} (%)	9.2 (1.8)	9.8 (2.0)	< 0.001
BMI (kg/m ²)	30.1 (6.3)	28.4 (5.9)	<0.001
Other hypoglycemic treatment for diabetes	72%	66%	<0.001
Basal insulin	54%	47%	
Premix insulin alone	23%	24%	0.003
Other insulin	23%	29%	
Intensified treatment	23%	28%	0.004
At one year			
HbA _{1c} (%)	7.6 (1.4)	7.8 (1.3)	0.004
Daily doses (IU)	31.2 (21.0)	38.9 (25.1)	<0.001

Is there still a place for human pre-mixed insulin in modern type 2 diabetes therapeutics?P. Mader¹, L. Czupryniak², R. Papis³, P. Bijos⁴¹NZOZPD-I, Kłodzko, ²Department of Clinical Diabetology, Łódź, ³Diabetic Clinic, Włocławek, ⁴Bioton S.A., Ożarów Mazowiecki, Poland.

Background: Increasing number of type 2 diabetes patients are treated with analog insulins. In some countries human insulin has been withdrawn by the manufacturers from the market. Analog insulins while effective, are also more expensive than human insulin preparations, and therefore using only insulin analogs contributes to the rising costs of diabetes treatment. We conducted a multicentre nationwide prospective study assessing whether traditional human insulin premixed compound preparations still may play a role in the treatment of type 2 diabetes.

Material and methods: The study group comprised 3372 patients with type 2 diabetes (52% women, mean \pm SD) 63.0 \pm 9.4 years, body weight 83.8 \pm 13.3 kg, BMI 30.1 \pm 5.4 kg/m², diabetes duration 9.3 \pm 7.4 years) in whom treatment with premixed insulin preparations 30/70 (Gensulin M30) was initiated. The treatment efficacy and safety were assessed after 12 weeks. The subjects were treated to achieve fasting plasma glucose <120 mg/dl and 2-hour postprandial plasma glucose <160 mg/dl. Hypoglycemia was diagnosed in cases: Slight hypoglycaemia: an event self controlled by the patient. Mild-severe hypoglycaemia: an event requiring assistance of another person. Severe hypoglycaemia: an event requiring administration intravenous glucose, glucagons, or hospitalization with a measured plasma glucose concentration <55 mg/dl (3 mmol/l).

Results: Treatment with premixed 30/70 insulin significantly improved daily plasma glucose profile in the studied cohort (table), and HbA_{1c} decreased from 8.5 \pm 1.2 at baseline to 7.6 \pm 0.9% (p<0.001). Mean insulin dose at the follow-up visit was 23 \pm 7 IU before breakfast and 17 \pm 7 IU before dinner, in addition 19% of patients required short acting insulin dose (11 \pm 6 IU) before meal. Severe (i.e. requiring help from another person) hypoglycaemia was noted in 31 patients (0.9%), and mild episodes of hypoglycaemia occurred in 657 patients (19.5%). Percentage of the patients declaring good health status increased from 50 at baseline to 62% at the follow-up, very good - from

6 to 12%, and percentage of the patients declaring moderate health status decreased from 35 to 22%, and poor - from 7 to 3% (all changes $p<0.05$). **Conclusion:** Introducing premixed human insulin 30/70 preparation is efficacious and safe in large majority of type 2 diabetes patients as it leads to significant improvement in metabolic control as well as better perception of the patients' own health status.

plasma glucose mg/dl	baseline	follow-up	p
fasting	159±39	127±25	<0.001
post-breakfast	191±47	152±29	<0.001
post-lunch	193±49	156±30	<0.001
post-dinner	188±47	150±29	<0.001

OP 20 Regulation of hepatic glucose production

115

Glucose appearance of large evening meals with low and high glycaemic load in type 1 diabetes

D. Elleri¹, J.M. Allen¹, J. Harris¹, A. Haidar¹, K. Kumareswaran¹, L. Leelarathna¹, M. Nodale¹, M.E. Wilinska¹, J. Weston², C.L. Acerini¹, N. Jackson³, A.M. Umpleby³, M.L. Evans¹, D.B. Dunger¹, R. Hovorka¹; ¹University of Cambridge, ²Addenbrooke's Hospital, Cambridge, ³University of Surrey, Guildford, UK.

Background and aims: Insulin dose adjustment can be challenging for people with type 1 diabetes (T1D) when eating complex meals with large carbohydrate (CHO) content and different glycaemic load (GL). Using novel methodology, we estimated the systemic glucose appearance of two meals with identical CHO content but differing GL in young people with T1D.

Materials and methods: Sixteen subjects with T1D (age 19.5 ± 3.8 yrs, BMI 23.4 ± 1.5 kg/m², HbA_{1c} $8.7\pm1.7\%$, diabetes duration 9.0 ± 6.9 yrs, total daily insulin 0.9 ± 0.2 U/kg/day; mean±SD) were studied on two separate visits at a clinical research facility. On both visits, from 1000 until 1730, variable intravenous (iv) insulin was infused to achieve normoglycaemia. On Visit 1 all subjects fasted until 1800. Then eight subjects consumed a low GL pasta meal (CHO:protein:fat 120:35:30g; GL 54) and another eight subjects consumed a high GL potato meal (CHO:protein:fat 120:20:9g; GL 105), each enriched with [U-¹³C]glucose. Until 0200 next day iv insulin was infused to mimic prandial bolus of rapid-acting insulin (14 ± 2 U vs. 15 ± 4 U; low vs. high GL; $p=0.370$) and basal insulin delivery (0.9 ± 0.3 U/h vs. 0.9 ± 0.2 U/h; $p=0.850$). On Visit 2 identical iv insulin was given as on Visit 1 but, instead of the meal, variable iv 20% dextrose enriched with [U-¹³C] glucose was infused to reproduce the plasma glucose profile observed on Visit 1. Iv infusion of [6,6-²H₂] glucose and [U-¹³C;1,2,3,4,5,6,6-²H₇] glucose were given on both visits in a fashion to mimic endogenous glucose production (EGP) and glucose appearance of total CHO content from the meal (Ra_{meal}), respectively. Plasma glucose enrichment with the 3 tracers was measured by gas chromatography mass spectrometry. Total glucose appearance (Ra_{total}) on Visit 1 was estimated by double tracer approach. Ra_{meal} on Visit 1 was calculated as "Ra_{total} - EGP", where EGP was obtained from Visit 2 and estimated by the double tracer approach.

Results: Glucose appearance from low GL meal was less pronounced, presented a sustained plateau, and extended over the duration of the study, see Figure; 25% of the glucose from low GL meal appeared 88 ± 21 min after meal consumption, 50% at 175 ± 39 min, and 75% at 270 ± 54 min. Glucose from high GL meal appeared significantly faster with 25, 50 and 75% of the total appearance at 56 ± 12 ($p=0.009$), 100 ± 25 ($p=0.005$) and 153 ± 39 min ($p=0.003$) respectively. Bioavailability of total CHO did not differ between low and high GL meals (102 ± 14 vs $87\pm12\%$, $p=0.088$).

Conclusion: High GL large meal accelerates appearance of meal-derived glucose in the systemic circulation, whereas low GL meal results in reduced but sustained appearance. This suggests need for tailored prandial insulin delivery matching both CHO content and glycaemic load of the evening meal in T1D.

Figure. Rate of appearance of total carbohydrate content from a high glycaemic load meal (black line; 120g CHO, 105 GL) and a low glycaemic load meal (grey line; 120g CHO, 54 GL) [mean(SD)]

Gluconeogenic glucose output could involve caveolin-1 dependent vesicles

J. Chilloux, M. Soty, G. Mithieux, A. Gautier-Stein;
Inserm 855, Lyon, France.

Background and aims: Endogenous glucose production is a crucial function maintaining glucose homeostasis. This function is composed of glycogenolysis and gluconeogenesis. According to the dogma, glucose is released via the glucose transporter Glut2. However, in Glut2 $-/-$ mice, a mechanism dependent on membrane traffic and able to compensate the absence of Glut2 has been evidenced. The aim of our study was to demonstrate the existence of a Glut2 alternative glucose output in wild type (WT) mice and characterize the vesicular pathway. Our hypothesis was that caveolin-1 dependent vesicles could play a role in glucose release in extracellular medium.

Materials and methods: Primary hepatocytes were isolated from fed and fasted C57/Bl6 mice (5 weeks males). Hepatocytes were incubated during 1h in DMEM 0g/L glucose and supplemented with lactate in the case of hepatocytes from fasted mice. Dynasore, a dynamin inhibitor was used at 80 μ mol/l and Cytochalasin B, a Glut2 inhibitor was used at 50 μ mol/l. Glucose release in the supernatant and intracellular glucose were measured by enzymatic assays. The same experiment was performed with hepatocytes from caveolin-1 $-/-$ mice (Cav1 $-/-$).

Results: We used hepatocytes from fed mice as a model of glycogenolysis and hepatocytes from fasted mice as a model of gluconeogenesis. To study the involvement of vesicles in glucose release we targeted dynamins which are known to be necessary to form the majority of vesicles. Glucose release from hepatocytes of fed mice was not inhibited by dynasore (48.2 \pm 5.6 vs 43.6 \pm 7.9 μ mol/l/million of cells/h). Glucose release from hepatocytes of fasted mice was decreased by 60% (22.9 \pm 3.1 vs 9.6 \pm 2.4 μ mol/l/million of cells/h, $p < 0.05$). In parallel, dynasore induced an accumulation of glucose within cells (2.3 \pm 0.2 vs 4.1 \pm 1.0 μ mol/l/million of cells, $p < 0.05$). These results suggest that a vesicular pathway might be implicated in gluconeogenic glucose output. Furthermore, glucose release from hepatocytes of fasted mice was nearly cancelled (3.1 \pm 0.7 μ mol/l/million of cells/h, $p < 0.05$) by a simultaneous treatment with dynasore and cytochalasin B, supporting the hypothesis of a complementary action of only two pathways: Glut2 and a vesicular output. Then, we used Cav1 $-/-$ mice to test the hypothesis that the vesicular pathway of glucose output could depend on caveolin-1. Glucose release from hepatocytes of fed Cav1 $-/-$ mice was equivalent to that of WT (37.4 \pm 8.1 μ mol/l/million of cells/h) and was not affected by dynasore treatment (40.4 \pm 7.1 μ mol/l/million of cells/h). Glucose release from hepatocytes of fasted Cav1 $-/-$ mice was 60% lower than that of WT mice (10 \pm 1.9 μ mol/l/million of cells/h, $p < 0.05$) suggesting that caveolin-1 was involved in glucose release. Moreover, dynasore had no effect on glucose release from hepatocytes of Cav1 $-/-$ fasted mice (7.6 \pm 1.6 μ mol/l/million of cells/h). In parallel to the lower glucose release in Cav1 $-/-$ hepatocytes, we measured an accumulation of intracellular glucose (4.0 \pm 0.6 μ mol/l/million of cells, $p < 0.05$), which was not further increased by dynasore treatment (4.9 \pm 0.8 μ mol/l/million of cells). These results suggest that gluconeogenic glucose output might be dependent on caveolin-1 and that this glucose output cannot be compensated by the glucose transporter Glut2. **Conclusion:** In conclusion, these results strongly suggest that a vesicular pathway is involved in the release of gluconeogenic glucose. Moreover, this Glut2 alternative pathway of glucose output would be dependent on caveolin-1, and would not be compensated by the presence of Glut2.

Meal-induced insulin sensitisation depends on hepatic parasympathetic nerves and requires the presence of aminoacids and glucose in the gut

R.A. Afonso¹, I. Lamarão¹, A.B. Fernandes¹, J.M. Gaspar¹, W. Lautz², M. Macedo^{1,3};

¹CEDOC, Faculdade Ciências Médicas, Lisboa, Portugal, ²Pharmacology & Therapeutics, Faculty of Medicine, Winnipeg, Canada, ³Associação Protectora dos Diabéticos de Portugal Research Center, Lisboa, Portugal.

Background and aims: Importance of analyzing postprandial glucose homeostasis has been highlighted by several studies suggesting that loss of postprandial glycemic control can precede deterioration of fasting glycemia in the course towards diabetes. Our group had previously reported that peripheral hypoglycaemic action of insulin increases from the fasted to the fed state and that this meal-induced insulin sensitization (MIS) mechanism is not triggered by glucose alone. We tested the hypotheses that the intestine plays an

essential role in activating MIS which is triggered by simultaneous presence of both carbohydrates and protein-based nutrients.

Materials and methods: 24 h-fasted Sprague-Dawley rats were used. Surgery involved gastric or enteric cannulation, and enteric band placement, to avoid intestine-stomach reflux. Three series of experiments were performed. 1) Insulin sensitivity (IS) was assessed by a rapid euglycaemic clamp both in fasting state (24 h-fast) and 120 min after administration of the liquid mixed-meal (carbohydrates, proteins and lipids, 10 ml/kg), either into the stomach (IG) or into the duodenum (IE). After hepatic parasympathetic inhibition (surgical ablation or atropine), IS was assessed. 2) Hepatic parasympathetic denervation was done in the fasted state; IS was assessed in fasted+denervated state and after the mixed-meal (IE). 3) The effect of meal composition on IS was studied by determining IS in the fasted state and after IE administration of the following liquid meals: (i) glucose + aminoacids + lipids (GAL); (ii) glucose + aminoacids (GA); (iii) aminoacids + lipids (AL); (iv) glucose + lipids (GL); (v) aminoacids (A).

Results: 1) IG mixed-meal did not produce MIS, unlike IE mixed-meal, which induced 77.4 \pm 11.2 % increase in IS (from 117.8 \pm 12.6 to 200.9 \pm 11.7 mg glucose/kg bw; $p < 0.001$ (fasting vs post-meal). Subsequent hepatic parasympathetic ablation reduced IS obtained after IE meal (denervation, 85.1 \pm 6.1 mg glucose/kg bw; atropine, 99.9 \pm 7.1 mg glucose/kg bw; $p < 0.001$ vs post-meal), but did not affect post-IG-meal IS. 2) When parasympathetic denervation was performed in the fasted state, it prevented IS increment after IE meal (3.8 \pm 13.3 %, ns). 3) The GAL meal induced significant insulin sensitization (MIS): IS increased from 97.9 \pm 6.2 mg/kg (fasted state) to 225.4 \pm 18.3 mg/kg ($p < 0.001$), which corresponds to 133.7 \pm 23.5 % potentiation of insulin action. The GA meal also produced MIS (IS increased from 115.3 \pm 15.3 to 241.6 \pm 35.2 mg/kg, after GA; $p < 0.05$), inducing 109.6 \pm 9.1 % potentiation of IS. None of the other meals tested produced a MIS close to the GAL or GA meals. Immediately before the post-meal IS assessment, insulinemias were similar in all groups. Furthermore, only GAL and GA meals induced sustained postprandial IS (higher than the fasting IS), as determined by a second post-meal IS test (data not shown).

Conclusion: Our data suggests that the MIS mechanism is triggered at the intestine and requires activation of the hepatic parasympathetic nerves. Glucose and aminoacids are required in the intestine in order to fully trigger the MIS mechanism.

Altered glucose excursions during a meal tolerance test in an impaired hepatic vagal model are mainly due to peripheral insulin resistance

I.S. Lima¹, A.B. Fernandes¹, J.G. Jones², B. Manadas², V. Mendes², M.P. Macedo^{1,3};

¹CEDOC - Faculty of Medical Sciences New University of Lisbon,

²CNC - Centre for Neurosciences and Cell Biology University of Coimbra,

³Portuguese Diabetes Association - Research Centre, Lisbon, Portugal.

Background and aims: In the last decades the hepatic parasympathetic system has emerged as a physiological modulator of insulin action having its main impact during the postprandial period. In the present work we investigated the hypothesis that the hepatic parasympathetic system is a determinant part in maintaining glucose and/or lipid homeostasis upon the ingestion of a meal. Moreover, the altered glucose excursions, as a consequence of the hepatic vagal impairment, are due to peripheral insulin resistance rather than to changes in insulin secretion/clearance or endogenous glucose production.

Materials and methods: Male Wistar rats (12 weeks old) were divided into two experimental groups: sham and hepatic parasympathetic denervated (HPNden) animals. A MTT was performed. The MTT consists in the intra enteric administration of a complete mixed meal: 38.2 mg/mL lipids; 84 mg/mL aminoacids; 173mg/mL glucose. To evaluate endogenous glucose production (EGP) a tracer - [U-13C] Glucose, representing 0.5% of the EGP - was administered as a continuous perfusion throughout the experiment. To assess glucose appearance rate, glucose clearance and glucose disposal the mixed-meal was enriched with a 5% [6,6-H2] Glucose as a tracer. Samples were evaluated by LC-MS (Liquid Chromatography - Mass Spectrometry). Plasma samples were collected at different times (0, 2, 5, 10, 20, 30, 40, 50, 60, 90 and 120 minutes) of the study. These samples were used to measure glycaemia, plasma insulin, c-peptide and free fatty acids. Insulin secretion was determined based on plasma c-peptide; insulin clearance was assessed as the AUC of [c-peptide]/[insulin]. Finally, insulin sensitivity was determined by a hyperinsulinemic euglycemic clamp.

Results: The results showed an increase in glucose excursions from the sham animals to the HPNden animals (AUC: 15650 ± 621.9 n=8 vs. 17980 ± 876.2 ; n=8; $P < 0.05$).

Insulin and c-peptide levels obtained for both groups were indistinguishable during the MTT, excluding insulin secretion as a contributor for the differences observed in the glycemic profiles. Likewise, insulin clearance and endogenous glucose production did not differ between both groups. Insulin sensitivity was evaluated before and after administration of the meal. The HPNden animals showed decreased postprandial insulin sensitivity, when compared with the control (113.4 ± 26.48 mg glucose/kg, n=4 vs. 203.4 ± 31.14 mg glucose/kg, n=4; $P < 0.05$).

Conclusion: The results indicate that in the absence of a fully functional hepatic parasympathetic system whole-body glucose homeostasis cannot be maintained. This leads to increased glucose excursions as a result of increased peripheral insulin resistance. Furthermore, while evaluating the pathways through which this system influences glucose homeostasis it was observed that pancreatic insulin secretion, insulin clearance, endogenous glucose production and plasma free fatty acids were not affected by hepatic vagal impairment throughout the MTT. These results allow us to conclude that the hepatic parasympathetic system is a critical component of postprandial glucose homeostasis.

CITED2 links hormonal signals to PGC-1 α acetylation for regulating fasting gluconeogenesis

M. Sakai¹, M. Matsumoto¹, M. Kasuga¹

¹Diabetes Research Center, National Center for Global Health and Medicine, Tokyo, Japan.

Background and aims: In mammals deprived of food, induction of hepatic gluconeogenesis is important to ensure energy homeostasis in response to the energy demand. Such induction is dysregulated, however, in type 2 diabetes, resulting in the development of fasting hyperglycemia. Hormonal and nutrient regulation of metabolic adaptation during fasting is mediated predominantly by the transcriptional coactivator PGC-1 α in concert with various other transcriptional regulators including the transcription factors FoxO1, HNF-4 α , GR and PPAR α as well as the histone acetyltransferase CBP/p300. Although CITED2 (CBP/p300-interacting transactivator with glutamic acid- and aspartic acid-rich COOH-terminal domain 2) interacts with many of these molecules, the role of this protein in regulation of hepatic gluconeogenesis has been unknown. The aim of this study was to elucidate the role of CITED2 in hepatic gluconeogenesis.

Materials and methods: To investigate the role of CITED2 in gluconeogenesis, we conducted gain-of- and loss-of-function experiments using adenoviruses encoding CITED2 and CITED2 shRNA, respectively.

Results: Depletion of CITED2 in primary mouse hepatocytes by infection with an adenoviral vector encoding CITED2 shRNA attenuated the expression of the gluconeogenic genes G6pc and Pck1 as well as glucose production induced by cAMP. Conversely, forced expression of CITED2 augmented these effects of cAMP on gluconeogenic gene expression and glucose production. Knockdown of CITED2 in the liver of obese diabetic db/db mice significantly reduced both gluconeogenic gene expression in the liver during fasting as well as blood glucose concentrations under fed and fasting conditions. In contrast, overexpression of CITED2 in the liver of lean mice increased hepatic G6pc and Pck1 expression as well as blood glucose levels during fasting. We also examined the effect of CITED2 on gluconeogenic gene expression induced by PGC-1 α . Overexpression of CITED2 enhanced, but its deletion attenuated PGC-1 α -induced gluconeogenic gene expression, suggesting that CITED2 upregulates PGC-1 α activity. Next we investigated the mechanism by which CITED2 augments PGC-1 α activity. We found that CITED2 inhibited the acetylation of PGC-1 α by blocking its interaction with GCN5, a key acetyltransferase for PGC-1 α . The consequent reduction in the level of PGC-1 α acetylation resulted in an increase in its transcriptional coactivation activity and up-regulation of the expression of gluconeogenic genes. In addition, we found that the interaction of CITED2 with GCN5 was disrupted by insulin in a manner dependent on phosphoinositide 3-kinase (PI3K) signaling, whereas fasting glucagon leads to CITED2 induction.

Conclusion: CITED2 functions as a transducer of glucagon and insulin signaling in the regulation of PGC-1 α activity associated with the transcriptional control of gluconeogenesis, and that this function is mediated through modulation of GCN5-dependent acetylation of PGC-1 α .

Inhibitors of endoplasmic reticulum stress prevent hepatic insulin resistance induced by prolonged lipid infusion

S. Pereira, S. Yoo, L. Lam, I. Fantus, A. Giacca;

University of Toronto, Canada.

Background and aims: To understand the mechanisms of fat-induced insulin resistance, we utilized the 48h Intralipid plus heparin (IH) infusion model, which leads to prolonged plasma elevation of free fatty acids. In this model, the anti-inflammatory sodium salicylate and the antioxidant N-acetyl-L-cysteine (NAC) prevented lipid-induced peripheral insulin resistance, but, in contrast to the 7h IH infusion model, did not prevent hepatic insulin resistance. Here we investigated whether the chemical chaperone 4-phenylbutyric acid (PBA), which alleviates endoplasmic reticulum stress, prevented hepatic and peripheral insulin resistance after prolonged (48h) lipid infusion.

Materials and methods: Cannulated Wistar rats (250-300g, n=5-9/group) were infused i.v. for 48h with Saline (5.5 μ l/min), IH (20% Intralipid + 20 U/ml heparin, 5.5 μ l/min), IH with PBA (2.08 μ mol kg⁻¹ min⁻¹), or PBA alone. After an overnight fast, a hyperinsulinemic (5 mU kg⁻¹ min⁻¹) euglycemic clamp was performed with tritiated glucose methodology to assess hepatic and peripheral insulin sensitivity.

Results: Insulin-mediated suppression of endogenous glucose production (EGP), expressed as percentage of basal EGP, was impaired by IH (10 \pm 9% in IH vs. 57 \pm 11% in Saline and 55 \pm 9% in PBA alone, $p < 0.05$) and at least partially restored by PBA co-infusion (40 \pm 6%). Insulin-stimulated glucose utilization was blunted by IH, but this impairment was completely prevented by PBA (Saline, 29.3 \pm 0.6 mg kg⁻¹ min⁻¹; IH, 24.3 \pm 1.0 mg kg⁻¹ min⁻¹; IH+PBA, 29.9 \pm 1.0 mg kg⁻¹ min⁻¹; PBA alone, 31.6 \pm 1.3 mg kg⁻¹ min⁻¹; $p < 0.05$ for IH vs. Saline, IH+PBA, and PBA alone).

Conclusion: In contrast to our previous studies involving sodium salicylate and NAC, the results herein indicate that PBA is effective at preventing both hepatic and peripheral insulin resistance in our model of prolonged lipid infusion. Since this chaperone is safe for human use, it may represent a new and upcoming therapy for fat-induced insulin resistance at the level of the liver and periphery.

Osteoprotegerin is increased in patients with type 1 diabetes and vascular complications and predicts cardiovascular mortality

A. Soro-Paavonen¹, D. Gordin¹, C. Forsblom¹, M. Rosengård-Bärlund¹, J. Waden¹, L. Thorn¹, N. Sandholm¹, M. Bjerre², A. Flyvbjerg², M. Thomas³, P.-H. Groop¹;

¹Department of Medicine, Helsinki University Central Hospital, Folkhälsan Institute of Genetics, Helsinki University, Finland, ²Aarhus University and Department of Endocrinology and Internal Medicine, The Medical Research Laboratories, Denmark, ³Baker IDI Heart and Diabetes Institute, Diabetic Complications, Melbourne, Australia.

Background and aims: The bone-related peptide osteoprotegerin (OPG) is produced by vascular cells and is involved in the process of vascular calcification. We investigated the effect of serum OPG concentration on the prediction of cardiovascular disease (CVD) events, deterioration of diabetic nephropathy (DN) and all-cause mortality in patients with type 1 diabetes (T1D). We further examined whether OPG is associated with other vascular complications such as retinopathy and arterial stiffness.

Materials and methods: Serum OPG was measured by a Time-Resolved Immunofluorometric Assay (TRIFMA) in 2,116 patients with T1D and in 212 healthy control subjects participating in the Finnish Diabetic Nephropathy (FinnDiane) study. Pulse-wave analysis with augmentation Index (AIx) measurement was performed in 180 patients with T1D and 112 controls. Data on progression of renal disease, incidence of CVD and cardiovascular as well as all-cause mortality were verified from medical files and patients were followed for 5.4 ± 2.0 (mean ± SD) years.

Results: Patients in the highest (fourth) OPG quartile were at a significantly higher risk for all-cause mortality than patients with low levels (first quartile) (covariate-adjusted hazard ratio [HR] 1.01 [1.01-1.01]; $P < 0.001$). High OPG also predicted an incident CVD event independently of clinical CVD risk factors [HR 1.02 (1.00-1.02); $P = 0.007$]. In addition, OPG predicted progression to ESRD during follow-up [1.02 (1.00-1.03); $P = 0.03$ with adjustment with age, gender, SBP, total cholesterol, HbA_{1c}, smoking, and previous CVD]. Serum OPG was significantly increased in the patients with diabetic nephropathy (in patients with macroalbuminuria; $2,073 \pm 78$ ng/l or ESRD; $2,700 \pm 144$ ng/l) than in patients without DN ($1,607 \pm 40$ ng/l) or healthy controls ($1,626 \pm 55$ ng/l). Serum osteoprotegerin was also significantly higher in patients with T1D who had diagnosis of CVD (coronary heart disease, stroke or amputation) than those without ($2,449 \pm 140$ ng/l vs $1,683 \pm 35$ ng/l, $P < 0.001$). The patients with laser-treated retinopathy had significantly increased OPG levels. OPG was positively associated with arterial stiffness as measured by AIx both in patients with T1D ($r = 0.27$, $P < 0.001$) as well as in controls ($r = 0.23$, $P < 0.05$).

Conclusion: In a large contemporary cohort of individuals with T1D, OPG was not only predictive of CVD events and progression of kidney disease but also of all-cause mortality. OPG levels were strongly associated with diabetic complications such as retinopathy and arterial stiffening.

Serum peroxiredoxin-4 and mortality in patients with type 2 diabetes (ZODIAC-28)

A. Alkhalaf^{1,2}, E.G. Gerrits³, G.W.D. Landman¹, K.J.J. van Hateren^{1,4}, K.H. Groenier⁵, J. Struck⁶, J. Schulte⁶, R.O.B. Gans³, S.J.L. Bakker³, N. Kleefstra^{1,4}, H.J.G. Bilo^{1,2};

¹Diabetes Centre, Isala Clinics, Zwolle, ²Internal Medicine, Isala Clinics, Zwolle, ³Internal Medicine, University Medical Center Groningen, ⁴Langerhans Medical Research Group, Zwolle, ⁵Department of General Practice, University Medical Center Groningen, Netherlands, ⁶Research Department, Thermo Fischer Scientific, BRAHMS Biomarkers, Henningsdorf, Germany.

Background and aims: Hyperglycaemia induces oxidative stress and endothelial damage leading to micro- and macrovascular complications in patients with diabetes. Recently, circulating levels of Peroxiredoxin 4 (Prx4) have been proposed as a novel biomarker of oxidative stress. We prospectively

investigated whether circulating levels of Prx4 predict mortality in patients with type 2 diabetes.

Materials and methods: This study is part of the ZODIAC study, a prospective observational study in primary care patients with type 2 diabetes from the Netherlands and incorporates two cohorts: one started in 1998 and the other in 2001. Prx4 was measured with an immunoluminometric sandwich assay in 2010. A Cox proportional hazard model was used to investigate the relationship of Prx4 with cardiovascular and all-cause mortality, before and after adjustment for potential confounders. Three models were chosen: model 1 included Prx4 without confounders, model 2 included age and gender as confounders, and model 3 included BMI, serum creatinine, smoking, diabetes duration, systolic blood pressure, cholesterol-HDL ratio, history of macrovascular complications, and albuminuria as additional potential confounders. Prx4 and serum creatinine were logarithmically transformed because of skewed distribution.

Results: Prx4 was assessed in baseline serum samples of 1067 patients [age 67.2 ± 11.4 years, 485 (45.5%) males. Median [interquartile range] Prx4 was 0.86 [0.61 - 1.34] U/L. Further baseline data include: median HbA_{1c} 53 [45 - 66] mmol/mol, diabetes duration 4 [2 - 9] years, estimated creatinine clearance 72 [57 - 91] ml/min and urinary albumin creatinine ratio 1.97 [0.92 - 7.01] mg/mmol. After a median follow-up period of 9.8 years, 344 (32.3%) patients had died, of which 148 deaths (43.0%) were attributable to cardiovascular causes. Increased levels of Prx4 were associated with high rates of cardiovascular and all-cause mortality [hazards ratios (HRs) (95% confidence interval) were 1.83 (1.46 - 2.30) and 1.80 (1.53 - 2.12), respectively]. Adjusted HRs (95%CI) for cardiovascular and all-cause mortality were 1.64 (95%CI 1.27 - 2.13) and 1.59 (95%CI 1.31 - 1.91) in model 2 and 1.52 (95%CI 1.13 - 2.04) and 1.51 (95%CI 1.24 - 1.82) in model 3, respectively. The figure shows adjusted survival curves according to Prx4 levels.

Conclusion: In this prospective study we found that increased levels of Prx4 are independently associated with increased risk of cardiovascular and all-cause mortality in patients with type 2 diabetes.

123

Circulating adrenomedullin levels are predictive of mortality and hospitalisation in heart failure patients with and without diabetes mellitus

P. Holmager¹, M. Schou², M. Egstrup³, I. Gustafsson⁴, J.P. Goetze⁵, F. Gustafsson⁶, P. Hildebrandt³, J. Faber¹, C. Kistorp¹;

¹Endocrinology, Herlev University Hospital, Copenhagen, ²Cardiology, Hillerød Hospital, ³Endocrinology and Cardiology, Frederiksberg University Hospital, ⁴Cardiology, Gentofte University Hospital, ⁵Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital, ⁶Cardiology, Rigshospitalet, Copenhagen University Hospital, Denmark.

Background and aims: Adrenomedullin is a vasoactive peptide, which is a potential biomarker of vascular injury in patients with cardiovascular disease and with diabetes mellitus. The aim of the present study was to investigate whether mid-regional pro adrenomedullin (MR-proADM) is predictive of outcome in patients with and without diabetes mellitus from an outpatient heart failure clinic.

Materials and methods: Prospective observational study of 366 unselected patients included at the baseline visit (31 % female, mean age 70 years), 62 % had ischemic heart disease, 19 % had a confirmed diagnosis of diabetes mellitus and were treated with anti-diabetic therapy. Patients were followed for a median of 55 months with respect to mortality and a combined endpoint of mortality or hospitalisation. A total of 189 of the patients died and 232 were hospitalized.

Results: At baseline mean (SD) MR-proADM levels were elevated in patients with diabetes and nephropathy (urinary albumin/creatinin ratio ≥ 30 mg/g) as compared with diabetic patients and patients without diabetes (1.12(0.86) vs. 0.84(0.54) vs. 0.75(0.43) nmol/l, $P=0.014$). Plasma MR-proADM was associated with increasing age ($r=0.28$, $P<0.001$), s-creatinine ($r=0.36$, $P<0.001$), NYHA-class ($r=0.14$, $P=0.007$) and with NT-proBNP ($r=0.32$, $P<0.001$). However, no relation with metabolic parameters such as HbA1c, BMI, HDL-cholesterol or triglycerides was observed. Using Cox proportional hazard analysis increasing levels of logMR-proADM was predictive of death Hazard ratio (HR) being 1.5 (95 % CI: 1.2–1.8, $P<0.001$) and of death or hospitalization HR 1.3 (1.1–1.4, $P=0.06$) per 1 SD increase adjusted for age and sex. The prognostic ability of MR-proADM with respect to overall mortality was not significantly attenuated after adjustment for s-creatinine, presence of diabetes, ischemic heart disease, NYHA functional class, or NT-proBNP HR 1.3 (1.1–1.5, $P=0.004$) however, with respect to the combined endpoint of death or hospitalization HR 1.1 (0.9–1.4) remained no longer significant. In patients with diabetes MR-proADM levels was equally predictive of death HR 1.5 (1.1–2.1, $P<0.001$) adjusted for age and sex, as compared with the total cohort. **Conclusion:** MR-proADM levels are elevated among cardiac patients with diabetes and nephropathy. This biomarker of vasculopathy predicts mortality independently of presence of diabetes mellitus, ischemic heart disease and kidney function and could be a novel biomarker of outcome with incremental prognostic information to traditional clinical risk factors and NT-proBNP in cardiovascular disease and in patients with diabetes mellitus.

Serum resistin is associated with coronary artery disease and predicts major cardiovascular events in type 2 diabetes patients

C. Menzaghi¹, S. Bacci², L. Salvemini¹, C. Powers³, G. Fini¹, S. Rizza⁴, E. Goheen³, C. De Bonis¹, A. Kanagaki³, D. Mangiacotti¹, M. Federici⁴, A. Doria^{3,5}, V. Trischitta¹

¹Research Unit of Diabetes and Endocrine Disease, IRCCS, San Giovanni Rotondo, ²Unit of Endocrinology, IRCCS, San Giovanni Rotondo, Italy,

³Research Division, Joslin Diabetes Center, Boston, USA, ⁴Department of Internal Medicine, University of Rome Tor Vergata, Rome, Italy,

⁵Department of Medicine, Harvard Medical School, Boston, USA.

Background and aims: High serum resistin has been associated with increased risk of cardiovascular events in the general population. At variance, only two small studies with conflicting results have been reported in patients with type 2 diabetes (T2D), of Asian ancestry. The aim of this study was to deeply investigate the role of serum resistin levels on cardiovascular disease in large samples of patients with T2D of European ancestry.

Material and methods: To accomplish this aim the following studies were carried out. (1) A case-control study for coronary artery disease (CAD) (from Gargano, Italy; Gargano Heart Study: GHS-cross sectional design) in 360 with angiographically diagnosed CAD - CAD positive - and 416 with no evidence of CAD - CAD negative - patients with T2D; (2) a case-control study for CAD (from Boston, MA; Joslin Heart Study - JHS) in 418 CAD positive and 433 CAD negative patients with T2D; (3) a prospective study for major cardiovascular events including cardiovascular death, non fatal myocardial infarction - MI - and non fatal stroke (from Gargano; Gargano Heart Study: GHS-prospective design) in 340 patients with T2D and CAD, so far followed up for 1-91 months. Serum resistin levels were measured by ELISA in all 1,977 participants.

Results: Compared to CAD negative, serum resistin concentrations were higher in CAD positive patients in both GHS-cross sectional (9.33 ± 5.03 vs. 10.72 ± 6.68 ng/ml, age, sex and smoking habit adjusted $p=0.02$) and JHS (6.46 ± 4.25 vs. 8.64 ± 5.99 ng/ml, adjusted $p<0.001$) patients. Among the participants to GHS-prospective, 32 cardiovascular deaths, 3 non fatal MIs and 8 non fatal strokes occurred during follow-up (annual incidence rate 0.04). Patients who had resistin levels above the median of the entire cohort (> 8.9 ng/ml) had a significantly increased risk of major cardiovascular events (adjusted HR=3.25; 95% CI: 1.58–6.68 $p=0.001$). These associations were unaffected by further adjustment for BMI, duration of diabetes and current therapy.

Conclusion: Elevated serum resistin concentration is a strong and independent risk factor for cardiovascular disease in patients with T2D. This points to resistin as a novel biomarker which might be useful in the clinical set in improving predictability of cardiovascular disease in patients with T2D.

125

Complement activation and prognosis in patients with myocardial infarction and type 2 diabetes: a report from the DIGAMI 2 trial

L.G. Mellbin¹, L. Rydén¹, M. Bjerre², T.K. Hansen²

¹Department of Cardiology, Karolinska Institutet, Stockholm, Sweden,

²Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Denmark.

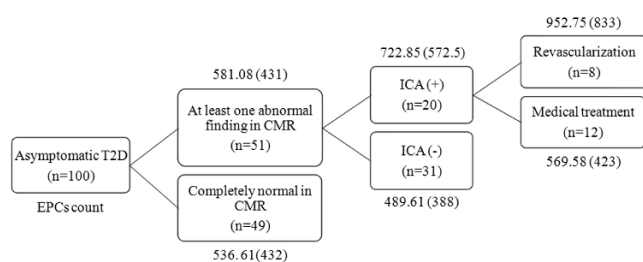

Background and aims: Activation of the complement system may enhance the negative impact of ischemia followed by reperfusion, but information on the effect of different levels of this system is conflicting. We characterized the complement end-product sC5b9 and the mannan-binding lectin associated serine protease 2 (MASP-2) in patients with type 2 diabetes (DM) and myocardial infarction (MI) with the aim to explore their potential as prognostic markers.

Materials and methods: Plasma-sC5b9 and MASP-2 was, at the time for hospital admission, determined in 391 patients with MI and DM (median age 70 years; male 67%). Adjudicated endpoints were cardiovascular events (CVE= cardiovascular mortality and nonfatal MI or stroke). **Results:** Median sC5b9 was 134 ng/mL (interquartile range (IQR) 101 - 190 ng/mL) and median MASP-2 333 μ g/L (IQR 235 - 463 μ g/L). There was no significant correlation between sC5b9 and MASP-2. Women had significantly higher sC5b9 than men (median 152 vs 130 ng/mL; $p=0.02$). Both sC5b9 and MASP-2 correlated to age and creatinine clearance. Furthermore MASP-2 correlated with BMI. During 2.3 years CVE occurred in 138 patients (35%). Both sC5b9 (HR 1.37, 95% CI 1.13 - 1.65; $p<0.01$) and MASP-2 (HR 0.68 (95% CI 0.51- 0.92; $p=0.01$) predicted CVE in unadjusted analyses. In the final models adjusting for age, creatinine clearance, BMI and previous MI and for MASP-2 also for admission glucose the predictive capacity remained for sC5b9 (HR 1.32, 95% CI 1.03-1.70; $p=0.03$) but not for MASP-2 (HR 0.86; 95%CI 0.62-1.20; $p=0.37$). The prognosis was less favourable in patients belonging to the highest sC5b9 tertile (logrank test $p=0.003$; Figure). **Conclusion:** In MI patients with DM high levels of sC5b9 predicted future CVE while the impact of MASP-2 was blunted by traditional risk markers. The prognostic implication of C5b9 deserves further studies exploring if mechanistic insights may help to improve the outcome for DM patients with MI.

Increased EPCs level can help the clinical decision on coronary intervention in asymptomatic type 2 diabetic subjects with abnormal finding in cardiovascular MRH. Kim¹, B.-W. Lee¹, J. Moon¹, M. Chae², H. Seok¹, Y. Kim³, H.-J. Chang¹, B. Cha¹, H. Lee¹;¹Department of Internal Medicine, Yonsei University College of Medicine, Seoul, ²Brain Korea 21 project for Medical Science, Yonsei University College of Medicine, Seoul, ³Department of Radiology, Yonsei University College of Medicine, Seoul, Korea, Republic of.**Background and aims:** We investigated endothelial progenitor cells (EPCs) and other risk factors for predicting occult coronary arterial disease (CAD) in asymptomatic subjects with type 2 diabetes (T2D) using cardiovascular MR (CMR).**Materials and methods:** We conducted a clinic-based, prospective study of asymptomatic patients with T2D. A total of 100 subjects (51 men and 49 women; mean age, 56.4 ± 7.6 years) were finally enrolled in this study. Clinical and laboratory parameters, including EPCs (CD34⁺/CD133⁺/CD309⁺) counts, and functional stress myocardial perfusion and anatomic image of coronary arteries using CMR were evaluated. Within 90 days after CMR, invasive coronary angiography (ICA), as determined a priori by the responsible cardiologist, was performed.**Results:** Total 51 patients had at least one abnormal finding in CMR (3 silent myocardial infarction, 11 inducible ischemia, 37 suspected CAD). ICA was performed in 20 patients. Eight of the 20 patients had significant CAD that was treated with revascularization (7 percutaneous coronary intervention and 1 coronary artery bypass graft). Compared to subjects without revascularization, patients treated with revascularization had significantly increased waist/hip ratio (0.90 ± 0.56 vs. 0.96 ± 0.07 , $p = 0.006$), HbA1c (7.0 ± 0.9 vs. 7.8 ± 1.4 , $p = 0.022$), and high EPCs level (525.08 (429.5) vs. 952.75 (833), $p = 0.033$). Interestingly, EPCs level was higher in patients who underwent ICA than in patients who were recommended observation (722.85 (572.5) vs. 489.61 (388), $p = 0.127$), and it was also increased in patients who had revascularization compared with the patients who were treated medically (952.75 (833) vs. 569.58 (423), $p = 0.157$) (Figure 1). Binary logistic regression analysis revealed that a high EPCs level and a high BMI were independently correlated with significant CAD requiring revascularization in patients who had abnormal findings in CMR. **Conclusion:** In this present study, obesity, control status of diabetes and EPCs count were associated with revascularization in asymptomatic patients with T2D. Considering the result of CMR, EPCs level was increased in patients who needed revascularization and it can help the clinical decision on coronary intervention in asymptomatic T2D subjects with abnormal finding in CMR.**Figure 1.** EPCs increased in patients who underwent ICA, especially with significant CAD. Data are presented as medians. EPCs = endothelial progenitor cells; ICA = invasive coronary angiography; CAD = coronary artery disease; T2D = type 2 diabetes; CMR = cardiovascular magnetic resonance.

The type 2 diabetes-associated zinc transporter ZnT8 is required in alpha cells for the normal stimulation of glucagon release in response to hypoglycaemiaG. Meur¹, S. Migrenne², E.A. Bellomo¹, P.L. Herrera³, C. Magnan², G.A. Rutter¹;¹Division of Medicine, Imperial College, London, UK, ²Université Paris Diderot, France, ³Department of Cell Physiology and Metabolism, University of Geneva, Switzerland.**Background and aims:** ZnT8 (SLC30A8) is a largely endocrine pancreas-restricted member of the zinc transporter (ZnT/slc30) family present in both β and, at lower levels, in α cells. Polymorphisms in the human SLC30A8 gene are associated with an increased risk of type 2 diabetes in man and mice inactivated for slc30a8 either systemically or in the β cell display abnormal glucose homeostasis. Whilst mice inactivated for ZnT8 selectively in the α cell display normal glucose tolerance, glucagon secretion in these animals in response to hypoglycaemia has not been previously examined.**Materials and methods:** Mice carrying floxed slc30a8 alleles on a mixed C57BL/6/sv129 background were crossed with animals expressing Cre recombinase under a 0.6 kb fragment of the preproglucagon promoter. Mice (10–14 weeks of age) homozygous for floxed alleles of slc30a8 and bearing the Cre transgene were compared to wild type or heterozygous control mice during hypoglycaemic clamp. Briefly insulin was infused through fixed catheters simultaneously with glucose to achieve levels of glycaemia of 2–2.5 mM for 90 min. Glucagon secretion from islets isolated by collagenase infusion was assessed during static incubations (30 min.) and quantified by radioimmunoassay.**Results:** Whereas fasting glucose concentrations were similar between genotypes, glucose-infusion rates required to maintain hypoglycaemia in α ZnT8 KO mice were significantly ($24 \pm 5\%$; $p < 0.01$ and $20 \pm 3\%$, $p < 0.05$ at 20 and 40 min. after the onset of glucose/insulin infusion; $n = 5$ –6 mice per condition) lower compared to wild-type mice. Measured at the end of the clamps (90 min.), plasma glucagon levels were elevated in α ZnT8 KO (620 ± 50 pg/ml) vs control (320 ± 60 pg/ml, $p < 0.05$) mice. By contrast, examined in isolated islets, decreased glucose concentrations (0.5 or 3 vs 17 mM) stimulated glucagon secretion significantly ($p < 0.05$) more weakly from α ZnT8 KO (0.05 ± 0.01 and $0.01 \pm 0.02\%$ of glucagon content / 30 min. respectively) than wild-type islets (0.15 ± 0.05 and $0.05 \pm 0.008\%$). No significant difference in glucagon release was apparent between genotypes at 17 mM glucose (0.02 ± 0.015 and $0.01 \pm 0.01\%$ released). Total glucagon content was higher in α ZnT8 KO islets (3.3 ± 0.05 ng/islet) than controls (2.05 ± 0.2 ng/islet).**Conclusion:** These findings demonstrate a previously-unexpected role for ZnT8 in the islet α cell. Importantly, we show that inhibition of ZnT8 selectively in these cells enhances glucagon release *in vivo* to enhance counter-regulatory responses. Since these changes were not, however, reflected by enhanced secretion *in vitro* in response to glucose deprivation, it seems likely that other mechanisms, possibly including enhanced responses to other stimuli (eg adrenaline) may mediate the enhanced release *in vivo*. Pharmacological modulation of ZnT8 activity may thus provide a novel means to control glucagon release in the context of type 1 and/or type 2 diabetes.

Impaired incretin-induced amplification of insulin secretion following glucose homeostatic dysregulation in healthy subjectsK.B. Hansen^{1,2}, T. Vilbøll³, J.I. Bagger³, J.J. Holst², F.K. Knop³;¹Clinical Physiological, Glostrup Hospital, ²Biomedical Sciences, Panum Institute; University of Copenhagen, ³Internal Medicine F, Gentofte Hospital, Hellerup, Denmark.**Background and aims:** Type 2 diabetes is characterised by impaired insulinotropic effect of the incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1). It remains unclear whether this impairment is a primary pathophysiological defect or whether it occurs as a consequence of glucose intolerance. Therefore, we aimed to inves-

tigate the insulinotropic effect of GIP and GLP-1 compared to placebo before and after 12 days of glucose homeostatic dysregulation in healthy subjects.

Materials and methods: The insulinotropic effect was measured using hyperglycaemic clamps and infusion of physiological doses of GIP, GLP-1 or saline in 10 healthy Caucasian males (age: 25 ± 1 years (mean \pm SEM); BMI: 23 ± 1 kg/m²; HbA_{1c}: $5.4 \pm 0.1\%$; no family history of diabetes) before and after intervention using high calorie diet, sedentary lifestyle and administration of prednisolone (37.5 mg/day) for 12 days.

Results: The intervention resulted in insulin resistance according to HOMA (1.2 ± 0.2 vs 2.6 ± 0.5 , $p=0.01$) and glucose tolerance deteriorated as assessed by the AUC for plasma glucose during OGTT (730 ± 30 vs 846 ± 57 mM \times 2h, $p=0.021$). While the amount of i.v. glucose needed to maintain the hyperglycaemic clamp during continuous saline infusion was unchanged ($p=0.738$), the amounts needed to maintain the clamps with GIP (125 ± 8 vs 93 ± 8 g; $p=0.008$) and GLP-1 infusions (146 ± 9 vs 85 ± 11 g; $p=0.0005$), respectively, were significantly lower following intervention. The subjects compensated for the induced IR by significantly increasing their post intervention insulin responses during saline infusion by 2.9 ± 0.5 fold; thus, disposition index was unchanged. In contrast, the insulin responses to GIP or GLP-1 were only weakly up-regulated (1.78 ± 0.3 and 1.38 ± 0.3 fold, $p=0.001$ vs saline). While C-peptide AUCs during the hyperglycaemic clamp were augmented 2.5 and 2.3 fold by GLP-1 and GIP before, the fold augmentation fell to 1.5 and 1.6 after the intervention ($p=0.003$ and 0.04).

Conclusion: These data show that impairment of the insulinotropic effect of both GIP and GLP-1 can be induced in healthy male subjects without risk factors for type 2 diabetes indicating that the reduced insulinotropic effect of the incretin hormones observed in type 2 diabetes most likely is a consequence of insulin resistance and glucose intolerance rather than a primary event causing type 2 diabetes.

Glucose-dependent insulinotropic polypeptide: a bifunctional glucose-dependent regulator of glucagon and insulin secretion in man

M. Christensen^{1,2}, L. Vedtofte¹, T. Vilbøll¹, J.J. Holst², F.K. Knop¹;

¹Diabetes Research Division, Department of Internal medicine F, Gentofte Hospital, University of Copenhagen, Hellerup, ²Department of Biomedical Sciences, Panum Institute, University of Copenhagen, Denmark.

Background and aims: Longstanding knowledge positions glucose-dependent insulinotropic polypeptide (GIP) as an incretin hormone in healthy humans, but controversy exists regarding the glucagonotropic effects of GIP. We hypothesized that the glucagonotropic effect of GIP, like its insulinotropic effect, is glucose-dependent. Therefore, we aimed to evaluate the effect of GIP on plasma concentrations of glucagon at three different glycaemic levels.

Research design and methods: Ten healthy male subjects (age: 23 ± 1 (mean \pm SEM) years; BMI: 22 ± 1 kg/m²; HbA_{1c}: $5.5 \pm 0.1\%$, no family history of diabetes) were studied on six separate days. Physiological doses of GIP or saline were administered intravenously (randomized and double-blinded) during 90 min of insulin-induced hypoglycaemia, euglycaemia or hyperglycaemia, respectively (randomized).

Results: During hypoglycaemia plasma glucose (PG) was gradually lowered from mean fasting level of 5.0 ± 0.1 mM (mean \pm SEM) to a plateau level of 2.8 ± 0.1 mmol/l. GIP infusion resulted in greater a glucagon response during the first 30 minutes compared to saline (AUC: 76 ± 17 vs 28 ± 16 pmol/l \times 30 min, $p<0.008$) and a small increment in insulin secretion rate (ISR) before PG was lowered (0–10 min). During euglycaemia with a mean PG of 5.0 ± 0.1 mmol/l, GIP infusion elicited larger glucagon responses (62 ± 18 vs -11 ± 8 pmol/l \times 90 min, $p<0.005$) and increased ISR only during the first 5 minutes compared to saline. During hyperglycaemia with a mean PG of 12.1 ± 0.3 mmol/l comparable suppression of plasma glucagon (-461 ± 81 vs -371 ± 50 pmol/l \times 90 min, $p=0.26$) was observed with GIP and saline infusions, whereas GIP infusion more than doubled ISR ($p<0.0001$).

Conclusion: GIP has no effect on glucagon responses during hyperglycaemia when it potentiates insulin secretion. In contrast, GIP increases glucagon levels during fasting and hypoglycaemic conditions, when it has little or no effect on insulin secretion. Thus, GIP seems to be a bifunctional physiological blood glucose stabilizer with diverging glucose-dependent effects on the two main pancreatic glucoregulatory hormones insulin and glucagon.

Two novel peptide analogues of glucagon show glucagon receptor antagonist activity *in vitro* as well as antidiabetic actions in obese diabetic ob/ob mice

F.P.M. O'Harte, Z.J. Franklin, E.P. Rafferty, N. Irwin;

School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: In addition to defective insulin secretion and insulin resistance, abnormal glucagon regulation leading to hyperglucagonaemia, contributes to the hyperglycaemia observed in type 2 diabetes. Here we examined the actions of two potential glucagon receptor antagonist peptides at blocking glucagon induced insulin secretion *in vitro* in clonal pancreatic BRIN-BD11 cells. We also examined their *in vivo* ability to improve glycaemic control in chronically treated hyperglycaemic obese diabetic ob/ob mice.

Materials and methods: The acute (20 min) dose dependent effects of glucagon, or desHis¹Pro⁴Glu⁹-glucagon amide, or its acylated analogue desHis¹Pro⁴Glu⁹Lys¹²glutamyl-PAL-glucagon amide (10^{-12} to 10^{-6} mol/l) were assessed in BRIN-BD11 cells cultured in 5.6 mmol/l glucose. To assess antagonist activity *in vitro* the actions of both analogues (10^{-12} to 10^{-6} mol/l) were tested on insulin secretion in these cells alone or in the presence of a fixed glucagon (10^{-7} mol/l) concentration. For *in vivo* studies three groups of mice ($n=8$, aged 12–18 weeks) were given twice daily i.p. injections (09:30 and 16:30 h) for 10 days, of either desHis¹Pro⁴Glu⁹-glucagon amide, or its acylated analogue desHis¹Pro⁴Glu⁹Lys¹²glutamyl-PAL-glucagon amide (25 nmol/kg) or saline control. Body weight, food intake, non-fasting blood glucose and plasma insulin were monitored at regular intervals. After 10 days of treatment, a glucose tolerance test was performed by oral gavage (18 mmol/l glucose) and the responses to acute i.p. glucagon challenge was assessed.

Results: BRIN-BD11 cell studies showed that glucagon stimulated insulin secretion in a dose-dependent manner ($P<0.05$ to $P<0.001$) showing a 1.9-fold increase at 10^{-6} mol/l glucagon versus 5.6 mmol/l glucose control. In contrast, neither of the glucagon peptide analogues alone (10^{-12} to 10^{-6} mol/l) stimulated insulin secretion in BRIN-BD11 cells, but both dose-dependently inhibited the insulinotropic action of glucagon (10^{-7} mol/l) working best at higher concentrations ($P<0.001$). In mice studies, no differences in body weight or food intake were observed following 10 days of treatment. However, non-fasting blood glucose was reduced (ANOVA, $P<0.01$) on days 5 and 10 and plasma insulin elevated ($P<0.05$ to $P<0.01$) on days 3, 5 and 10 in desHis¹Pro⁴Glu⁹Lys¹²glutamyl-PAL-glucagon treated ob/ob mice. No differences were observed in non-fasting blood glucose or plasma insulin between the desHis¹Pro⁴Glu⁹-glucagon and saline treated mice. Following the 10 day treatment period, oral glucose tolerance was improved in the acylated analogue group ($P<0.05$) but not in the desHis¹Pro⁴Glu⁹-glucagon treated group. Notably when glucagon (25 nmol/kg) was administered to fasted mice 16 h after the normal twice daily peptide treatments (at 08.30 h), an overall blood glucose reduction was observed in both peptide analogue treated groups versus saline groups (AUC, 0–60 min, $P<0.05$).

Conclusion: DesHis¹Pro⁴Glu⁹-glucagon amide and its acylated analogue desHis¹Pro⁴Glu⁹Lys¹²glutamyl-PAL-glucagon amide antagonized glucagon induced insulin secretion in cultured BRIN-BD11 cells. *In vivo* studies showed that chronic treatment with both peptide analogues inhibited glucagon induced hyperglycaemia and that desHis¹Pro⁴Glu⁹Lys¹²glutamyl-PAL-glucagon amide was more effective at improving glucose tolerance and alleviating hyperglycaemia in an animal model of type 2 diabetes.

Prohormone convertase 2 positive enteroendocrine cells are more abundant in patients with type 2 diabetes: a potential source of gut-derived glucagon?

F.K. Knop¹, K.J. Hare¹, J. Pedersen², J.W. Hendel³, J.J. Holst², S.S. Poulsen², T. Vilbøll¹;

¹Diabetes Research Division, Department of Internal Medicine F, Gentofte Hospital, University of Copenhagen, Hellerup, ²Department of Biomedical Sciences, The Panum Institute, Faculty of Health Sciences, University of Copenhagen, ³Department of Gastroenterology, Herlev Hospital, University of Copenhagen, Herlev, Denmark.

Background and aims: In a cells, the precursor proglucagon (from the glucagon gene) is processed by prohormone convertase (PC)2 to glucagon, whereas enteroendocrine L cells utilize PC1 in the processing of proglucagon to the glucagon-like peptides 1 and 2 (GLP-1 and GLP-2). Hyperglucagonaemia

following oral glucose in type 2 diabetes mellitus (T2DM) is thought to arise as a consequence of dysfunctional α cells combined with β cell insufficiency. However, in contrast to oral glucose, i.v. glucose does not elicit hypersecretion of glucagon in T2DM. Therefore, we hypothesized that T2DM patients possess the potential to release glucagon directly from the gut.

Materials and methods: Ten male patients with T2DM (age: 51(41–62) years; BMI: 32(28–39) kg/m²; HbA_{1c}: 7.1(5.4–8.7)%) and 10 male healthy control subjects (age: 58(48–67) years; BMI: 31(26–36) kg/m²; HbA_{1c}: 5.5(5.2–6.0)%) underwent a 4h meal test and a jejunoscopy (including jejunal biopsies) on two separate days.

Results: Patients with T2DM exhibited exaggerated postprandial plasma glucose excursions (379±76 (mean±SEM) vs 77±33 mM×4h, $p=0.001$). Postprandial insulin (30±6 vs 27±5 nM×4h, $p=0.7$) and C-peptide responses (175±25 vs 188±24 nM×4h, $p=0.7$) were similar in the two groups, but patients with T2DM exhibited higher postprandial glucagon responses (3.0±0.5 vs 1.9±0.2 nM×4h, $p=0.02$). No differences in glucose-dependent insulinotropic polypeptide (GIP), GLP-1, GLP-2 or peptide YY responses were observed. Similar numbers of endocrine cells (all stained for PC1) from jejunal biopsies were observed in the two groups; including GIP, GLP-1, and GLP-2 positive cells. Significantly more PC2 positive cells were found among T2DM patients (70±8 vs 44±4 cells/mm², $p=0.01$). Similar levels of PC1 and PC2 gene expression were observed in the two groups.

Conclusion: Our results show that a high number of small intestinal endocrine cells in T2DM patients are equipped with PC2, which potentially - through processing of proglucagon to glucagon - contribute to the hyperglucagonaemia of these patients; shifting the 'pancreacentric' view on type 2 diabetic hyperglucagonaemia towards a role for the gut in this pathophysiological trait.

Evaluation of beta cell function in proglucagon-EGFP knock-in mice

A. Fukami¹, Y. Seino¹, N. Ozaki¹, J. Kato¹, E. Sakamoto¹, S. Tsunekawa¹, Y. Hayashi², Y. Murata², Y. Oiso¹;

¹Department of Endocrinology and Diabetes, Nagoya University Graduate School of Medicine, ²Department of Genetics, Division of Stress Adaptation and Recognition, Research Institute of Environmental Medicine, Nagoya University, Japan.

Background and aims: Under normal physiological conditions, glucagon signaling is important for glucose homeostasis. Hyperglucagonemia has been known to be associated with hyperglycemia in diabetic subjects. Glucagon receptor knockout mice and mice treated with glucagon receptor antagonist exhibited improved glucose tolerance and β -cell function because of increase of GLP-1 production in islets. In this study, we investigated the role of glucagon in glucose metabolism by using mice deficient for proglucagon-derived peptides.

Materials and methods: We generated *Gcg*-EGFP (enhanced green fluorescent protein) knock-in (*Gcg*^{EGFP/EGFP}) mice, which cannot produce glucagon, glucagon-like peptide-1 (GLP-1), and glucagon-like peptide-2 (GLP-2). We evaluated glucose tolerance by OGTT and IVGTT (2g/kg BW), morphological analysis of pancreatic islets, and insulin secretion in isolated islets.

Results: The serum glucose levels were not different between *Gcg*^{+/+} mice and *Gcg*^{EGFP/EGFP} mice in the fasted and fed states. *Gcg*^{EGFP/EGFP} mice showed low insulin levels in the fed state but not in the fasted state. At 15min after the intravenous glucose loading, the serum insulin levels in *Gcg*^{EGFP/EGFP} mice were significantly higher than those in the *Gcg*^{+/+} mice (*Gcg*^{+/+}, 902±132; *Gcg*^{EGFP/EGFP}, 1537±252pg/ml, $p<0.05$). Furthermore, the isolated islets of *Gcg*^{EGFP/EGFP} mice secreted more insulin than that of *Gcg*^{+/+} mice when stimulated by 2.8mM and 16.7mM glucose concentrations. These results indicated that the glucose-stimulated insulin secretion (GSIS) was enhanced in *Gcg*^{EGFP/EGFP} mice more than in *Gcg*^{+/+} mice. Compared to *Gcg*^{+/+} mice, *Gcg*^{EGFP/EGFP} mice displayed α -cell hyperplasia, increased α/β -cell ratio (*Gcg*^{+/+}, 1.04±0.11; *Gcg*^{EGFP/EGFP}, 2.15±0.12, $p<0.001$), and increased islet numbers (*Gcg*^{+/+}, 0.225±0.025; *Gcg*^{EGFP/EGFP}, 1.776±0.151/10⁶ μ m², $p<0.001$). The β -cell area in *Gcg*^{EGFP/EGFP} mice was similar to that in *Gcg*^{+/+} mice. *Gcg*^{EGFP/EGFP} mice showed low glucose levels (*Gcg*^{+/+}, 445±16; *Gcg*^{EGFP/EGFP}, 343±23mg/dl, $p<0.005$) and enhanced insulin levels (*Gcg*^{+/+}, 704±70; *Gcg*^{EGFP/EGFP}, 2610±614pg/ml, $p<0.05$) at 15 min after the oral glucose administration. In addition, the serum GIP levels of *Gcg*^{EGFP/EGFP} mice at 15 min after the oral glucose administration, were increased compared to those of *Gcg*^{+/+} mice (*Gcg*^{+/+}, 544±69; *Gcg*^{EGFP/EGFP}, 930±138 pg/ml, $p<0.05$). The mice were intraperitoneally pretreated with atropine and saline during the OGTT. In the *Gcg*^{EGFP/EGFP} mice, the enhancement of the insulin secretion observed at 15 min after

the oral glucose loading was partially inhibited by pretreatment with atropine (saline, 4623±894; atropine, 1975±387 pg/ml, $p<0.01$).

Conclusion: These results suggest that enhanced GIP secretion, the activation of the vagus nerves and the facilitation of GSIS are involved in increased insulin secretion in the *Gcg*^{EGFP/EGFP} mice. Here, we present the *Gcg*^{EGFP/EGFP} mice as a useful model for investigating the role of proglucagon-derived peptides in glucose homeostasis.

OP 23 Brain metabolism and food intake

133

Both ageing and body mass modulate the human brain response to food cues

Y.S. Cheah¹, S. Lee^{1,2}, Y. Nathan¹, G. Ashoor¹, B.M. Wilson¹, A.M. Pernet¹, F.O. Zelaya³, M.J. Brammer², S.A. Amiel¹;

¹Diabetes Research Group, ²Brain Imaging Analysis Unit, Department of Neuroimaging, Institute of Psychiatry, ³Department of Neuroimaging, Institute of Psychiatry, King's College London, UK.

Background and aims: Functional magnetic resonance imaging (fMRI) data suggest the corticolimbic responses to food cues, which control eating behaviour, mature from childhood to early adulthood in man. Changes in such higher functioning brain responses observed in obesity and Type 2 diabetes may be implicated in their aetiology. As the risk of these disorders rises as one ages further, we investigated the effect of advancing age in adults on these neural responses.

Materials and methods: 24 (12 male) non-diabetic subjects (mean age 35.9 [range 19.5 - 52.6] years, BMI 24.9±0.8 kg/m²) were studied twice in random order following an overnight fast. Subjects viewed food and non-food related object images during Blood Oxygenation Level Dependent fMRI 20 minutes after either 554 kcal standard meal (fed) or 50 ml water (fasted). Using a 10-point visual analogue scale, meal-induced satiety was measured intermittently post-ingestion, with concurrent blood sampling for circulating glucose and gut peptides. Food cue-induced hunger was also measured during BOLD data collection. Imaging data were analysed using XBAM software to determine associations between brain responses to food cues with age and BMI. Cluster level maps were obtained with a threshold at <0.5 expected type I error cluster per brain and all cluster-level correlation coefficients were >0.5.

Results: Satiety scores were higher after feeding (AUC above baseline 82.2±13.4 vs 7.1±7.2 units-min, $p < 0.001$). Visual food cues elicited higher hunger scores than non-food cues in both fed and fasted states and all hunger scores were greater when fasted than fed (general linear model main effects: food ingestion $p < 0.001$, image viewing $p = 0.002$). Whilst age was correlated with BMI ($r = 0.56$, $p = 0.004$), neither was significantly associated with satiety or hunger ratings.

In both fasted and fed states, age and BMI positively correlated with the effect size of responses to food vs non-food in the right insula; rising BMI was associated with greater precuneus responses; and increasing age with smaller thalamic responses. When fasted, age was negatively correlated with dorsolateral prefrontal cortex (DLPFC) responses and BMI negatively correlated with anterior cingulate responses. After eating, the effect size of activation by food cues was positively correlated in the middle frontal gyrus with age and BMI, ventral striate (age only) and thalamus (BMI only). Negative correlations in the fed state were observed between age and anterior cingulate and precuneus responses, and between both age and BMI with orbitofrontal cortex activity.

Conclusion: Whilst it is established that BMI influences regional brain responses to food cues, age may independently influence such frontocortical higher executive (DLPFC) and limbic reward (thalamus, ventral striate) neural network responses to food that control appetite and eating behaviour. Reduced activation of these pathways may result in reduced control of food intake, which may be involved in the increased risk of obesity with rising age.

Abrogation of glutamate consumption in the central nervous system modifies brain metabolism and reshapes peripheral energy distribution

M. Karaca¹, F. Frigerio¹, S. Carobbio¹, V. Mlynárik², D. Skytt³, R. Martín-del-Río⁴, M. De Roo⁵, P.L. Herrera¹, D. Muller⁵, J. Tamarit-Rodriguez⁴, F. Rohner-Jeanraud¹, H.S. Waagepetersen³, R. Gruetter², P. Maechler¹;

¹Department of Cell Physiology and Metabolism, University of Geneva, ²Laboratory for Functional and Metabolic Imaging, EPFL, Lausanne, Switzerland, ³Department of Pharmacology and Pharmacotherapy, University of Copenhagen, Denmark, ⁴Department of Biochemistry, Complutense University, Madrid, Spain, ⁵Department of Neuroscience, University of Geneva, Switzerland.

Background and aims: Glucose is the prominent source of energy delivered to the central nervous system (CNS) by peripheral organs. However, within the brain, oxidative catabolism of the neurotransmitter glutamate is suspected to contribute to maintenance of energy homeostasis. Upon glutamatergic transmission, intersynaptic glutamate clearance is achieved mostly by astrocytes. Following its uptake by astrocytes glutamate may be amidated to glutamine and then recycled back to neurons. Alternatively, glutamate may be deaminated to alpha-ketoglutarate via the mitochondrial enzyme glutamate dehydrogenase (GDH) before further oxidation in the TCA cycle, thereby promoting ATP generation. Here, we generated transgenic mice with brain-specific deletion of GDH, named CnsGlud1^{-/-} to question the importance of GDH as a key enzyme connecting glucose and glutamate metabolism within the CNS.

Materials and methods: GDH deletion in the CNS was assessed by western blot and by enzymatic activity. Mitochondrial oxygen consumption and cytosolic ATP levels were measured in isolated brain tissues. Glucose uptake was estimated by incorporation of injected 2-deoxy-D-[¹⁴C]glucose. Brain metabolites were measured by NMR in living animals, otherwise on isolated tissues using commercial kits. The excitatory transmission was analyzed by electrophysiology. The study has been carried out along the "Principles of laboratory animal care".

Results: Glutamate oxidation was inhibited in knockout brains, correlating with elevated intra-cellular glutamate plus glutamine pool and impaired glutamate-induced ATP generation. This was compensated by increased brain glucose consumption. Consequently, central glucose concentrations were lower in CnsGlud1^{-/-} mice (-47%, $p < 0.05$), while systemic glucose levels were similar to controls. The lack of glutamate oxidation in CnsGlud1^{-/-} brains enhanced brain glucose uptake (+32%, $p < 0.05$) and promoted enhanced liver gluconeogenesis. Redirection of energy substrates to the CNS resulted in lower body weights of CnsGlud1^{-/-} mice, correlating with muscle autophagy and elevated plasma corticosteroid levels (+82%, $p < 0.01$). Fat turnover was modified with increased circulating free fatty acids and ketone bodies as well as enhanced metabolism of peripheral adipose tissue. CnsGlud1^{-/-} mice were glucose intolerant, partly due to lower glucose utilization rate. Electrophysiological studies showed that the phenotype was not associated with any alterations in excitatory transmission in the CNS.

Conclusion: Impairment of glutamate oxidation in the CNS induced by brain-specific GDH deletion led to central hypoglycaemia mimicking severe fasting conditions, in turn mobilizing energy substrates from the periphery.

Impact of type 2 diabetes on hunger and brain responses to eating: a continuous arterial spin labelling functional magnetic resonance imaging study

S. Lee^{1,2}, Y. Nathan¹, Y.S. Cheah¹, T. Evans³, S. Coates³, B.M. Wilson¹, A.M. Pernet¹, M.J. Brammer², S.A. Amiel¹, F.O. Zelaya⁴;

¹Diabetes Research Group, King's College London, ²Brain Image Analysis Unit, Department of Neuroimaging, King's College London, ³Paxton Green Health Centre, London, ⁴Department of Neuroimaging, King's College London, UK.

Background and aims: Central control of appetite is an attractive target for weight reduction and diabetes control. Continuous arterial spin labelling (cASL) functional magnetic resonance imaging (fMRI) of the brain quantifies changes in regional cerebral blood flow (rCBF), a surrogate marker of neuronal activation, and has been applied to examine the effect of type 2 diabetes (T2DM) on neuronal responses to feeding.

Methods: 11 right (R) handed people (7 male) with T2DM on

lifestyle±metformin (age 54.7±7.0 yr; BMI 31.1±3.7 kg/m²) and 12 (7 male) right-handed non-diabetic control (age 45.3±4.8 yr; BMI 27.1±3.7 kg/m²) were scanned in a 1.5 Tesla MR Scanner after an overnight fast. Baseline cASL scan was acquired (~14 min), subjects consumed either a 554 kcal mixed meal (fed) or 50mls water (fasted) in random order (~6 min) and 3 further cASL scans were acquired at 0, 8 and 28 min. Appetite was measured using visual analogue scale (VAS) with concurrent blood sampling at -15, -7, 7, 15, 27 and 35 min. VAS data were analysed using SPSS and a flexible factorial design analysis in Statistical Parametric Mapping 5 was applied to cASL data to examine the effect of T2DM on rCBF changes to food. All clusters were at a corrected cluster-level p-value< 0.05.

Results: Hunger scores were lower in T2DM ($p<0.01$), but did not fall in the fed state, in contrast to the controls, where scores of the range 1 to 10 fell from 6.25±1.05 to 5.00±0.87. Preliminary analysis of the regional responses, corrected for the global differences, in the T2DM group during fasting, compared to controls, showed greater rCBF in R-hypothalamus, R-thalamus, R-medial globus pallidus, L-posterior cingulate, R-lingual gyrus and bilateral(B)-pons and lower rCBF in R-dorsolateral prefrontal gyrus (DLPFC), R-insula, R-frontal gyrus, B-precuneus, and R-superior occipital gyrus. After eating, the T2DM group showed greater rCBF in R-inferior temporal gyrus, fusiform gyri and parahippocampal gyri and lower rCBF in R-medial frontal gyrus, L-DLPFC, B-precuneus and cingulate gyri, compared to controls.

Conclusion: During fasting, T2DM subjects exhibited lower hunger; with greater neuronal activation in brain regions associated with homeostasis and gustatory system, and reduced responses in neural networks associated with reward and satiation modulation. In response to a small meal, T2DM subjects had less relief of hunger and less neuronal activation in reward networks, with greater activation in regions associated with hunger. Altered central satiety signalling in T2DM may be a barrier to weight reduction and lifestyle management in the treatment of T2DM.

GLP-1 differentially affects blood-brain glucose transfer and metabolism in humans

L. Egeford¹, M. Gejl¹, B. Bibby², N. Møller³, B. Brock², J. Rungby¹, A. Gjedde⁴; ¹Inst. of Pharmacology, Aarhus University, ²Aarhus University, ³Aarhus University Hospital, ⁴University of Copenhagen, Denmark.

Background and aims: Glucagon-like peptide-1 (GLP-1) has pronounced effects on glucose metabolism, and results in cells and intact animals suggest a protective effect on brain tissue. The mechanism is unknown. Glucose transport across the blood-brain barrier (BBB) has few known regulatory mechanisms other than the arterial glucose concentration and the cerebral capillary density or capillary surface area. We recently reported reduction of blood-brain glucose transfer with elevated GLP-1 in humans in whom glucose and insulin concentration were maintained at constant levels. This change could be due to changes of maximum glucose transport capacity or glucose transporter affinity or both. Thus, the working hypothesis claims that GLP-1 influences the transport of glucose across the BBB.

Materials and methods: To test this claim, we determined blood-brain glucose transfer and brain glucose metabolic rate by means of PET of FDG uptake at low and high glucose concentrations with and without GLP-1 and correction for lumped constant changes. With the PET, we also determined the blood-brain clearance of glucose, intracerebral glucose concentration and phosphorylation rate of hexokinase.

Results: At low plasma glucose levels, GLP-1 did not change cerebral glucose uptake, net clearance, cerebral metabolic rate, or phosphorylation rate. In hyperglycemia, GLP-1 increased the net clearance of glucose by 5–11% ($P=0.046$) in individual grey and white matter regions. In thalamus, the metabolic rate of glucose increased by 8% ($P=0.03$), with a similar trend throughout the brain. The same regions revealed a uniform trend toward increased phosphorylation rate (8–14%, $P=0.08$), significantly so in thalamus ($P=0.04$), and decreased intracerebral glucose concentrations (5–8%, $P=0.12$). Determined from low and high glucose levels together, GLP-1 affected maximum BBB glucose transport capacity in striatum by raising the T_{max} significantly from 1.1 to 1.3 μmol/g/min (18%, $P=0.03$) with a similar trend in the other regions, and the transporter affinity K_t insignificantly from 5 to 7 mM. The data reveals the same trend towards increased glucose metabolism by raising the maximum phosphorylation rate V_{max} from 0.29 to 0.31 μmol/g/min, and the hexokinase affinity K_m from 0.01 mM to 0.08 mM (means of regions).

Conclusion: These preliminary results suggest that GLP-1 increases glucose clearance in the brain and significantly changes glucose transport capacity

in striatum, with a uniform trend for the grey matter as a whole. Thus, the metabolic rate increased and the cerebral tissue glucose concentration decreased, together with a trend towards increased phosphorylation rates and decreased affinity of hexokinase towards glucose. These changes appear to be opposite the changes reported by Gjedde and Crone in chronic hyperglycemia of experimentally diabetic rats in which T_{max} declined significantly and K_t tended to decline but did not reach significance.

Clinical Trial Registration Number: NCT01185119

The brain's response to food ingestion after Roux-en-Y gastric bypass: a [¹⁸F]-fluorodeoxyglucose positron emission tomography (FDG-PET) study

K.F. Hunt¹, J.T. Dunn², A.M. Pernet¹, P.K. Marsden², S.A. Amiel¹;

¹Diabetes Research Group, Diabetes and Nutritional Sciences Division,

²The PET Imaging Centre, King's College London School of Medicine, UK.

Background: The mechanisms whereby Roux-en-Y gastric bypass (RYGB) causes weight loss and improved glycaemic control in Type 2 diabetes are not fully understood. One possibility is that changes in gut to brain communication may modulate central control of appetite. Anecdotally people who have had RYGB report increased fullness when eating. **Aim:** To investigate the brain's response to food ingestion in people who have lost weight post RYGB using [¹⁸F]-fluorodeoxyglucose positron emission tomography (FDG-PET) functional neuroimaging.

Materials and methods: Four groups of people have been studied: four individuals 27±12months post RYGB (BMI 36.6±3.0kg/m², weight loss 32.7±12.1% pre-surgical weight, HOMA2IR 0.55 ± 0.10); seven non-operated obese insulin sensitive, ObIS (BMI 34.6±2.4kg/m², HOMA2IR 0.54±0.11); seven non-operated obese insulin resistant, ObIR (BMI 33.5±1.9kg/m², HOMA2-IR 1.83±0.64); and eight normal weight, NW (BMI 22.3±1.2kg/m², HOMA2-IR 0.55±0.17). Individuals underwent FDG-PET brain imaging on 2 occasions in random order after an overnight fast: once FED (400kcal mixed meal consumed 15mins prior to FDG injection) and once FASTED (no calorie intake). Brain FDG uptake, a marker of neuronal activation, was compared using Statistical Parametric Mapping. Satiety was assessed using visual analogue scales and post-scan ad-libitum meal.

Results: For all groups combined, satiety scores increased at the 10minutes post meal timepoint in the FED state ($p<0.001$) with no difference between the four groups (rmANOVA, $p=0.365$). For all groups combined, the FED state was associated with reduced food consumption in the post scan ad-libitum meal (mean decrease 147±43kcal, $p=0.002$) with no difference in the decrease between the four groups. The post RYGB group consumed significantly less in the ad-libitum meal at the FASTED visit than the other three groups (ANOVA, $p=0.016$). Preliminary analysis shows that in the post RYGB group the FED, compared to the FASTED, state was associated with significant decreases (cluster-level corrected $p<0.05$) in FDG uptake in precuneus, areas of the prefrontal cortex (PFC) including the dorsolateral prefrontal cortex (DLPFC) and the orbitofrontal cortex and in the thalamus. Relative deactivation after food was also seen in precuneus and areas of the PFC, including the DLPFC, in NW. In contrast, there were no areas of decreased neuronal activation in the FED state in either of the non-operated obese groups. The extensive neuronal activation in the FED state in the ObIR group was not seen post RYGB.

Conclusion: The pattern of central neuronal deactivation in response to food ingestion in people who have had RYGB is similar to normal weight subjects' responses and different from those of obese subjects who have not had surgery. These changes are compatible with an effect of RYGB surgery on central responses to food ingestion which may explain increased satiation with eating and the weight loss seen post RYGB.

It's between the ears: role of hypoxia inducible factor 1alpha (HIF1alpha) activity in obesity

N. Deters¹, R.A. Stokes¹, K. Ho¹, S. Lau¹, K. Cheng¹, C. Scott¹, S. Lau¹, C. Girgis¹, M. Adams¹, K. Cha¹, F. Gonzalez², J.E. Gunton¹;

¹Diabetes and Transcription Factors Group, Garvan Institute of Medical Research, Darlinghurst, Australia, ²Laboratory of Metabolism, National Cancer Institute, Bethesda, USA.

Background and aims: We previously reported that the transcription factor HIF1alpha is down regulated by 90% in islets from people with type 2 diabetes. Mice lacking beta-cell HIF1alpha have mild glucose intolerance. Mice on a high fat diet (HFD) plus iron chelator (IC), to increase protein levels of HIF1alpha, had improved glucose tolerance and beta-cell function. An unexpected finding was that mice on a HFD+IC had significantly reduced weight gain. The hypothalamus regulates energy expenditure, body temperature and food intake. We hypothesised that decreased obesity was due to hypothalamic activation of HIF1alpha. To test this hypothesis, we have made hypothalamic HIF1alpha knockout mice.

Materials and methods: Using floxed HIF1alpha mice and adenovirus expressing Cre-recombinase, we generated mice with a hypothalamic-specific deletion of HIF1alpha by direct bilateral stereotaxic injection into the arcuate nuclei in the hypothalamus. Mice were given HFD±IC to increase HIF1alpha. Mice underwent DEXA body composition scanning, Oxymax respiratory rate- and food intake measurements.

Results: Hypothalamic HIF1alpha deletion blocked ~50% of the weight-protection effect of IC in HFD fed mice ($p<0.01$). Food intake and brown adipose tissue weights were increased in both control and hypothalamic HIF1alpha knockout HFD+IC mice, but hypothalamic HIF1alpha knockout mice gained a greater amount of weight.

Conclusion: This data demonstrates a novel role for hypothalamic HIF1alpha activity in control of weight and metabolic rate. Arcuate nucleus HIF1alpha is necessary for the full weight-protection effect of IC in HFD fed mice demonstrating that a substantial part of the effect is via hypothalamic HIF1alpha. These studies identify a novel mechanism of weight regulation.

Beta cell dysfunction and loss induced by ablation of mitochondrial chaperone prohibitin-2 in pancreatic beta cells promotes diabetes in transgenic Bet-Phb2^{-/-} mice

S. Supale¹, T. Brun¹, F. Thorel¹, C. Merkwirth², T. Langer², P.L. Herrera¹, P. Maechler¹;

¹Department of Cell Physiology and Metabolism, University of Geneva, Switzerland, ²Institute for Genetics, University of Cologne, Germany.

Background and aims: Prohibitin-1 and -2 are homologues of prohibitin family implicated in cell cycle, ROS production, cancer, obesity, and inflammation. They form ring-shaped complexes in the inner mitochondrial membrane, controlling cristae remodeling and apoptosis. In pancreatic beta cells, mitochondria play pivotal role in metabolism-secretion coupling. Nevertheless, there is paucity of information regarding mitochondrial dynamics in general and putative role of prohibitins in particular. We generated β -cell specific Phb-2 knockout mice (Bet-Phb2^{-/-}) to study prohibitins and mitochondrial integrity in the regulation of glucose homeostasis, beta cell physiology and survival. **Materials and methods:** Bet-Phb2^{-/-} mice were generated by mating mice with Phb2 alleles flanked by lox-P sites (Phb2^{fl/fl}) with animals carrying Cre-recombinase driven by the rat insulin promoter. Phb2 deletion was confirmed by genomic PCR and immunoblotting on isolated tissue extracts. *In vivo* glucose homeostasis was characterized by glucose tolerance test and measurement of plasma insulin levels by ELISA. We studied glucose-stimulated insulin secretion (GSIS) by *in-situ* pancreatic perfusions. Glucose-stimulated changes in insulin release, mitochondrial membrane potential and cytosolic calcium concentrations were measured in isolated islets. mtDNA copy number was analyzed by qPCR. Islet morphology, β - and α -cell mass, proliferation and beta cell loss were studied using immuno-histochemistry. The study has been carried out along the "Principles of laboratory animal care".

Results: Bet-Phb2^{-/-} mice which were normoglycaemic until the age of 4 weeks became hyperglycaemic at 6 weeks (average glycaemia 14.6 mM, $p<0.05$), and thereafter exhibited severe diabetes. At 6 weeks, Bet-Phb2^{-/-} mice were glucose intolerant (ipGTT: AUC +133%, $p<0.001$) with lower fasting plasma insulin levels (-66%, $p<0.01$) compared to littermate control (Phb2^{fl/fl}) mice. *In-situ* pancreatic perfusions revealed that both phases of GSIS were markedly reduced in Bet-Phb2^{-/-} mice (-75%, $p<0.001$). Compared to Phb2^{fl/fl} islets, those isolated from 4-week old Bet-Phb2^{-/-} mice were poorly responsive to glucose stimulation regarding insulin secretion, mitochondrial membrane potential, ATP generation, and cytosolic calcium rise. In addition, mtDNA copy number was reduced by 50% in Bet-Phb2^{-/-} islets. Strikingly, β -cell proliferation was 2.5-fold higher in Bet-Phb2^{-/-} than controls at the age of 4 weeks. However, beta cell mass progressively declined with age in Bet-Phb2^{-/-} mice, showing 35% and 90% reduction at 4 and 10 weeks of age respectively, accompanied by remodeling of islet architecture. On the contrary, α -cell mass was increased at 10 weeks in Bet-Phb2^{-/-} compared with control littermates.

Conclusion: This study demonstrates that impairment in mitochondrial integrity per se, i.e. not induced by toxic agents, secondary to deletion of prohibitin-2 results in β -cell dysfunction and gradual loss promoting diabetes. This emphasizes the importance of PHB2 in beta cell physiology and survival. Interestingly, β -cell proliferation compensated beta cell loss and postponed diabetes during pre-adult stage, whereas loss of β -cells at a later stage of life enlarged α cell mass.

Survival of rat pancreatic islets is partly controlled by a TCF7L2-p53-p53INP1 dependent pathway

Y. Zhou¹, E. Zhang², C. Berggreen³, X.-J. Jing², P. Osmark¹, S. Lang¹, C. Cilio², O. Göransson⁴, L. Groop¹, E. Renström², O. Hansson¹;

¹Endocrinology and Diabetes, Lund University Clinical Research Center, Malmö, ²Lund University Clinical Research Center, Malmö, ³Lund University Experimental Medical Science, Lund, ⁴Lund University Experimental Medical Science, Malmö, Sweden.

Background and aims: TCF7L2 is both an activator and an inhibitor of transcription and the most highly associated type 2 diabetes gene known to date.

It influences beta cell survival and function, i.e. incretin hormonal effects, insulin processing and secretion. However, its target genes in pancreatic islets are not fully described and the molecular mechanism whereby it propagates its effects on islet function is not known. The aim of this study is to identify the molecular mechanisms through which TCF7L2 influence beta cell survival and function.

Materials and methods: Wistar rat primary islets and INS-1 (832/13) cells were incubated with siRNA against Tcf7l2, both Tcf7l2 and TP53INP1 or both TCF7L2 and TP53 in 5.5 mM and 14.3 mM glucose. TCF7L2 activity, p53 activity and target gene expression (using qPCR) were measured after siRNA treatment. INS-1 cell apoptosis was measured by DNA degradation levels, caspase-3/7 levels and by using antibodies against Annexin V, and 7-AAD, visualized using confocal microscopy. Rat islet viability was estimated measuring metabolic rate. Rat islet apoptosis was estimated by measuring Caspase-3/7 level.

Results: The type 2 diabetes associated genes TP53INP1, FTO, GIPR and ADAMTS9 were identified as TCF7L2 potential target gene using chromatin immunoprecipitation on microarrays. In INS-1 cells, siRNA mediated Tcf7l2 knock down (69.5 %) resulted in decreased TCF7L2 activity (91%) and differential expression of the target genes: Tp53 (14.5% increase), TP53INP1 (65.9% increase) and ADAMTS9 (82.8% decrease). TCF7L2 knockdown also lead to reduced cell viability (65%) and increased apoptosis (113%). The TCF7L2 induced cell death was replicated in rat primary islets. When restoring (decreasing) the Tp53inp1 expression level in TCF7L2 depleted islets, the decrease in cell viability and increase in apoptosis were prevented, suggesting that the Tcf7l2 effect is mediated via Tp53inp1. Furthermore, p53 depletion prohibited TCF7L2 down regulation induced cell death and elevation of Tp53inp1 expression in both INS-1 cells and rat primary islets.

Conclusion: The type 2 diabetes associated genes TP53INP1 and ADAMTS9 are target genes of TCF7L2 in pancreatic islets. TCF7L2 induced apoptosis and decreased cell viability are mediated through activation of p53 and increased p53INP1 expression.

Pancreatic beta cells activate a JunB/ATF3-dependent survival pathway during inflammation

J. Barthson¹, E.N. Gurzov¹, I. Marhfour¹, F. Ortis¹, N. Naamane¹, M. Igoillo-Esteve¹, L. Marselli², P. Marchetti², D.L. Eizirik¹

¹Université Libre de Bruxelles, Belgium, ²University of Pisa, Italy.

Background and aims: Infiltrating immune cells contribute to beta cell apoptosis in type 1 diabetes (T1D) at least in part via release of the pro-inflammatory cytokines IL-1 β , IFN- γ and TNF- α . These cytokines activate several downstream transcription factors, including STAT1, NF- κ B and Activator Protein-1 (AP-1). While the role of STAT1 and NF- κ B in beta cell apoptosis has been studied in detail, the role of AP-1 members is less known. We therefore aimed to elucidate the contribution of JunB/AP-1 in cytokine-induced beta cell apoptosis.

Materials and methods: The experiments were performed in human islets from non-diabetic organ donors, FACS-purified primary rat beta cells, insulin-producing INS-1E cells, islets from Ubi-JunB transgenic mice or wild type littermates, and pancreas from pre-diabetic NOD or control mice. Islets, INS-1E cells or rat beta cells were cultured in the presence or absence of cytokines (TNF- α + IFN- γ) and microarray analysis, real time RT-PCR, Western blot, immunohistochemistry, small interfering RNA (siRNA), chromatin immunoprecipitation, adenoviral vector infection, promoter reporter assays and cell viability assays (Hoeschst 33342/propidium iodide staining) were used to clarify the gene networks involved in the cytokine-induced JunB/AP-1 pathway in beta cells.

Results: The cytokine combination TNF- α + IFN- γ up-regulated the expression of the AP-1 component JunB in human islets at both mRNA (2.8 fold increase relative to the controls, n=6, P<0.001) and protein levels. Similar results were observed in primary rat beta cells and clonal INS-1E cells. Increased JunB expression was confirmed by immunohistochemistry in pancreatic islets of pre-diabetic NOD mice. JunB knockdown (KD) by RNA interference (>60% KD) exacerbated cytokine induced beta cell death in primary rat beta cells and INS-1E cells (56–62% increase compared to controls, n=3–5, P<0.05). The gene networks affected by JunB were studied by microarray analysis of INS-1E cells exposed to TNF- α + IFN- γ with or without simultaneous JunB KD by siRNA. We observed that JunB regulates 20–25% of the cytokine-modified beta cell genes including the transcription factor ATF3. ATF3 expression was increased in cytokine-treated human islets (6.2 fold induction compared

to controls, n=6, P<0.01) and *in vitro* JunB silencing led to >60% reduction in ATF3 overexpression. We confirmed direct JunB regulation of the ATF3 promoter activity by its binding to an ATF/CRE site. Importantly, silencing ATF3 aggravated TNF- α + IFN- γ -induced cell death in dispersed human islets (28% increase versus controls, n= 4, P<0.02). Genetic overexpression of JunB in the Ubi-JunB transgenic mouse model increased ATF3 expression in the pancreatic islets and reversed the pro-apoptotic effects of cytokines on beta cells (47 % protection, n=4, P<0.001).

Conclusion: The AP-1 component JunB regulates a complex gene network in differentiated beta cells, leading to improved beta cell survival during exposure to pro-inflammatory cytokines. A key pro-survival gene induced by JunB is ATF3, and cytokine induction of the JunB/ATF3 pathway in beta cells may be critical for preserving beta cell viability in early T1D.

Exendin-4 protects beta cells from palmitate-induced apoptosis by reducing GPR40 expression and interfering with activation of the MKK4/7-JNK pathway

A. Natalicchio¹, R. Labarbuta¹, F. Tortosa¹, M.R. Orlando¹, A. Leonardini¹, A. Cignarelli¹, M. Melchiorre¹, A. Pescechera¹, P. Marchetti², S. Perrini¹, L. Laviola¹, F. Giorgino¹

¹Endocrinology & Metabolism, University of Bari, ²Endocrinology and Metabolism of Transplantation, AOUI, University of Pisa, Italy.

Background and aims: Free fatty acids (FFA) induce beta cell damage when their levels are chronically increased, thus contributing to the pathogenesis of type 2 diabetes. GLP-1 and its receptor agonist exendin-4 (ex-4) increase the survival of beta cells exposed to various pro-apoptotic stimuli, including FFA. The aim of this study was to investigate the mechanisms of the protective effects of GLP-1 mimetics on FFA-induced beta cell apoptosis.

Materials and methods: Isolated human islets and rat insulin-secreting INS-1 cells were incubated with 10 nM ex-4 for 16 h in the presence or absence of 0.5 mM palmitate. Protein content and phosphorylation of intracellular signaling intermediates were evaluated by immunoblotting and immunofluorescence techniques. Gene expression was evaluated by qRT-PCR. Silencer pre-designed siRNAs and silencer non-targeting siRNAs (negative control) for IB1 were used. Beta-cell apoptosis was quantified by an ELISA assay evaluating oligosome release into the cytosol.

Results: Exposure of human and rat beta-cells to 0.5 mM palmitate induced a 2.5-fold increase in cell apoptosis measured by evaluation of cytosolic oligosomes and cleaved caspase-3 (p<0.05). Palmitate increased the phosphorylation levels of both JNK and p38 (3.5-fold and 2-fold, respectively; p<0.05) evaluated both by immunoblotting and immunofluorescence. Inhibition of JNK (using the JNK inhibitors SP600125 and JNKi) or p38 (using the p38 inhibitor SB203580) phosphorylation prevented/reduced palmitate-induced apoptosis, respectively (p<0.05). Treatment with 10 nM ex-4 inhibited JNK and reduced p38 phosphorylation levels, and prevented apoptosis in response to palmitate (p<0.05). Furthermore, ex-4 inhibited palmitate-induced phosphorylation of the upstream kinases MKK4 and MKK7, which are implicated in JNK and p38 activation (p<0.05), and increased the protein content of Islet-Brain 1 (IB1), an endogenous JNK blocker (p<0.05). However, RNAi-mediated suppression of IB1 protein levels did not impair the ability of ex-4 to inhibit JNK and to prevent apoptosis. Finally, ex-4 reduced the mRNA levels of GPR40, a cell-surface FFA transporter (p<0.05). The inhibitory effects of ex-4 on JNK and GPR40 were abrogated in the presence of the PKA inhibitor H89.

Conclusion: The activation of the stress-kinases JNK and p38 is involved in palmitate-induced apoptosis in rat and human beta cells. The GLP-1 analog ex-4 counteracts the palmitate effects by reducing GPR40 gene expression and inhibiting MKK7- and MKK4-dependent phosphorylation of JNK and p38 in a PKA-dependent manner.

143

The mitochondrial Atp8 mutation induces mitochondrial ROS generation, secretory dysfunction and beta cell mass adaptation in conplastic B6mt^{FVB} mice

H. Weiss, M. Tiedge;

Institute of Medical Biochemistry and Molecular Biology, University of Rostock, Germany.

Background and aims: The conplastic mouse strain B6mt^{FVB} carries a mitochondrial DNA mutation in the Atp8 gene coding for the regulatory subunit 8 of ATP-synthase. In comparison to B6mt^{AKR} mice the B6mt^{FVB} strain showed elevated H₂O₂ production in isolated mitochondria. It was the aim of the study to investigate the effect of the Atp8 mutation (1) on the mitochondrial ROS production and secretory function in beta cells under conditions of glucolipotoxicity, and (2) on the metabolic profile under conditions of a high fat diet in vivo.

Materials and methods: Isolated pancreatic islet cells from B6mt^{AKR} (AKR) and B6mt^{FVB} (FVB) mice were exposed to 5 or 30 mM glucose in the presence or absence of 500 μ M palmitic acid. Mitochondrial ROS production was quantified by fluorescence microscopy after Mitosox loading of islet cells. B6mt^{AKR} and B6mt^{FVB} mice were fed high fat diet (HFD, 34% fat) or control diet (CD, 4% fat) for 26 weeks directly after weaning. Body weight, blood glucose, serum insulin, i.p. glucose tolerance, i.p. insulin sensitivity and beta cell mass were monitored at different time points of the diet.

Results: At 5 mM glucose islet cells from B6mt^{FVB} mice showed a 3-fold higher mitochondrial ROS production than islet cells from B6mt^{AKR} (24 h incubation, ratio Mitosox/Dapi: 0.9 ± 0.1 vs. 3.2 ± 0.2 ; $n = 6-8$; $p < 0.05$). Incubation of islet cells at 30 mM glucose resulted only in a minor increase in ROS production in both strains whereas ATP levels were significantly lower in beta cells from the FVB strain. Islets from FVB mice showed a more pronounced impairment of glucose stimulated insulin secretion (GSIS) after incubation with 500 μ M palmitic acid at high and low glucose concentrations. GSIS was significantly reduced in islets from FVB animals after incubation with 30 mM glucose for 24 hours. Feeding high fat diet for 26 weeks resulted in a more pronounced gain of body weight in the FVB strain with a gender dimorphism in favour of female mice. After 18 weeks of high fat diet FVB mice showed significantly elevated blood glucose levels (9.0 vs. 8.2 mM, $p < 0.05$) and an impaired glucose tolerance in comparison to AKR control mice (AUC: 1633 ± 104 vs. 1481 ± 60 ; $p < 0.05$). Serum insulin levels were significantly reduced in FVB mice reflecting secretory dysfunction after HFD. Insulin sensitivity of FVB and AKR mice was comparable after 6 month of HFD. Beta cell mass was increased in FVB mice after HFD by 92% while AKR mice showed a reduction of 18%.

Conclusion: The mutation of the Atp8 subunit of the ATP synthase induced an increased mitochondrial ROS production in isolated pancreatic beta cells at physiological glucose concentrations. However, mitochondrial dysfunction rather than oxidative damage appeared to be crucial for loss of secretory responsiveness under conditions of metabolic stress. Notably, high fat diet induced an adaptive increase of beta cell mass in FVB mice. The data implicate a dual role of mitochondrial ROS for regulation of beta cell mass and dysfunction.

144

Could miRNAs derived from lymphocytes trigger beta cell death in type 1 diabetes?C. Guay¹, E. Roggli¹, C. Briet², V. Menoud¹, S. Gattesco¹, C. Boitard², R. Regazzi¹;¹DBCM, University of Lausanne, Switzerland, ²Hôpital Cochin/St Vincent de Paul, INSERM U986, Paris, France.

Background and aims: During type 1 diabetes development, lymphocytes infiltrate pancreatic islets, resulting in beta-cell dysfunction and death. These events are thought to be mediated by proinflammatory cytokines. However, immune cells release also microvesicles, like exosomes, containing mRNAs, microRNAs and proteins that can be transferred in active form to recipient cells. Since during insulinitis beta cells and T cells are brought in close proximity and microRNAs are important regulators of beta cell functions, we hypothesized that exosome-mediated transfer of specific microRNAs from T cells to pancreatic beta cells could contribute to the dysfunction of insulin-secreting cells in the early phases of type 1 diabetes.

Materials and methods: To test this novel concept, exosomes were isolated by ultracentrifugation from culture media of the Jurkat T cell line or from

primary T effector cells of NOD mice. These microvesicle preparations were analyzed to determine their microRNA content and were used to study microRNA transfer from T cells to the beta cell line MIN6 or to dispersed primary rat islet cells.

Results: We first observed that five microRNAs, miR-142-3p, miR-142-5p, miR-150, miR-155 and miR-216, are highly upregulated in pancreatic islets during insulinitis in pre-diabetic NOD mice. Except for miR-216, these microRNAs are over a thousand times more abundant in T cells compared to beta-cells. These microRNAs were also found to be released in microvesicles originating from Jurkat T cells and primary T effector cells. When microvesicles of Jurkat T cells were applied to beta-cells, miR-142-3p, miR-142-5p, miR-150 and miR-155 were increased in recipient cells but not miR-216 or miR-29a, a microRNA highly expressed in beta cells. We next investigated the functional effect of Jurkat-derived microvesicles on MIN6 cells and on dispersed primary islet cells. We found that the cells exposed to T cell-derived vesicles display an increase in apoptosis measured by Hoechst and AnnexinV staining and a reduction in insulin secretion in response to glucose. To correlate the increase in microRNA expression to the functional effect observed upon exposure to the microvesicles, we investigated the impact of miR-142-3p and miR-142-5p overexpression on beta-cell functions. Increased miR-142-5p expression in MIN6 cells or dispersed islet cells promoted cell death while miR-142-3p overexpression reduced glucose-induced insulin secretion.

Conclusion: Taken together, our results suggest that microRNAs associated with microvesicles released by T cells can be picked up in active form by beta cells. The transfer of these regulators of gene expression correlates with alterations of beta cell functions. More experiments will be needed to proof that beta cell dysfunction is due to the microRNAs associated with the microvesicles. However, our results support the concept that microRNA transfer constitute a novel cell-to-cell communication mechanism.

OP 25 SGLT-2 inhibitors

145

Dapagliflozin, Metformin-XR, or both together to initiate pharmacologic therapy for type 2 diabetes

R.R. Henry¹, A.V. Murray², M. Herrera Marmolejo³, D. Hennicken⁴, A. Ptaszynska⁵, J.F. List⁵;

¹University of California, San Diego School of Medicine, San Diego,

²PharmQuest, Greensboro, USA, ³Torre Medica Providencia, Jalisco,

Guadalajara, Mexico, ⁴Bristol-Myers Squibb, Braine-l'Alleud, Belgium,

⁵Bristol-Myers Squibb, Princeton, USA.

Background and aims: Combining metformin-XR (MET) with another oral antidiabetic agent as initial therapy for T2DM may be advantageous in patients who have high HbA_{1c} with diet and exercise. Dapagliflozin (DAPA) is a selective SGLT2 inhibitor that lowers hyperglycaemia independently of insulin secretion or action by inhibiting renal glucose reabsorption. We report results from 2 randomised, double-blind, active-controlled, 24-week trials of DAPA and MET; combined or alone, in treatment-naïve patients with T2DM inadequately controlled with diet and exercise. Study 1 (MB102021) compared treatment regimens of once daily DAPA 5 mg + MET, DAPA 5 mg, and MET. Study 2 (MB102034) compared regimens of once daily DAPA 10 mg + MET, DAPA 10 mg, and MET.

Materials and methods: Patients with age range 18–77 years and HbA_{1c} 7.5–12% were eligible for inclusion. In each trial MET was titrated up to 2000 mg, with the majority of patients receiving MET 2000 mg daily. The primary endpoint was change from baseline in HbA_{1c} at week 24 (LOCF). Secondary endpoints included changes from baseline in fasting plasma glucose (FPG) and weight at week 24 (LOCF).

Results: In both trials DAPA+MET was more effective than either drug alone in reducing HbA_{1c} and FPG, and more effective than MET in reducing weight (table). In a pre-specified comparison of groups in Study 2, DAPA 10 mg was non-inferior to MET in reducing HbA_{1c}, and was superior in reducing both FPG and weight. Signs and symptoms suggestive of genital infection were reported in 6.7%, 6.9%, 2.0% (Study 1) and 8.5%, 12.8%, 2.4% (Study 2) of patients in the respective DAPA+MET, DAPA and MET arms. Signs and symptoms suggestive of urinary tract infection were reported in 7.7%, 7.9%, 7.5% (Study 1) and 7.6%, 11.0%, 4.3% (Study 2) of patients in the respective DAPA+MET, DAPA and MET arms. No event of major hypoglycaemia was reported in either study.

Conclusion: DAPA+MET used to initiate pharmacologic therapy for T2DM was generally well tolerated and effective in reducing HbA_{1c}, FPG and weight.

Results at Week 24 (LOCF)

Sustained efficacy of dapagliflozin when added to metformin in type 2 diabetes inadequately controlled by metformin monotherapy

C.J. Bailey¹, J.L. Gross², M. Yadav³, N. Iqbal⁴, T.A. Mansfield⁴, J.F. List⁴;

¹Aston University, Birmingham, UK, ²Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil, ³Bristol-Myers Squibb, Mumbai, India, ⁴Bristol-Myers Squibb, Princeton, USA.

Background and aims: The selective SGLT2 inhibitor dapagliflozin (DAPA) reduces hyperglycaemia independently of insulin secretion or action by inhibiting renal glucose reabsorption. This study (MB102014) is a randomised double-blind, placebo (PBO)-controlled trial of DAPA added to metformin (MET) in T2DM (n=546) inadequately controlled with MET alone. Previously reported short-term data at week 24 showed significant mean reductions in the primary [HbA_{1c}] and secondary [fasting plasma glucose (FPG) and weight] endpoints with DAPA compared to PBO. Here we report efficacy and safety results at week 102 of the long-term extension.

Materials and methods: Patients aged 18–77 years with HbA_{1c} 7–10% received DAPA 2.5 mg, 5 mg, 10 mg or PBO, plus open-label MET (≥1500mg/d). Exploratory endpoints at week 102 included changes from baseline in HbA_{1c}, FPG and weight, and were analyzed by longitudinal repeated measures analysis.

Results: Overall 71.2% of patients completed 102 weeks of the study; fewer on PBO (63.5%) than on DAPA 2.5 mg, 5 mg, and 10 mg (68.3%, 73.0%, 79.8%), due mainly to more patients on PBO discontinuing for lack of efficacy. At week 102, all DAPA groups showed greater mean reductions from baseline in HbA_{1c}, FPG and weight compared to PBO (table), effects that were similar to those observed at week 24 and maintained throughout the trial. More patients at week 102 also achieved a therapeutic response of HbA_{1c} <7% with DAPA 2.5 mg, 5 mg, and 10 mg (20.7%, 26.4%, 31.5%) than with PBO (15.4%). Adverse events (AEs), serious AEs and AEs leading to discontinuation were balanced across all groups. Signs and symptoms suggestive of genital infection (GenInf) were reported in 11.7%, 14.6%, 12.6% (DAPA 2.5 mg, 5 mg, 10 mg) and 5.1% (PBO) of patients, with 1 discontinuation due to GenInf. Signs and symptoms suggestive of urinary tract infection (UTI) were reported in 8.0%, 8.8%, 13.3% (DAPA 2.5 mg, 5 mg, 10 mg) and 8.0% (PBO), with 1 discontinuation due to UTI. No event of pyelonephritis was reported.

Conclusion: In comparison to PBO, DAPA added to MET over 102 weeks demonstrated greater and sustained improvements in glycaemic control, clinically meaningful reduction in weight, and no increased risk of hypoglycaemia in patients with T2DM inadequately controlled with MET alone.

ENCORE: efficacy and safety of BI 10773, a new sodium glucose co-transporter-2 (SGLT-2) inhibitor, in type 2 diabetes patients inadequately controlled on metformin

L. Seman¹, J. Rosenstock², A. Jelaska¹, S. Pinnett³, S. Hantel³, H.J. Woerle⁴;

¹Boehringer Ingelheim Pharma Inc., Ridgefield, ²Dallas Diabetes & Endocrine Center, Dallas, USA, ³Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach/Riss, ⁴Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany.

Background and aims: Sodium glucose cotransporter-2 (SGLT-2) inhibition is a novel insulin-independent glucose-lowering target in type 2 diabetes (T2D). The aim of this double-blind, placebo-controlled 12-week study was to assess the efficacy and safety of 5 doses of BI 10773, a potent SGLT-2 inhibitor in T2D patients inadequately controlled on metformin.

Materials and methods: A total of 495 subjects (mean baseline HbA_{1c} 7.9%, age 58 years, male 51%, BMI 31.4 kg/m²) were randomized to BI 10773 (1mg, 5mg, 10mg, 25mg, or 50mg once daily [qd]), or placebo (PBO), or open-label sitagliptin 100mg (SITA), added to metformin, for 12 weeks. Primary endpoint was change in HbA_{1c} from baseline to week 12.

Results: Significant and dose-dependent reductions in HbA_{1c} vs PBO were shown with BI 10773 with a maximum PBO-subtracted lowering of about 0.7% with the 10mg and 25mg doses, whereas SITA lowered HbA_{1c} by about 0.6% vs PBO. Significant reductions in fasting plasma glucose (FPG) and body weight vs PBO were observed in all BI 10773 groups except 1mg. A maximum PBO-corrected reduction in systolic BP of about 6 mmHg was seen with BI 10773 25mg. Frequency of adverse events (AEs) was similar in all groups (BI 10773: 38.5%, PBO: 36.6%, SITA: 35.2%). The most frequently reported AEs in the BI 10773 groups vs PBO were urinary tract infection (UTI) (3.1% vs 2.8%) and pollakiuria (2.5% vs 1.4%). Genital infections were reported on BI 10773 (2.5%) and SITA (1.4%) but not PBO. Rates of hypoglycemia were similar between groups.

Conclusion: Thus BI 10773 resulted in dose-dependent reductions in HbA_{1c}, FPG, body weight and was well tolerated with slightly increased frequency of genital infections but not UTIs vs PBO.

A novel potent and highly selective renal sodium-glucose co-transporter 2 (SGLT2) inhibitor, TS-071, improves glycaemic control and lowers body weight in Japanese patients with type 2 diabetes mellitus

Y. Seino¹, T. Sasaki², A. Fukatsu³, Y. Samukawa⁴, S. Sakai⁴, T. Watanabe⁴;

¹Kansai Electric Power Hospital, Osaka, ²Jikei University School of Medicine, Chiba, ³Kyoto University Hospital, ⁴Taisho Pharmaceutical Co.,LTD., Tokyo, Japan.

Background and aims: Renal sodium-glucose co-transporter 2 (SGLT2) inhibition is known as a new approach for the treatment of type 2 diabetes mellitus (T2DM). TS-071 is a novel, orally bioavailable, and highly selective SGLT2 inhibitor. The aim of this study was to investigate the exploratory efficacy and safety in Japanese patients with T2DM.

Materials and methods: In double-blind, placebo (PBO) -controlled, parallel group, exploratory dose-ranging study, subjects (N=236) were randomized to TS-071 0.5, 2.5, 5 mg once daily (QD) or PBO for 12 weeks. The primary endpoint was the change in HbA_{1c} from baseline after 12 weeks of treatment.

Results: Mean baseline characteristics in each group (HbA_{1c} 7.91-8.17 %, fasting plasma glucose (FPG) 152.0-159.9 mg/dL, postprandial plasma glucose at 2-hours after meal-test (PPG) 235.3-254.9 mg/dL, age 55.1-58.3 years, BMI 24.5-25.5 kg/m², body weight 65.4-69.7 kg) were similar across treatment groups. HbA_{1c} decreased significantly and dose-dependently, differences from PBO were -0.43, -0.70 and -0.82 % in 0.5, 2.5 and 5 mg groups respectively. Both FPG and PPG decreased significantly. Differences from PBO in FPG were -14.6, -25.9 and -27.9 mg/dL, and those in PPG were -36.1, -43.0 and -57.3 mg/dL in 0.5, 2.5 and 5 mg groups respectively. Body weight significantly decreased in 2.5 and 5 mg groups compared to PBO. Differences in body weight change compared to PBO were -1.8 kg (about 3 % of total body weight) in both 2.5 and 5 mg groups respectively. There was a trend to modestly systolic blood pressure reductions without relevant change in pulse in 2.5 and 5 mg groups. No major or serious safety concern was observed in all TS-071 groups. No hypoglycaemia (less than 70 mg/dL blood glucose level) was observed. Six pollakiuria or urine output increase were observed in

2.5 and 5 mg groups however all events were mild in severity. There were no clinically meaningful changes in serum creatinine or cystatin C, electrolytes.

Conclusion: Once daily administration of TS-071 demonstrated clinically meaningful reduction in HbA_{1c} and other glycemic parameters. Furthermore TS-071 induced significant body weight reduction, and showed favorable safety profile.

Figure 1. Time-Course of Changes in HbA_{1c}

Ipragliflozin improved glycaemic control with additional benefits of reductions of body weight and blood pressure in Japanese patients with type 2 diabetes mellitus: BRIGHTEN Study

A. Kashiwagi¹, Y. Takinami², K. Kazuta², S. Yoshida², A. Utsuno², I. Nagase²;

¹Shiga University of Medical Science, ²Astellas Pharma Inc., Tokyo, Japan.

Background and aims: Ipragliflozin (ASP1941) is a novel and selective sodium-dependent glucose co-transporter 2 (SGLT2) inhibitor. Here we report the results of a double-Blind Randomized study of Ipragliflozin to show the efficacy as monotherapy in Type 2 diabetes mellitus (T2DM) patients, the BRIGHTEN study; the first report of Japanese phase 3 study with a SGLT2 inhibitor.

Materials and methods: This study consisted of a randomized placebo-controlled parallel-group trial with a 16-week follow-up study in Japanese patients with T2DM. The primary objective of the study was to assess the efficacy (superiority versus placebo) of 50 mg ipragliflozin based on HbA_{1c} changes from baseline. After a 4-week screening period followed by a 2-week placebo run-in period, patients were randomized in strata depending on washout of previous anti-diabetic drugs or drug-naivety (8 weeks prior to screening), and received either ipragliflozin 50 mg (n=62) or placebo (n=67) once-daily for 16 weeks. At the end of treatment, patients were followed up for further 4 weeks.

Results: Mean baseline HbA_{1c} levels (8.32%) were significantly decreased (p<0.001) by 1.23% in the ipragliflozin group, as compared with a placebo group after 16 weeks of treatment. In addition, 43.5% of patients in the ipragliflozin group achieved the HbA_{1c} target goal of <7.4% as compared with 4.5% of patients in the placebo group. Fasting plasma glucose was also significantly decreased in ipragliflozin group, but adiponectin was significantly (p=0.001) increased; and fasting insulin tended to decrease. Mean body weight was significantly (p<0.001) decreased in the ipragliflozin group (-1.47kg as compared with placebo) and there was also reduction of systolic blood pressure (BP) (mean=-3.2 mmHg) and in diastolic BP (mean=-2.5 mmHg) from baseline. The overall incidence of treatment emergent adverse events was comparable between two groups. One mild case of symptomatic hypoglycemia was observed in the ipragliflozin group. One urinary tract infection was observed in the placebo group but none in the ipragliflozin group. Two genital infections were observed in the ipragliflozin group but none in the placebo group. **Conclusion:** The BRIGHTEN study demonstrates that once daily 50 mg of ipragliflozin treatment is safe, well tolerated, and superior to placebo in Japanese T2DM patients, with a significant decrease in HbA_{1c} of 1.23% versus placebo, as well as the additional benefits of weight loss and BP reduction.

Table: Baseline values and adjusted mean change from baseline at Week 16*

	HbA _{1c} [†] (%)	FPG (mg/dL)	Adiponectin (μg/mL)	Fasting insulin (μU/mL)	Body weight (kg)

Single doses of LX4211, a dual inhibitor of SGLT1 and SGLT2, improves parameters of glycaemic control and increases GLP-1 and PYY in patients with type 2 diabetes

D. Powell¹, J. Freiman¹, K. Frazier¹, A. Turnage¹, P. Banks¹, J. Bronner¹, K.A. Boehm¹, D. Ruff², A. Sands¹, B. Zambrowicz¹;¹Lexicon Pharmaceuticals, Inc., The Woodlands, ²Healthcare Discoveries LLC d/b/a ICON Development Solutions, San Antonio, USA.

Background and aims: LX4211 is a dual inhibitor of sodium-glucose co-transporters SGLT1/SGLT2, designed to block glucose (G) absorption in the GI tract via SGLT1 inhibition and renal G reabsorption via SGLT2 inhibition. This study compared the PK and PD of a liquid and solid formulation of LX4211 in T2D. PD endpoints included biomarkers hypothesized to reflect (1) inhibition of SGLT1 including total and active GLP-1, PYY; (2) inhibition of SGLT2, 24-hr urinary G; and (3) cumulative effect on glycemic parameters including fasting plasma G (FPG), mean plasma G (MPG), and insulin.

Materials and methods: After a 14-day washout of metformin, patients received single 300 mg oral doses of LX4211 before breakfast as two (2) 150 mg tabs, six (6) 50 mg tabs, or 300 mg solution in a randomized sequence using an open-label, Latin Square crossover design, with a 5-day washout between doses. PK and PD endpoints were assessed on days -1 (baseline [BL] untreated control), 1, 6, and 11.

Results:

	2x150 mg			6x50 mg			300mg liquid		
	BL	Day of Dose	Change from BL	Day of Dose	Change from BL	Day of Dose	Change from BL	Day of Dose	Change from BL
FPG (mg/dL) ^a	161.3	142.6	−18.7 ^c	131.4	−29.9 ^a	129.6	−31.7 ^a		
MPG (mg/dL) ^a	201.9	174.9	−27.0 ^a	171.0	−30.9 ^a	171.5	−30.4 ^a		
Insulin (μU•hr/mL) ^{**}	563.5	480.4	−83.1 ^a	492.9	−70.6 ^a	462.7	−100.8 ^a		
Total GLP-1 (pmol•hr/L) ^{**}	85.3	99.2	13.9 ^c	100.3	15.0 ^a	99.5	14.2 ^a		
Active GLP-1 (pmol•hr/L) ^{**}	42.3	49.5	7.2 ^b	51.1	8.8 ^b	45.3	3.0		
Total PYY (pmol•hr/L) ^{**}	387.8	484.5	96.7 ^c	511.6	123.8 ^a	505.1	117.3 ^a		
24-hr urinary G (g) ^a	17.3	73.1	55.8 ^a	77.5	60.2 ^a	84.8	67.5 ^a		

^aP<0.001^bP<0.05^cP<0.01^a2 hrs post dose^aHrs 2–13 after dosing^{**}Mean AUC for the day

Conclusion: PK and PD were similar between the formulations of LX4211 with favorable changes observed in indices of glycemic control including reduction of FPG, MPG, and insulin. LX4211 produced significant increases in total and active GLP-1, PYY, and urinary G excretion. AEs were infrequent. Single doses of LX4211 markedly increased GLP-1 and PYY and rapidly im-

proved FPG and MPG, consistent with the hypothesis that dual inhibition of SGLT1 and SGLT2 may provide an effective means of treating T2D. Further study of LX4211 as a potential treatment for diabetes is warranted.

Postprandial blood glucose predicts cardiovascular events and all-cause mortality in type 2 diabetes in a 14-year follow-up: lessons from the San Luigi Gonzaga diabetes study

F.L. Cavalot, A. Pagliarino, M. Valle, L. Di Martino, K. Bonomo, P. Massucco, G. Anfossi, M. Trovati;

Internal Medicine and Metabolic Disease Unit, Dept of Clinical and Biological Sciences, University of Turin, Orbassano, Italy.

Background and aims: The relationships between the parameters of blood glucose control, cardiovascular events and mortality in type 2 diabetes mellitus are a matter of strong debate. In a previous study, we demonstrated that postprandial blood glucose predicts cardiovascular events in a cohort of type 2 diabetic patients followed-up for 5 years also after adjustment for glycosylated haemoglobin A1C (A1C) and the main cardiovascular risk factors. Aim of the present study was to evaluate whether the predictive power of postprandial blood glucose persists in a long-term follow-up and whether postprandial blood glucose also predicts all-cause mortality.

Materials and methods: 505 consecutive type 2 diabetic patients followed-up at our diabetes clinic (M=53.1%; age: 62.2±9.6 years; known diabetes duration: 9.4±8 years; previous cardiovascular events: 16.8%; 44.6% on diet alone, 43.0% on oral agents, 7.3% on oral agents and insulin, 5.1% on insulin alone) were evaluated at baseline (in 1995) for the main cardiovascular risk factors and for five blood glucose (BG) control parameters (fasting BG, BG 2 hours after breakfast, BG 2 hours after lunch, BG before dinner and A1C); all-cause mortality and the first cardiovascular events occurring during a 14-year follow-up were measured. The statistical analysis has been carried out by Cox analysis with backward method. Non categorical variables were categorized according to the achievement of the therapeutic targets of the American Diabetes Association (ADA) (for BG variables: A1C <7%, preprandial BG ≤130 mg/dl and postprandial BG <180 mg/dl) or evaluated as continuous variables.

Results: We observed 172 cardiovascular events (34.1% of the population) and 147 deaths (29.1% of the population). Categorizing the variables according to the achievement of ADA therapeutic targets, we observed that: a) when the five glycaemic control parameters were considered together, the following resulted predictors: i) for cardiovascular events, BG 2 hours after lunch (HR:1.507, p=0.010) and A1C (HR:1.792, p=0.002); ii) for all-cause mortality, BG 2 hours after lunch (HR:1.885, p=0.000) and A1C (HR:1.907, p=0.002); b) when BG 2 hours after lunch and A1C were considered together with the main cardiovascular risk factors (gender, age, diabetes duration, body mass index, systolic and diastolic blood pressure, smoking status, LDL and HDL-Cholesterol, Triglycerides, Creatinine, Albumin Excretion Rate) the following glycaemic control parameters resulted predictors: i) for CV events BG 2 hours after lunch (HR:1.452, p=0.021) and A1C (HR:1.732, p=0.004); ii) for all-cause mortality, BG 2 hours after lunch (HR:1.846, p=0.001) and A1C (HR:1.896, p=0.004). By evaluating the non categorical parameters as continuous variables, the predictive power of A1C and BG 2 hours after lunch persisted for both CV events and all-cause mortality.

Conclusion: In type 2 diabetic patients, both postprandial blood glucose and A1C -but not fasting blood glucose- predict cardiovascular events and all-cause mortality in a long-term follow-up. Postprandial blood glucose, therefore, should be considered as a useful tool in the cardiovascular risk assessment in type 2 diabetes.

The effect of changes in HbA_{1c} during 7 years on aortic stiffness in a population at high diabetes risk: ADDITION DK

N.B. Johansen¹, D. Vistisen¹, S.S.S. Rasmussen², N. Wiinberg³, K. Borch-Johnsen⁴, A. Sandbæk⁵, T. Lauritzen⁵, D.R. Witte¹;

¹Epidemiology Group, Steno Diabetes Center A/S, Gentofte, ²Department of Endocrinology, Copenhagen University Hospital, ³Department of Clinical Physiology, Frederiksberg Hospital, ⁴Institute of Public Health, University of Southern Denmark, Odense, ⁵Institute of Public Health, Department of General Practice, University of Aarhus, Denmark.

Background and aims: Aortic stiffness is an independent risk factor for cardiovascular disease and is increasingly used as an intermediate end point in clinical trials. Diabetes and hyperglycaemia are associated with higher aortic stiffness, but whether changes in glycaemia affect aortic stiffness remains unknown. The aim of this study was to examine the effect of changes in HbA_{1c} on aortic stiffness in a population at high diabetes risk.

Materials and methods: A Danish population at high risk of diabetes identified by a multi-stage screening programme in general practice had measurements of HbA_{1c} at baseline and at follow-up 7 years later. Assessment of aortic stiffness by carotid-femoral pulse wave velocity (PWV) was performed at the follow-up examination. The effect of changes in HbA_{1c} from baseline to follow-up on PWV was analysed by linear regression analysis adjusted for age, sex, mean blood pressure at follow up, baseline waist circumference, baseline HbA_{1c}, incident diabetes (WHO 1999 definition), and antidiabetic treatment. Participants identified with diabetes based on an OGTT at baseline were not included in the analysis.

Results: A total of 896 participants free of diabetes at baseline (mean age: 60.1 years (SD: 5.9), 56% men) attended the baseline and follow-up examination. Mean follow-up time was 7.1 years (SD: 1.1). Baseline HbA_{1c} was 5.7% (SD: 0.4) and mean change in HbA_{1c} per year was 0.02% point (SD: 0.07, or range: -0.2 to 0.8). During follow-up 188 participants were diagnosed with diabetes, of which 54 participants were treated with antidiabetic medication. A yearly increase in HbA_{1c} of 0.1% point was associated with a 0.24 m/s (95% CI: 0.04;0.45) higher PWV at follow up. The effect of age on PWV was 0.12 m/s (95% CI: 0.09;0.14) per year. Leaving out participants with incident diabetes slightly elevated the effect of change in HbA_{1c} on PWV: 0.36 m/s (95% CI: 0.09;0.62), whereas the effect of age remained unaltered. The effect of change in HbA_{1c} on PWV was independent of baseline HbA_{1c} level.

Conclusion: People without diabetes who experience a faster increase in HbA_{1c} over 7 years have a higher level of aortic stiffness at the end of this period. In this high risk population, the effect of a yearly 0.1% point faster increase in HbA_{1c} on aortic stiffness corresponds to the effect of being 2 years older. This study suggests that not only the current HbA_{1c} level but also the velocity of HbA_{1c} deterioration plays a role in the development of early macrovascular changes in people at high diabetes risk.

Association of HbA_{1c} with the risk of cardiovascular events in patients with type 2 diabetes: a cohort study of 40,204 patients in primary care

C.I. Östgren¹, J. Sundström², B. Svennblad³, L. Lohm⁴, P.M. Nilsson⁵, G. Johansson⁶;

¹Department of Medical and Health Sciences, Linköping University,

²Department of Medical Sciences, Uppsala University, ³Uppsala Clinical Research Center, ⁴Medical Department, AstraZeneca Nordic, Södertälje,

⁵Department of Clinical Sciences, Lund University, Malmö, ⁶Department of Public Health and Caring Sciences, Uppsala University, Sweden.

Background and aims: Previous results of both interventional and observational studies in patients with type 2 diabetes have led to conflicting results about the safety of aiming for normal blood glucose concentrations. We explored the association of HbA_{1c} with risk of cardiovascular events (CVD) in patients with type 2 diabetes.

Materials and methods: We identified a cohort of 40,204 patients with type 2 diabetes aged 35 years and older by in 2010 extracting data from electronic patient records for all patients who had a diagnosis of type 2-diabetes or had glucose lowering agents prescribed between 1999 and 2008 in 76 Swedish primary care centers. In addition, the data was linked to the Statistics Sweden, National Cause of Death- and National Hospital Discharge Register. Risk of a primary composite endpoint of major cardiovascular events (acute

myocardial infarction, heart failure, stroke, or cardiovascular death) was estimated by Cox regression with HbA_{1c} as annual updated means as exposure. In the model, age and systolic blood pressure were entered as annual updated means, gender and previous CVD level as fixed covariates.

Results: During follow-up, 10,018 (24.9 %) patients experienced a major cardiovascular event. The relation of HbA_{1c} to risk of major cardiovascular events was J shaped (figure), with the lowest risk observed at an HbA_{1c} level of 6.3 % (45 mmol/mol). When further adjusted for index year and three categories of educational level the results were virtually unchanged.

Conclusion: In this observational retrospective cohort study we were able to confirm some previous results reporting that low and high mean HbA_{1c} values were associated with increased major cardiovascular events and cardiovascular mortality. The results lend support to the hypothesis that future diabetes guidelines might include a minimum HbA_{1c} value for patients subjected to treatment with glucose lowering agents with the potential of inducing hypoglycemia.

Glucose lowering therapy and long-term mortality in patients with type 2 diabetes undergoing coronary angiography

A. Norhammar¹, A.-M. Svensson², K. Eeg-Olofsson³, S. Gudbjornsdottir⁴, B. Lagerqvist⁵, N. Saleh¹;

¹Unit of Cardiology, Karolinska University Hospital, Stockholm, ²Center of Registers in Region Västra Götaland, Gothenburg, ³Institute of Medicine, Sahlgrenska University Hospital, University of Gothenburg, ⁴Center of Registers in Region Västra Götaland, Gothenburg, ⁵Uppsala Clinical Research Center, Uppsala University Hospital, Sweden.

Background and aim: Patients with type 2 diabetes mellitus (DM) undergoing Percutaneous Coronary Intervention (PCI) are at increased mortality risk compared to those without and insulin treatment has been discussed to be associated with adverse prognosis after PCI. The aim was to investigate the association between glucose lowering treatment and long-term mortality in patients with type 2 DM undergoing coronary angiography adjusting for diabetes variables indicating a more severe diabetes state as well as for cardiovascular risk factors.

Materials and methods: By merging the Swedish coronary angiography and angioplasty registry (SCAAR) and the National Diabetes registry (NDR) 14080 patients were identified in both registries between the years 2001–2009. Long-term mortality until end of 2009 was analysed by glucose lowering treatment adjusting for baseline cardiovascular-, diabetes- and angiographic characteristics.

Results: Patients with insulin only and insulin in combination with oral glucose lowering drugs at baseline had more severe coronary artery disease and higher rate of microvascular diabetes complications. Multivariate analysis, including diabetes variables as HbA_{1c} and duration, identified treatment with insulin (OR 1.19 95% CI 1.03–1.37, $P < 0.01$) and insulin in combination with oral anti diabetes drugs (OR 1.22 95% CI 1.06–1.40, $P < 0.005$) as predictors for long-term mortality. **Conclusion:** Insulin treatment alone or in combination with oral anti diabetic drugs in patients with type 2 DM admitted for angiography is associated with higher risk for mortality and such patients should be regarded as a high risk population. The role of insulin per se in this context needs to be better explored.

155

Population attributable risk (PAR) of macrovascular events associated with HbA_{1c} , blood pressure or weight in patients with type 2 diabetes mellitus: evidence from a Dutch cohort

E.M. Heintjes¹, F.J.A. Penning-van Beest¹, S.V. Parasuraman², S. Grandy², M. Pollack², R.M.C. Herings¹;

¹Research, PHARMO, Utrecht, Netherlands, ²Health Economics & Outcomes Research, AstraZeneca Pharmaceuticals LP, Wilmington, USA.

Background and aims: To determine the PAR of macrovascular events associated with HbA_{1c} , blood pressure, or weight in patients with type 2 diabetes mellitus (T2DM).

Materials and methods: A population-based, patient centric data tracking system in the Netherlands, the PHARMO database, was used which includes complete information on drug dispensing, hospital morbidity, clinical laboratory and primary care diabetes monitoring data for approximately 11,000 patients. From this dataset, all T2DM patients monitored in 2000–2008 were included in a cross-sectional cohort if cardiovascular risk factors HbA_{1c} , SBP and BMI were assessed during a one year baseline period after at least 6 months of antidiabetic treatment. Patients without baseline macrovascular events were followed until monitoring ended. Cox regression modeling of the composite outcome of macrovascular events was used to estimate the expected number of events after 2 and 5 years, either with unchanged risk factors (base-case) or with reductions in risk factors. PAR is the percent incidence of an outcome in the population that would be eliminated if a risk factor was reduced, compared with its actual exposure pattern. PAR was calculated as the number of averted events divided by the number of expected events in the base-case analysis.

Results: Mean age of 5841 included patients was 66 years (55% male), 45% had HbA_{1c} levels $\geq 7\%$, 66% had a SBP ≥ 140 mmHg and 85% had a BMI ≥ 25 kg/m². The base case expected number of macrovascular events at 2 years was 333, and 284 after reduction to target of all 3 risk factors. The overall PAR of HbA_{1c} , SBP and BMI for the composite outcome of macrovascular events was 15%, ranging from 6% among those with only one elevated risk factor to 23% among those with all three elevated risk factors. At 5 years, the base case expected number of macrovascular events was 796, and 687 after reduction to target of all 3 risk factors the PAR was 14% overall, ranging from 5% among those with only one elevated risk factor to 21% among those with all three elevated risk factors. The PAR of reducing HbA_{1c} to target (7%) or by 0.5

percent points ranged from 2–11% at 2 years, and 2–10% at 5 years. The PAR of reducing SBP to target (135 mmHg) or by 10 mmHg ranged from 3–13% at 2 years, and 3–12% at 5 years. There was no meaningful effect of reduction in BMI alone. However, meaningful effects of HbA_{1c} or SBP reduction were observed in patients with high BMI.

Conclusion: Reducing elevated HbA_{1c} and blood pressure levels was associated with improvements in cardiovascular risk. Even modest reductions in risk factors lead to significant reductions in macrovascular events in patients with T2DM.

Risk of cardiovascular disease associated with sulphonylurea or metformin use in older patients with type 2 diabetes mellitus

A.Z. Fu¹, Y. Qiu², M.J. Davies², S.S. Engel²;

¹Cleveland Clinic, Cleveland, ²Merck Sharp & Dohme Corp., Whitehouse Station, USA.

Background and aims: Sulphonylurea therapies have been associated with the potential for increased risk of cardiovascular disease (CVD), but remain a commonly used antihyperglycaemic medication particularly in the elderly. This retrospective cohort study examined the potential association between initial monotherapy with sulphonylurea or metformin and subsequent CVD in older patients with type 2 diabetes mellitus (T2DM).

Materials and methods: A cohort of patients who were ≥65 years old with T2DM and received their first prescription of sulphonylurea or metformin monotherapy between 2003 and 2007 (index period) and remained on it for at least 90 days were selected from the GE Centricity electronic medical record database. Patients had to have no prescriptions for antihyperglycaemic agents and no CVD events (ischaemic heart disease [IHD], myocardial infarction, stroke, transient ischaemic attack, and peripheral arterial disease) within the 1-year period prior to the index date (baseline) and also had at least 2 years of follow-up after the first prescription. Logistic regression evaluated the likelihood of having a CVD event. Cox regression estimated time to first CVD event. Differences in baseline characteristics (demographics, clinical and laboratory measures, and comorbidities) were controlled for using propensity score matching (PSM).

Results: Overall, 8,502 patients were included with 4,251/group. Mean age was 75 years and 49% were males. While controlling for differences in baseline characteristics using PSM, patients who initiated with a sulphonylurea had a significantly ($p<0.001$) higher incidence of CVD events (12.4% vs. 10.4%) compared to those initiated with metformin after 2 years of follow-up. The difference was mainly driven by the increased incidence of IHD with sulphonylurea (7.2%) compared to metformin (5.5%) ($p=0.002$). The likelihood of having a CVD event was higher in patients initiated with sulphonylurea than with metformin (odds ratio [95% CI] = 1.23 [1.08, 1.41]; $p=0.002$). Sulphonylurea use was associated with shorter time to first CVD event compared to metformin (hazard ratio [95% CI] = 1.15 [1.03, 1.28]; $p=0.004$). Sensitivity analyses with 1 or 3 years of follow-up yielded similar results.

Conclusion: In a cohort of older patients with T2DM initiating antihyperglycaemic therapy, the likelihood of experiencing a CVD event was higher and these events occurred sooner in patients who started with sulphonylurea monotherapy than those who started with metformin.

EURODIAB childhood type 1 diabetes incidence registers - results from the first 20 years

C.C. Patterson¹, G. Dahlquist², E. Gyürüs³, G. Soltész³, EURODIAB Childhood Type 1 Diabetes Registers;

¹Centre for Public Health, Queen's University Belfast, UK, ²Department of Clinical Science, Pediatrics, Umeå University, Sweden, ³Department of Pediatrics, University of Pécs, Hungary.

Background and aims: In 1989 a number of registries in Europe began recording new cases of type 1 diabetes diagnosed in children aged under 15 years using a common protocol as part of the EURODIAB sub-area A project. Trends in incidence rate during the first 20 years of registration are described covering the period 1989–2008.

Materials and methods: All registries operate in geographically defined regions and are based on a clinical diagnosis. When possible, registries assess their completeness by capture-recapture methodology using a primary and a secondary source of ascertainment and noting the numbers of cases identified by the primary source only, by the secondary source only and by both the primary and the secondary source.

Results: Other registries have joined the group since 1989, and 21 registries in 15 countries continue to submit registration data. In the first five years (1989–93) incidence rates varied from 3.2 per 100,000 in the Former Yugoslav Republic of Macedonia to 25.8 per 100,000 in the Stockholm area of Sweden. In the last five years (2004–2008) these two registries again had the lowest and highest incidence, but rates had increased to 5.8 per 100,000 and 36.6 per 100,000, respectively. During the 20 year period all but one of the 21 registries showed statistically significant rates of increase (median rate of increase 4% per annum), and similar figures were obtained when this median rate of increase was estimated for the first half of the period (1989–1998) and for the second half (1999–2008). However, rates of increase differed significantly between the first half and the second half of the period for eight of the 17 registries with adequate coverage of both periods; four showed significantly higher rates of increase in the first half and four significantly higher rates in the second half.

Conclusion: The childhood type 1 diabetes incidence rate continues to rise across Europe by approximately 4% per annum, but the increase in a registry is not necessarily uniform with periods of less rapid and more rapid increase in incidence occurring in some registries. This pattern of change suggests that important risk exposures differ over time in different European countries. Further time trend analysis and comparison of the patterns in defined regions is warranted.

Identification and assessment of glycan profiles as a biomarker for maturity onset diabetes of the young (MODY) due to hepatocyte nuclear factor 1 alpha (HNF1A) mutations

A.L. Gloyn¹, G. Thanabalasingham¹, G. Lauc², J.F. Wilson³, H. Campbell³, I. Rudan^{3,4}, J.E. Huffman⁵, C. Hayward⁵, R.M. Reynolds⁶, I. Klimes⁷, T. Hansen⁸, P.R. Njolstad⁹, P.M. Rudd¹⁰, M.I. McCarthy¹, K.R. Owen¹;

¹Oxford Centre for Diabetes Endocrinology & Metabolism, University of Oxford, UK, ²Department of Biochemistry & Molecular Biology, University of Zagreb, Croatia, ³Centre for Population Health Sciences, University of Edinburgh, UK, ⁴Croatian Centre for Global Health, University of Split, Croatia, ⁵MRC Human Genetics Unit, Western General Hospital, Edinburgh, ⁶Western General Hospital, Edinburgh, UK, ⁷DIABGENE, Slovak Academy of Sciences, Bratislava, Slovakia, ⁸Hagedorn Research Institute, Gentofte, Denmark, ⁹Department of Clinical Medicine, University of Bergen, Norway, ¹⁰Dublin-Oxford Glycobiology Lab, University College Dublin, Ireland.

Background and aims: A molecular diagnosis of monogenic diabetes confers important clinical benefits; however the majority of HNF1A-MODY patients remain misdiagnosed. Biomarkers could help identify subjects for genetic testing. A recent genome-wide association study identified HNF1A as the master regulator of plasma protein fucosylation. Enhanced HNF1A transcriptional activity is associated with an increased proportion of plasma glycans containing antennary fucose. We hypothesised that inactivating HNF1A

MODY mutations would be characterised by reduced antennary fucosylation of plasma proteins. We aimed to assess the value of protein fucosylation as a biomarker for HNF1A-MODY.

Materials and methods: Glycan plasma or serum profiles were analysed by HPLC in a pilot study of 33 HNF1A-MODY and 41 type 2 diabetes ([T2DM], diagnosed <45 years) subjects. Glycan peaks providing optimum discrimination between diabetes subtypes were validated in an independent dataset: HNF1A-MODY (n=199), GCK-MODY (n=127), HNF4A-MODY (n=44), type 1 diabetes (T1DM, n=98), T2DM (n=173) and non-diabetic controls (n=98). Receiver operating characteristic (ROC) curve analysis was used to evaluate the discriminative power of antennary fucosylation with respect to diabetes aetiology. Subjects with T1D or T2D with glycan profiles overlapping with HNF1A-MODY (n=37) underwent HNF1A sequencing.

Results: In the pilot study the ratio of glycan peak GP13 (contains glycans mostly without antennary fucose) to glycan peak DG9 (contains mainly antennary fucosylated glycans) levels were significantly higher in HNF1A-MODY compared with T2DM subjects; 4.9 vs. 1.3, $p < 5 \times 10^{-8}$. In the validation group the GP13:DG9 levels were substantially higher than all other groups ($p < 5 \times 10^{-8}$). Median (IQR) GP13:DG9 levels were: HNF1A-MODY 4.90 (2.88–7.14); GCK-MODY 1.43 (1.00–2.33); HNF4A-MODY 2.08 (1.04–4.11); T2DM 1.19 (0.75–2.05); T1DM 1.07 (0.65–1.74) and non-diabetic controls 1.24 (0.79–1.63). C-statistic was 0.90 for HNF1A-MODY vs. T2DM and 0.93 for HNF1A-MODY vs. T1DM indicating that glycan profiles confer high discriminative accuracy between diabetes subtypes. HNF1A sequencing identified 2 diabetic subjects (1 T1D & 1 T2D) with previously reported mutations consistent with a diagnosis of HNF1A-MODY.

Conclusion: We provide the first evidence that glycan profiles provide discrimination between HNF1A-MODY and other diabetes aetiologies and can identify subjects with unrecognised HNF1A-MODY. Glycan profiles offer a promising biomarker for HNF1A-MODY, which could be developed into a robust screening tool.

Parietal cell autoantibodies in type 1 diabetes based on molecularly-defined antigen epitopes

J.M. Wenzlau;

Barbara Davis Center for Childhood Diabetes, Aurora, USA.

Background and aims: Around 10–20% of type 1 diabetic patients are reported to express circulating gastric parietal cell autoantibodies, a classical marker for atrophic body gastritis (ABG) marker found in 2% of the general population which may lead to manifest clinical manifestation of pernicious anemia (PA) 0.15–1%. Current PCA assays typically rely on immunohistochemical detection to human stomach sections or ELISA based on binding of autoantibodies to H+/K+ ATPase (ATP4) biochemically purified from porcine stomach microsomes. A key question is whether PCA antibodies in T1D recognize the same or a homologous antigen in islets. To address this issue we developed assays for antibodies directed at recombinantly expressed alpha and beta subunits to human (ATP4) and their subdomains predicted from 3D modeling of ATP4A on the closely-related Na+/K+ ATPase. Further refinement and optimization of the assay to defined epitopes was performed by truncation analysis and site-directed mutagenesis.

Materials and methods: pCDNA 3 constructs were 35S-methionine labeled in vitro transcription / translation and incubated with sera derived from 463 newly diagnosed T1D individuals (9.8±4.4yr old), 150 patients with diabetes of >20 yr duration (30.4±8.7yr old) and 212 controls (median 6.3±13.2yr; range 0.7–51yr) and 60 patients with bioscopically confirmed ABG (55±14.8yr old). Immune complexes were captured on Protein A coated agarose bead radioactivity determined by scintillation counting in a96 well format.

Results: A major antigenic determinant of T1D autoantibodies to ATP4A was mapped to a 30aa epitope within 230aa domain within an intracellular loop of the molecule. 26% recent onset patients tested positive vs. 6% of control subjects. Significant reactivity at a low titer was observed in 5% T1D subjects with an equivalent domain of ATP12A, the most-closely related (78% identity) H+/K+ ATPase found in skin and other tissues but not to Human Na/K ATPase (ATP1A) above a 99% cut off (191 samples) and more distantly related Ca ATPases. In contrast to the gold standard T1D autoantibodies (GAD65, insulin, IA-2, and ZnT8) whose titers generally decrease with age and duration of T1D, ATP4A prevalence increased with age of onset of T1D from an average of 8% prevalence at 5 yr age to >30% at 60 yr. Immunoreactivity to ATP4A, unlike that of T1D antigens, displays a significant gender

bias in newly diagnosed T1D individuals and longstanding disease (60/40 ratio). Comparison of the ATP4A RIA with that of standard PCA commercial ELISA using sera from 60 individuals with ABG showed higher sensitivity (95% vs 80% respectively at 95% specificity) but otherwise excellent concordance in titer. Quantitative PCR and sequence analysis of human islet cDNA failed to detect ATP4A.

Conclusion: We demonstrate that assays developed to molecularly defined epitope of ATP4A that is detected in 8–30% of T1D patients is equivalent to the major epitope found in ABG patients. The antigen is not expressed in islets to a significant extent nor does the assay detect antibodies to structurally-related homologous ATPases which are found in islets. The association of PCA with type 1 diabetes is likely to be attributable to a more generalized polyendocrine autoimmune response arising from a defect in central immune tolerance.

Analyses of the rate of decline in stimulated C-peptide 12 months after diagnosis in children with newly diagnosed type 1 diabetes: results from 4 European cohorts during a period of 20 years

M.-L.M. Andersen¹, S. Pörksen¹, P. Hougaard², L.B. Nielsen¹, J. Svensson¹, J. Johannesen¹, J.V. Jørgensen³, J. Thomsen⁴, T. Hertel⁵, M. Wallensteen⁶, E. Örtqvist⁷, J.S. Petersen⁸, A.E. Karlsen⁹, L. Hansen¹, H.B. Mortensen¹;

¹Pediatrics, Glostrup and Herlev University Hospital, Glostrup, ²Department of Statistics, University of Southern Denmark, Odense, ³Department of Pediatrics, Skejby University Hospital, Aarhus, ⁴Pediatrics, Kolding Hospital, ⁵Pediatrics, Odense University Hospital, Odense, Denmark, ⁶Pediatrics, Centrallasarettet, Västerås, ⁷Woman and Child Health, Astrid Lindgrens Children's Hospital, Stockholm, Sweden, ⁸Diabetes Biology & Pharmacology, Novo Nordisk A/S, Måløv, ⁹Hagedorn Research Institute, Novo Nordisk A/S, Gentofte, Denmark.

Background and aims: The aim was to characterize the natural history of the decline in stimulated C-peptide (SCP) the first 12 months after diagnosis in children with new onset type 1 diabetes (T1D) in four independent cohorts collected over a time interval of 20 years and construction of a historic control group with the aim to reduce the required placebo group in paediatric intervention studies.

Materials and methods: The Wallensteen Swedish cohort, yr 1986–1988: 39 children; the Örtqvist Swedish cohort, yr 1995–1998: 29 children; the International Hvidoere European cohort, yr 1999–2000: 262 and the Danish cohort, yr 2005–2006: 130 children. All patients went through a 90-minutes liquid mixed meal test 1, 3 (not the Hvidoere cohort), 6 and 12 months after onset to characterize the residual beta-cell function. In all children ≥ 5 years the linearity of the slope of decline in SCP was analyzed from 3–12 months on a logarithmic scale. Linear mixed-effect models (random coefficient regression) were used to determine cohort differences.

Results: Maximum values of SCP were reached three months after diagnosis. Thereafter there was a linear decline in SCP for all age groups ≥ 5 years in all cohorts. The mean slope for the rate of decline in SCP was 7.5 ± 1.7 %/month for the Wallensteen cohort, 5.7 ± 1.9 %/month for the Örtqvist cohort, 7.2 ± 0.8 %/month for the Hvidoere cohort and 9.3 ± 1.0 %/month for the Danish cohort. The differences in slope between the cohorts was not statistically significant ($p=0.18$). The combined disappearance rate for SCP for the four cohorts was 7.8 ± 0.6 %/month. The combined standard deviation for the slope for one individual: 0.0997%/months measured 3, 6 and 12 months after diagnosis can be used in the construction of a historic control group based on the present data. With a target difference for the decline in stimulated C-peptide at 4 %/month, corresponding to 50 % reduction in slope, we want 80 % power to demonstrate a difference in fall in SCP at a 5 % level. Using the combined cohorts described above as a historical placebo group we only need 58 patients in the intervention group.

Conclusion: Residual beta cell function as assessed by SCP decline appears to have remained unchanged over time in Europe during the last 20 years despite more intensive insulin treatment regimens and better glycaemic control have been introduced during this period of time. With the construction of a historic placebo control group the number required in the intervention group can be reduced to 58 patients compared to 99 patients per group (198 in total) in a standard two-group comparison. Besides it is possible to randomize relatively fewer patients to the placebo group for confirmation within a study if desired.

161

Time dependent C-peptide decline in 4411 patients with recent onset type 1 diabetes followed for up to 10 years: a meta-analysis from 8 European centres

P. Pozzilli¹, N.C. Schloot², N. Hosszúfalusi³, A. Lauria⁴, J. Ludvigsson⁴, C. Mathieu⁵, D. Mauricio⁶, E. Rubinat⁶, M. Nordwall⁴, B. Van Der Schueren⁵, T. Mandrup-Poulsen⁷, W.A. Scherbaum², I. Weets⁸, F. Goris⁹, D. Leslie¹⁰,
¹University Campus Bio-Medico, Rome, Italy, ²Heinrich Heine University, Düsseldorf, Germany, ³Semmelweis University, Budapest, Hungary, ⁴Linköping University, Sweden, ⁵Katholieke Universiteit, Leuven, Belgium, ⁶Hospital Arnau de Vilanova, Lleida, Spain, ⁷University of Copenhagen, Denmark, ⁸Vrije Universiteit Brussel, ⁹Vrije Universiteit, Brussel, Belgium, ¹⁰Blizard Institute of Cell and Molecular Science, London, UK.

Background and aims: C-peptide is a valuable indicator of residual beta cell function in patients with type 1 diabetes (T1D). Critical factors associated with decline of C-peptide after diagnosis include age at onset, autoantibody and HLA status, severity of initial metabolic derangement, insulin use and quality of glucose control. Whilst recent studies suggest that significant beta cell function may be preserved for several years after diagnosis, C-peptide data must be corrected for these variables and robust data is lacking. To this aim, we collected retrospectively data on C-peptide from T1D patients from 8 different European centres followed-up from diagnosis and up to 10 years.

Materials and methods: We performed a meta-analysis of 4411 T1D patients in total (57.2% males; mean age at onset: 18.5 yrs. \pm 11.7 SD, age range 1–60). Records were extracted for age at diagnosis, fasting and stimulated C-peptide, Body Mass Index, HbA_{1c} and insulin requirement at diagnosis, and from 1 to 10 years follow-up.

Results: Data on C-peptide (nmol/l) at diagnosis were available from 3648 patients who were subdivided according to age at diagnosis in three groups: Group A n=1356 (0–11 yrs.); Group B n=647 (12–18 yrs.); Group C n=1645 (>18 yrs). There was a significant trend ($P<0.001$) age-dependent increase in fasting C-peptide at diagnosis (0.20 \pm 0.20 in Group A, 0.28 \pm 0.26 in Group B, and 0.30 \pm 0.35 in Group C), not observed for stimulated C-peptide (0.46 \pm 0.43 in Group A, 0.47 \pm 0.32 in Group B and 0.44 \pm 0.38 in Group C). In Group A the percentage decline of baseline C-peptide at 1, 2, 5 and 10 years was 25, 70, 75, 90 percent, respectively; in Group B, 76, 60, 67 and 85 percent, respectively; in Group C, 23, 43, 75 and 77 percent, respectively (p for trend <0.001).

Conclusions: This study (the largest of this kind) reveals an inverse correlation between age at T1D onset and basal C-peptide at diagnosis with a more rapid decline in beta-cell function in the very young patients. The data will be useful for the calculation of treatment effects and sample sizes in trials aiming to preserve insulin secretion with C-peptide as end-point.

162

Examination of GAD65 in human serum as a possible marker of ongoing beta cell destruction in autoimmune diabetes

K. Seifert¹, K. Tornow¹, U. Walschus¹, H. Kenk², M. Schlosser¹;

¹Research Group of Predictive Diagnostics, Department of Medical Biochemistry and Molecular Biology, ²Research Group of Predictive Diagnostics, Institute of Pathophysiology, University Greifswald, Karlsburg, Germany.

Background and aims: Autoantibodies (AABs) against beta cell antigens are established serological markers of autoimmune-mediated diabetes, and are detectable at clinical onset but also years in advance. Most frequently are AABs against the 65 kD isoform of glutamate decarboxylase GAD65 (GADA) in both patients with type 1 diabetes (T1D) and latent autoimmune diabetes in adults (LADA), beside AABs against islet cell antigen-2 (IA-2A), insulin (IAA) and zinc transporter 8. GADA are probably secondarily generated after release of GAD65 from injured beta cells. Recently, the detection of GAD65 in serum has been proposed as a non-degradable biomarker for early diagnosis of T1D, and an average concentration of 58 ng/ml (range 0.10 to 514.7 ng/ml) in 64 randomly selected samples from a blood bank was reported. However, previously reported results from own work and another study demonstrated that GAD65 is rapidly degraded in vitro and in vivo. The aim of the present study was the quantification of GAD65 in serum samples from different defined proband groups to evaluate its diagnostic relevance in addition to the established AABs.

Materials and methods: Sera from 103 patients with newly diagnosed T1D (median age 13 years, interquartile range (IQR) 8–20 years) and positivity for GADA (n=82) and/or IA-2A (n=59) and/or IAA (n=38), 93 LADA patients

(median age 59 years, IQR 48–66 years; median latency to insulin treatment 5 years, IQR 2–9 years) and positivity for GADA (n=85) and/or IA-2A (n=20) and 100 healthy blood donors (all negative for GADA and IA-2A) were analyzed. Additionally, sera from 151 schoolchildren positive for GADA (n=86) and/or IA-2A (n=49) and/or IAA (n=46) and 100 AAB negative schoolchildren (median age 11 years, IQR 9–13 years) without first-degree diabetes heredity were included. GAD65 was quantified by a sandwich ELISA based on two monoclonal antibodies with different epitope specificities and a detection limit of 30 pg/ml. Statistical analysis was performed with the non-parametric Mann-Whitney test.

Results: The median GAD65 concentration was significantly higher in T1D patients compared to healthy blood donors (0.949 ng/ml; IQR 0–1.76 ng/ml vs 0.573 ng/ml; IQR 0.32–0.81 ng/ml; $p=0.044$), while levels of LADA patients (0.758 ng/ml; IQR: 0.24–1.25 ng/ml) did not differ from blood donors. Furthermore, the median GAD65 concentration in sera from AAB positive schoolchildren was significantly higher than in sera from AAB negative schoolchildren (0.684 ng/ml; IQR 0.31–1.45 ng/ml vs 0.425 ng/ml; IQR 0.11–0.98 ng/ml; $p=0.0096$). Highest individual values were 5.8 ng/ml (T1D), 16.6 ng/ml (LADA), 4.9 ng/ml (blood donors) and 5.8 ng/ml respectively 2.8 ng/ml (AAB positive/ negative schoolchildren).

Conclusion: The results demonstrate that GAD65 can be detected in sera from patients with newly diagnosed T1D or LADA, from AAB negative and AAB positive schoolchildren and from healthy blood donors. However, the measured concentrations are about 100fold lower than previously published data and differ only slightly between the examined groups. Taken the reported degradation kinetics of GAD65 into consideration, the detection of GAD65 is therefore, at most, only of minor diagnostic relevance in autoimmune diabetes.

Genome-wide associations between gene expression in peripheral blood and fasting and 2-hour glucose levels in the population-based KORA Survey F4

C. Herder¹, M. Carstensen¹, S. Landwehr², W. Rathmann², B. Thorand³, C. Meisinger³, K. Heim⁴, T. Meitinger⁴, H.-E. Wichmann⁵, S. Martin⁶, W. Koenig⁷, H. Finner², T. Illig⁸, M. Roden^{1,9}, H. Prokisch⁴

¹Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf,

²Institute of Biometrics and Epidemiology, German Diabetes Center, Düsseldorf, ³Institute of Epidemiology II, Helmholtz Zentrum München, Neuherberg, ⁴Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, ⁵Institute of Epidemiology I, Helmholtz Zentrum München, Neuherberg, ⁶Verbund der Katholischen Kliniken Düsseldorf, ⁷University of Ulm Medical Center, ⁸Institute of Molecular Epidemiology, Helmholtz Zentrum München, Neuherberg, ⁹Department of Metabolic Diseases, University Hospital Düsseldorf, Germany.

Background and aims: Gene expression profiles represent quantitative traits that are inherited, but also determined by environmental influences. However, it is not known to what extent the human transcriptome is influenced by changes of glucose metabolism. As primary glucose-metabolising tissues are not easily accessible in epidemiological studies, we used peripheral blood to assess if gene expression levels were associated with fasting and 2-hour glucose levels after an oral glucose tolerance test.

Materials and methods: Whole-blood samples in PAXgene tubes were obtained between 8 and 11 a.m. from fasting study participants of the population-based KORA Survey F4 (Augsburg/Germany). Whole-genome gene expression analysis was performed using the Illumina HumanHT-12v3 Expression BeadChip which measures the relative abundance of >32,000 transcripts covering the vast majority of the protein-coding genes annotated in the RefSeq database. Associations between expression levels of RefSeq annotated genes and glucose (fasting and 2-hour) were quantified by linear regression models using normalised gene expression levels as dependent variables. Correction for multiple testing was performed using a multiple testing procedure based on Storey critical values which controls the false discovery rate (FDR) at a level of 0.05.

Results: This study is based on expression data from 815 individuals (48.2% men) between 62 and 81 years without previously known diabetes (63.2% normal glucose tolerance, 5.9% impaired fasting glucose, 23.7% impaired glucose tolerance, 7.2% newly diagnosed type 2 diabetes) with a body mass index (BMI, mean±SD) of 28.5±4.3 kg/m². In age- and sex-adjusted analyses, 343 and 1595 transcripts were associated with fasting and 2-hour glucose at an FDR of less than 0.05. After additional adjustment for BMI, these numbers were reduced to 5 and 688, respectively. For fasting and 2-hour glucose, 3 (60.0%) and 444 (64.5%), respectively, of these transcripts were positively associated with glucose levels. The transcripts showing the most pronounced associations with 2-hour glucose represent several biological pathway that include among others insulin resistance, oxidative phosphorylation and cell proliferation.

Conclusion: Gene expression levels in peripheral blood from fasting individuals are more strongly associated with 2-hour than fasting glucose levels. These results will be available for pathway analyses in order to identify novel pathophysiological mechanisms that contribute to type 2 diabetes, and prospective studies will have to assess whether these transcripts improve the prediction of incident type 2 diabetes.

The association and causal inference between circulating 25-hydroxy vitamin D concentration and the risk of type 2 diabetes

N.G. Forouhi¹, Z. Ye¹, A.P. Rickard¹, K.-T. Khaw², R. Luben², C. Langenberg¹, N.J. Wareham¹

¹MRC Epidemiology Unit, Cambridge, ²Department of Public Health and Primary Care, Cambridge, UK.

Background and aims: Epidemiological evidence suggests that circulating 25-hydroxy vitamin D [25(OH)D] is inversely associated with risk of type 2 diabetes (T2D). No meta-analysis of prospective evidence exists and the caus-

al nature of the association is unknown. Our aim was to conduct a systematic review and meta-analysis of prospective studies and examine causality.

Materials and methods: A systematic review identified all prospective studies on 25(OH)D and incident T2D published in MEDLINE or EMBASE until 20 January 2011. We performed a random effects meta-analysis combining available evidence with new results from EPIC-Norfolk. We genotyped four single nucleotide polymorphisms known to be robustly associated with 25(OH)D, and computed a genetic score. In Mendelian randomisation analyses we compared the odds ratio observed for the association between genetic score and T2D (5,791 cases; 7,786 controls) to that expected based on the mean difference in 25(OH)D by genetic score (n=628, Ely Study), and the summary estimate from our 25(OH)D-T2D meta-analysis.

Results: The combined relative risk of T2D comparing the highest with lowest quartile of 25(OH)D was 0.53 (95% CI 0.45, 0.61), with little heterogeneity ($I^2=0\%$, $p=0.91$) between 7 studies included in the meta-analysis (2,654 cases, 44,236 non-case participants). The mean difference in 25(OH)D was -5.81 (95% CI -7.82, -3.79) nmol/l per tertile of genetic score, corresponding to an expected OR for T2D of 1.05 (1.04, 1.07), compared with an observed OR of 1.00 (0.95, 1.05).

Conclusion: Higher 25(OH)D is associated with a reduced risk of T2D, but the absence of a lower risk of T2D in participants with genetically raised 25(OH)D levels raises caution about the causal nature of the 25(OH)D-T2D association. However, genetic approaches alone may be insufficient to resolve the issue of causality. Given the potential public health importance, randomised trials of vitamin D supplementation are warranted to resolve the issue of causality and the potential for prevention.

Rs10906115 in CDC123/CAMK1D locus and rs1359790 near SPRY2 are associated with susceptibility to type 2 diabetes in a Japanese population

M. Imamura¹, M. Iwata², H. Maegawa³, H. Watada⁴, H. Hirose⁵, Y. Tanaka⁶, K. Tobe⁷, K. Kaku⁷, A. Kashiwagi³, R. Kawamori⁸, Y. Nakamura⁹, S. Maeda¹

¹Laboratory for Endocrinology and Metabolism, Center for Genomic Medicine, RIKEN, Yokohama, ²First Department of Internal Medicine, University of Toyama, ³Department of Medicine, Shiga University of Medical Science, Otsu, ⁴Department of Medicine, Metabolism and Endocrinology, School of Medicine, Juntendo University, Tokyo, ⁵Health Center, Keio University School of Medicine, Tokyo, ⁶Department of Internal Medicine, Division of Metabolism and Endocrinology, St. Marianna University School of Medicine, Kawasaki, ⁷Division of Endocrinology and Metabolism, Department of Internal Medicine, Kawasaki Medical School, Kurashiki, ⁸Sportology Center, Graduate School of Medicine, Juntendo University, Tokyo, ⁹Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Japan.

Background and aims: Recently, new genetic risk variants for type 2 diabetes (T2D), rs10906115 in CDC123/CAMK1D and rs1359790 near SPRY2, have been identified by a genome-wide association study (GWAS) in Chinese populations. To know the role of these variants in conferring susceptibility to T2D in the Japanese, we determined the association of the 2 single nucleotide polymorphisms (SNPs) with T2D in 11,839 Japanese individuals.

Materials and methods: We genotyped these SNPs using 8,719 T2D cases and 3,120 controls enrolled in several medical institutes in Japan. The genotype of each SNP was determined by multiplex PCR-invader assay. To test the additive model of each SNP, genotype distribution differences between the case and control groups were analyzed using a logistic regression analysis with or without adjusting age, sex and log-transformed (ln)BMI. The association of rs10906115 was further evaluated in a conditional analysis using rs12779790, which had been reported by a previous European GWAS of T2D, in the same logistic model for 2,798 cases and 2,403 controls. We also performed quantitative traits analyses for fasting plasma glucose (FPG), homeostasis model assessment (HOMA)- β and HOMA-IR in 1,392 non-diabetic Japanese individuals by multiple linear regression analysis with or without adjusting age, sex and lnBMI.

Results: The observed T2D risk alleles, rs10906115-A and rs1359790-G, were in accord with those previously reported in other East Asian populations, and both of variants were significantly associated with susceptibility to T2D in the present Japanese population (rs10906115; OR = 1.14, 95% CI = 1.08 - 1.21, $p = 9.38 \times 10^{-6}$, rs1359790; OR = 1.13, 95% CI = 1.06 - 1.21, $p = 3.04 \times 10^{-4}$). Adjustment of age, sex and lnBMI did not have significant effect on the association of these SNPs with the disease. The result of conditional analysis revealed

that the association of rs10906115 with T2D ($p=0.001$ before conditioning on rs12779790), remained significant even after conditioning on rs12779790 ($p=0.0051$). We could not observe significant associations of the 2 SNPs with any of BMI, FPG, HOMA- β or HOMA-IR ($p>0.05$).

Conclusion: Rs10906115-A and rs1359790-G had significant association with T2D in a Japanese population. Therefore, these two variants are considered as common susceptibility variants for T2D among East Asian populations.

Genome-wide joint meta-analysis of SNP by BMI interaction on fasting insulin: a MAGIC study

R.A. Scott¹, A.K. Manning², M.-F. Hivert³, N. Bouatia-Naji⁴, J. Grimsby⁵, C.-T. Liu², H. Chen², L.F. Bielak⁶, L. Rasmussen-Torvik⁷, N.J. Wareham¹, R.M. Watanabe⁸, J.C. Florez^{5,9}, C. Langenberg¹, J. Dupuis^{2,10}, J.B. Meigs^{9,5}, ¹MRC Epidemiology Unit, Cambridge, UK, ²Boston University School of Public Health, Boston, USA, ³Université de Sherbrooke, Quebec, Canada, ⁴Pasteur Institute, Lille, France, ⁵Massachusetts General Hospital, Boston, ⁶University of Michigan School of Public Health, Ann Arbor, ⁷Northwestern University Feinberg School of Medicine, Chicago, ⁸Keck School of Medicine of USC, Los Angeles, ⁹Harvard Medical School, Boston, ¹⁰National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, USA.

Background and aims: Type 2 diabetes (T2D) is a complex disease resulting from both genetic and lifestyle/behavioural factors. A large number of genetic regions associated with T2D or related traits have recently been reported. Most of these appear to be associated with β -cell function rather than insulin resistance (IR). For example, in recent meta-analyses, 16 loci were significantly associated with fasting glucose (FG), but only two were significantly associated with fasting insulin (FI). As body mass index (BMI) is a key risk factor for both IR and T2D, heterogeneity introduced by BMI may obscure genetic IR signals. We aimed to identify novel genetic IR signals by accounting for both BMI and gene by BMI interactions in a genome-wide association study of FI.

Materials and methods: We conducted study-level single nucleotide polymorphism (SNP) by BMI (SNP×BMI) interaction regression models on ln(FI) and meta-analysed SNP and SNP×BMI associations across 29 cohorts comprising up to 51,750 individuals without T2D, using the newly developed joint meta-analysis method. Thirty-one SNPs reaching a threshold of $P<10^{-5}$ were taken forward to replication in 18 additional cohorts comprising up to 27,518 individuals. For these SNPs, we also investigated SNP associations with ln(FI), stratified by level of BMI (less than vs greater than or equal to 28 kg/m²).

Results: We identified 6 genomic regions newly associated with FI at $P<5\times 10^{-8}$ in combined discovery and replication analyses. A SNP near GRB14 was the most significant signal ($P=1.3\times 10^{-19}$), and showed a larger effect size in heavier ($\beta=0.038$, $P=1.6\times 10^{-8}$) compared to lighter individuals ($\beta=0.018$, $P=3.0\times 10^{-5}$) ($P_{\text{interaction}}=0.04$). In contrast, a SNP near IRS1 was associated with FI ($P=4.4\times 10^{-14}$), but showed similar effect sizes in both BMI strata (lighter $\beta=-0.018$, $P=3.8\times 10^{-10}$; heavier $\beta=-0.021$, $P=1.7\times 10^{-5}$). Additional SNPs near PPP1R3B, PDGFC, PEPD, and LYPLAL1 also showed genome-wide significant associations with FI. All newly identified FI-raising alleles were also found to be associated with both lower HDL ($P<0.001$) and higher triglyceride levels ($P<0.02$): a combination which is a hall-mark of IR.

Conclusion: We identified novel genetic signals for IR by accounting for heterogeneity in BMI. These findings demonstrate the importance of accounting for other key risk factors when studying the genetic determinants of complex and multifactorial traits. Results for GRB14 also suggest that variation in BMI may modify genetic associations with IR.

167

High fibres intake associates with elevated risk increase of incident type 2 diabetes by TCF7L2 risk variant: evidence for putative mechanism by apoptosis

G. Hindy, X.-J. Jing, Y. Zhou, E. Sonestedt, U.C. Ericson, O. Hansson, E. Renström, E. Wirfält, M. Orho-Melander;
Department of Clinical Sciences, Lund University, Malmö, Sweden.

Background and aims: TCF7L2 rs7903146 is the strongest and most widely replicated T2D susceptibility locus and has also been shown to associate with increased fasting plasma glucose and HbA_{1c} levels. As at least part of this risk increase has been indicated to be mediated by attenuated insulin response,

possibly due to diminished incretin effect, we investigated if dietary intakes of carbohydrates, fats, whole grains or fibers modify the increased risk of T2D by this variant. We then studied if butyrate, a fermentation product of dietary fibers, may affect apoptosis of β -cells, as this has been reported earlier to occur in colon cancer cells via activation of TCF4 encoded by TCF7L2.

Materials and Methods: Altogether 24,799 non-diabetic individuals (45-74 years) from the Malmö Diet and Cancer cohort with diet data based on a 7-day food diary, a 168-items diet questionnaire and a 1-h diet-history interview were followed-up for 12 years and 1,649 incident T2D cases were recorded. Risk of T2D in strata of diet tertiles and quintiles was analyzed by logistic regression adjusting for potential confounders. Among 5,251 non-diabetic individuals we analyzed association between rs7903146 and fasting plasma glucose and HbA_{1c} in diet tertiles adjusting for potential confounders. Interactions were assessed by adding diet tertiles, genotypes and their multiplicative term to the analysis. INS-1 832/13 cells were cultured for 48 hours in different butyrate concentrations. Cell death detection ELISA kit was used to measure apoptosis level at 100 μ M, 500 μ M, 1mM, 5mM, and 10mM of butyrate. Insulin secretion was measured by a RIA kit at 1mM butyrate concentration after 1 hour stimulation by 2.8 mM and 16.7 mM glucose.

Results: TCF7L2 T-allele was associated with a 44% (95% CI: 33-56%) increased risk of T2D ($p=4.6\times 10^{-19}$) and each additional T-allele associated with 0.070 mmol/L higher fasting plasma glucose ($P=0.001$) and 0.026% higher HbA_{1c} ($P=0.019$). No significant interactions were found between rs7903146 and intake level of carbohydrates, whole grains or fats on T2D risk. The risk of T2D by rs7903146 increased significantly by increasing fibers intake [OR: 1.27, 1.50, and 1.67 for low, medium and high tertiles ($P_{\text{interaction}}=0.05$) and OR: 1.19, 1.42, 1.52, 1.58, and 1.71 from lowest to highest quintiles ($P_{\text{interaction}}=0.006$)]. The associated effect size per each T-allele on HbA_{1c} increased with increasing fibers and whole grains intakes ($P_{\text{interaction}}=0.088$ and 0.044, respectively). Apoptosis level of INS-1 832/13 increased by rising butyrate concentrations ($p<0.0001$), with a significant increase at 1mM ($p=0.004$). Insulin secretion of INS-1 832/13 was 6-fold ($P=3\times 10^{-6}$) and 3-fold ($P=5\times 10^{-4}$) higher in the butyrate treated cells compared to non-treated cells after 2.8mM and 16.7mM glucose stimulation, respectively.

Conclusion: Although higher intake of fiber-rich foods has been indicated to be beneficial for health including the risk of T2D, our results suggest that the risk increase of T2D by the TCF7L2 T-allele may be accentuated by higher fibers intakes. TCF7L2 activation by increased systemic butyrate levels and subsequent β -cell apoptosis could be a possible mechanism for our epidemiologic findings.

A gene variant near ATM is significantly associated with metformin treatment response in type 2 diabetes: a replication and meta-analysis of two Dutch and two UK cohorts

L.M., t Hart^{1,2}, N. van Leeuwen³, K. Zhou³, M.L. Becker⁴, B.H.C. Stricker⁴, J.M. Dekker⁵, G. Nijpels⁵, H.M. Colhoun³, R.R. Holman⁶, M.I. McCarthy⁶, E.R. Pearson³;

¹Molecular Epidemiology, Leiden University Medical Center, ²Molecular Cell Biology, Leiden University Medical Center, Netherlands, ³Biomedical Research Institute, University of Dundee, Dundee, UK, ⁴Epidemiology, Erasmus University Medical Center, Rotterdam, ⁵EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, Netherlands, ⁶Oxford Center for Diabetes, Endocrinology and Metabolism, University of Oxford, UK.

Background and aims: Recently we have demonstrated that the rs11212617 SNP near the ATM gene is significantly associated with metformin treatment response in type 2 diabetes patients from the UK. In this study we attempt to replicate our original observation in two additional cohorts from the Netherlands and perform a meta-analysis of all available replication cohorts.

Materials and methods: From the Diabetes Care System West-Friesland (DCS, n=929) and the Rotterdam study (n=182) in the Netherlands we selected incident users of metformin, either as mono therapy or in combination with stable sulphonylurea treatment. Subjects were included regardless of the baseline pre-treatment HbA_{1c} and all subjects were genotyped for rs11212617 (MAF=0.44) using standard techniques. Association between the SNP and treatment success, defined as the ability to reach the treatment target of an HbA_{1c} $\leq 7\%$ (53 mmol/mol) was tested using logistic regression with adjustment for potential confounders; baseline HbA_{1c}, baseline gap, drug adherence, daily dose, treatment group and creatinine clearance. Meta-analysis

was performed using the above described cohorts and two UK replication cohorts from our original publication (GoDARTS, $n=1965$; UKPDS, $n=1113$). Furthermore we performed a meta-analysis of the linear regression with the treatment HbA1c as continuous outcome.

Results: In the DCS cohort we observed a significant association between rs11212617 and treatment success on metformin ($OR=1.27$; 95% CI 1.03–1.58; $p=0.028$). In the smaller Rotterdam cohort a similar but non-significant trend was observed ($OR=1.45$; 95% CI 0.87–2.39; $p=0.15$). In a meta-analysis of all replication cohorts including in total 4189 subjects but excluding the original discovery cohort from the UK, this SNP is significantly associated with metformin treatment success ($OR=1.26$; 95% CI 1.14–1.39; $p=5.0 \times 10^{-6}$). The observed positive effect of this SNP was numerically greater in those on mono therapy compared to the dual therapy group ($OR_{mono}=1.32$; 95% CI 1.16–1.50 versus $OR_{dual}=1.23$; 95% CI 1.02–1.50). We also noted a significant association with treatment HbA1c in the meta-analysis (Beta -0.063 ; 95% CI -0.103 – -0.022 , $p=2.3 \times 10^{-3}$).

Conclusion: A gene variant near *ATM* is significantly associated with metformin treatment response in type 2 diabetes patients from the Netherlands and the UK. This is the first robustly replicated common susceptibility locus associated with metformin treatment response and our results warrant further genetic studies to identify other loci affecting diabetes treatment response.

Adipose tissue alterations and liver disease in morbidly obese adolescent prior to bariatric surgery

J. Aron-Wisniewsky^{1,2}, J. Tordjman², J.-L. Bouillot³, A. Basdevant^{1,2}, K. Clément^{1,2};

¹Assistance Publique-Hôpitaux de Paris, Endocrinology and Nutrition Department, and Center of Human Nutrition (CRNH), ²Institut national de la santé et de la recherche médicale (INSERM), UMRS 872 team 7, Nutriomique ; Université Pierre et Marie Curie-Paris 6, Centre de Recherche des Cordeliers, ³Assistance Publique-Hôpitaux de Paris, Surgery Department, Cochin Hospital, Paris, France.

Background and aims: The growing epidemics of obesity affect adolescent and young adults. Early onset and severe obesity frequently persists at adult age. Therefore, obesity related conditions should be investigated early. The putative deterioration of adipose tissue (AT) or liver, two key tissues contributing to obesity related comorbidities are not well known in early onset obesity. We took advantage of a bariatric surgery programs in adolescent and young adults to explore liver and adipose tissue histopathology and compared them to adults with or without early onset obesity.

Materials and methods: After multidisciplinary and medical assessments, 15 adolescent (aged 19 ± 1.5 range [15–21]) were operated from bariatric surgery (group 1). We also chose two groups of 15 adults for comparison: group 2 was aged 47 ± 6 years with early onset obesity and group 3 was aged 52 ± 7 years with obesity starting after the age of 20. Group 2 had normal BMI at 20 years old (23.2 ± 1.7 kg/m²) whereas group 3 was already obese (BMI= 32.9 ± 4.5 kg/m²). All patients were evaluated for a series of bioclinical phenotypes. Importantly neither BMI nor body composition (DXA evaluated fat mass and fat free mass) differed among the three groups (48 ± 7 ; 46 ± 4 ; $\pm 43 \pm 6$ kg/m² respectively). During surgery, liver and paired surgical biopsies of subcutaneous (scWAT) and visceral (oWAT) adipose tissue were obtained. Adipocyte size and the number of HAM56 (a macrophage marker) positive cells normalized to 100 adipocytes was determined by immunohistochemistry.

Results: Histopathological evaluation of adipose tissue revealed that adolescent already had adipose tissue and liver alteration comparable to that of obese adults. We observed no difference in macrophage infiltration (scWAT $16.2 \pm 7\%$, oWAT= $19.4 \pm 6.2\%$) or adipocyte size (scWAT= 69.7 ± 13.3 , oWAT= 64.5 ± 13.4 μm) in the two sites of (AT) among the three groups. Regarding liver alterations in adolescent, 50% of the population presented steatosis (6 patients had grade I and 2 patients had grade II); 50% had fibrosis (6 patients scored 1 and 2 patients scored 2); none had overt NASH (Median NAS score was 1). Among adults in group 2, 50% of the population displayed steatosis (6 patients had grade III); 75% of this group had fibrosis (6 patients with stage 1 and 4 patients with stage 2); 20% had overt NASH (median NAS score of 3). Finally among group 3, 100% of the population presented steatosis grade II or III; 86 % of them had fibrosis (4 patients with stage 1, 5 patients with stage 2, 4 patients with stage 3); 33% of this group had overt NASH (Median NAS score was 4).

Conclusion: We demonstrate herein that young morbidly obese patients already have adipose and liver tissue perturbations. Their adipose tissue does not present any difference with that of adults presenting either early or latter onset obesity. Yet, both crown-like structures and macrophage phenotype (M2/M1) remain to be evaluated. On the contrary, our results suggest that liver alterations develop in a dose response manner to age and obesity duration.

CCR5 deficiency attenuates obesity-induced insulin resistance through M2 dominant shift in adipose tissue macrophage

T. Ota¹, K. Sawamoto¹, H. Kitade¹, Y. Yamamoto², H. Inoue¹, T. Takamura³, H. Yamamoto², N. Mukaida⁴, S. Kaneko³;

¹Frontier Science Organization, ²Biochemistry and Molecular Vascular Biology, ³Disease Control and Homeostasis, ⁴Cancer Research Institute, Kanazawa University, Japan.

Background and aims: Adipose tissue macrophage (ATM) accumulation through monocyte chemoattractant protein-1 (MCP-1) and its receptor CCR2 is considered pivotal in the development of insulin resistance. However, deficiency of MCP-1 or CCR2 does not normalize obesity-induced ATM recruitment and insulin resistance. Therefore, other chemokine systems could

also play a role in these processes. Recently, we demonstrated that loss of a different C-C chemokine receptor, CCR5, prevents insulin resistance induced by high fat (HF) feeding or leptin deficiency independently of MCP-1-CCR2. In the present study, we show that CCR5 plays a crucial role in the inflammatory response to HF feeding and obesity by regulating both macrophage recruitment and M1/M2 status.

Materials and methods: We compared gene expression levels of CCR5 and its ligands in stromal vascular (SV) fraction to adipocyte fraction of epididymal white adipose tissue (eWAT) of genetically (ob/ob) and HF diet-induced obese (DIO) mice. To quantify CCR5⁺ ATMs in lean and obese mice, fluorescence-activated cell sorter (FACS) analysis was performed on SV cells from eWAT of HF diet-induced obese (DIO) mice. Next, we performed bone marrow transplantation (BMT) of CCR5^{-/-} mice or wild type (WT) C57BL/6J mice donor cells into irradiated either WT or ob/ob recipient mice to generate myeloid cell specific chimeric mice.

Results: Expression of mRNA for CCR5 and its all ligands (MIP-1 α , MIP-1 β , RANTES, MCP-2) was markedly increased in SV fraction compared to adipocyte fraction of eWAT of ob/ob and DIO mice. Immunohistochemistry on eWAT in DIO mice localized CCR5⁺ cells to F4/80⁺ macrophages in crown-like structure. FACS analysis revealed that ATMs identified as CD45⁺CD11b⁺F4/80⁺ cells were increased in DIO mice by 12.2-fold compared with WT mice. Only a small percentage of ATMs coexpressed CCR5 in WT mice. However, DIO mice had 11.9-fold increase in CCR5⁺ cells within ATMs, indicating that CCR5⁺ macrophages accumulate in eWAT of obese mice. On a chow diet, no differences were observed in either CD11c⁺ MGL1⁺ (M1) or CD11c⁺ MGL1⁺ (M2) expression within ATMs from WT and Ccr5^{-/-} mice. However, on a HF diet, in addition to reduction of total ATM content, Ccr5^{-/-} mice had 39% fewer M1 ATMs whereas and 33% more M2 ATMs than WT mice, resulting in predominance of M2 over M1 ATM population. Importantly, chimeric mice lacking CCR5 only in myeloid cells (BM transplant of Ccr5^{-/-} into WT) were protected from HF diet-induced hyperinsulinemia (BM transplant of Ccr5^{-/-} into WT 2.6 \pm 0.3 vs WT into WT 5.1 \pm 1.1 ng/ml, p <0.05) and glucose intolerance. Furthermore, ob/ob mice reconstituted with Ccr5^{-/-} myeloid cells were strikingly resistant to the development of insulin resistance and glucose intolerance compared to ob/ob mice reconstituted with Ccr5^{+/+} myeloid cells.

Conclusion: CCR5⁺ ATMs accumulate in obese mouse models. Deficiency of CCR5 causes M2 dominant phenotypic shift in ATM, which contributes to attenuation of obesity-induced insulin resistance. Therefore, CCR5 plays a critical role in obesity-induced adipose tissue inflammation and insulin resistance by regulating both macrophage recruitment and M1/M2 status.

Visceral adipose tissue from obese diabetic patients has a stronger proliferative effect on smooth muscle cells and is characterised by higher expression and release of novel adipokines

R. Schlich¹, M. Willems^{1,2}, F. Ruppe², W.T. Knoefel², J. Eckel¹, H. Sell¹

¹Paul-Langerhans-Group, German Diabetes Center, ²University Hospital, Düsseldorf, Germany.

Background and aims: The accumulation of adipose tissue (AT) in obesity is an important risk factor for the development of metabolic syndrome. AT is known as a highly active endocrine organ, which is involved in many physiological processes by secreting adipokines. In a previous study, we characterized the secretome of *in vitro* differentiated human adipocytes using an unbiased proteomics approach, revealing novel adipokines like heme oxygenase-1 (HO-1), dipeptidyl peptidase-4 (DPP-4), factor H and alpha crystallin-B (CRYAB). The aim of this study is to characterize differential secretion and expression of these novel adipokines in visceral (VAT) and subcutaneous (SAT) AT of diabetic and non-diabetic patients and the impact of these various fat depots on the proliferation of human smooth muscle cells (SMC).

Materials and methods: SAT and VAT were obtained from lean ($n=14$, BMI 22.1 kg/m², mean age 65.9 yrs) and obese ($n=14$, BMI 34.7 kg/m², age 55.1 yrs) non-diabetics or lean ($n=5$, BMI 21.2 kg/m², age 70.8 yrs) and obese ($n=6$, BMI 36.7 kg/m², age 56.2 yrs) diabetics undergoing visceral surgery. Conditioned media (CM) were generated by using fat explants from paired SAT and VAT of each patient. VEGF and DPP-4 release were measured in CM by ELISA and protein level of novel adipokines in SAT and VAT were measured by Western Blot. Proliferation of primary human SMC treated with CM was measured by BrdU incorporation into DNA.

Results: The protein expression of CRYAB was significantly enhanced in VAT of obese non-diabetics (1.9-fold) as well as obese diabetics (1.6-fold)

compared to SAT of obese non-diabetics and diabetics. In contrast, there was no difference in CRYAB expression between fat depots of lean patients. Protein expression of factor H was elevated in VAT of lean and obese patients compared to their respective subcutaneous control. Expression of HO-1 was increased in VAT of obese non-diabetics (1.6-fold) as well as lean (1.8-fold) and obese (2.5-fold) diabetics compared to SAT of respective patients. In contrast to these novel adipokines, we also assessed adiponectin expression as a control and found decreased expression in VAT of lean and obese non-diabetics and diabetics as compared to SAT. Protein expression and secretion of DPP-4 was significantly enhanced in VAT of lean and obese patients with no differences between diabetics and non-diabetics. CM of VAT from obese non-diabetics significantly increased the proliferation of SMC (173.2 \pm 27.9 %) compared to SAT. Additionally, CM of SAT of obese diabetics induced a 1.5-fold increase of proliferation compared to SAT from lean diabetics. VAT from obese diabetics showed the strongest proliferative effect (233.5 \pm 17.5 %) compared to SAT of obese diabetics or VAT of lean non-diabetics. Proliferative effects were consistent with VEGF content of CM, which was significantly increased in VAT of obese non-diabetics (4.7-fold) and diabetics (6.1-fold).

Conclusion: This study revealed, that the protein level of novel adipokines, such as DPP-4, HO-1, factor H and CRYAB, was significantly increased in VAT from obese patients, especially obese diabetics. Furthermore VAT from obese diabetics had the strongest proliferative effect on SMC, indicating that the increased expression and release of these adipokines have an essential relevance linking obesity, diabetes and vascular dysfunction.

172

Lack of SIRT1 leads to angiogenesis deficiency in adipose tissue through macrophage and adipocyte dysfunction

F. Xu¹, D. Burk², Z. Gao², J. Yin², J. Ye², J. Weng¹

¹Endocrinology, The Third Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China, ²Pennington Biomedical Research Center, Baton Rouge, USA.

Background and aims: SIRT1 (Mammalian sirtuins 1) is a class III histone deacetylase whose activation is dependent on NAD⁺ in cells. The biological activity of SIRT1 remains to be investigated in the regulation of microcirculation. Angiogenesis in adipose tissue is regulated by angiogenic factors from adipocytes and macrophages. However, the relative importance is unclear for adipocytes and macrophages. In this study, we addressed these issues by analysis of adipocytes and macrophages in adipose tissue of SIRT1^{-/-} and SIRT1^{+/+} mice.

Materials and methods: SIRT1^{-/-} mice on 129/J background were interbred with C57BL/6 mice for generations to get SIRT1^{+/+} mice with C57BL/6 background. Then SIRT1^{-/-} male and female mice on C57BL/6 gene background were set up breeding to get SIRT1^{-/-} mice. The assay was based on an adipose tissue imaging with specific dye under a confocal microscope. Reconstruction of 3D data sets was accomplished using Imaris.

Results: We observed that the density of vascular network was decreased by 50% in the tip portion of epididymal adipose tissue in the SIRT1^{-/-} mice, but no significant reduction in SIRT1^{+/+} mice. The cellular basis of decreased angiogenesis was investigated with a focus on macrophages and adipocytes. Macrophage function is impaired in the SIRT1^{-/-} mice. Macrophage number is significantly reduced in adipose tissue and their expression of angiogenic factors were reduced in SIRT1^{-/-} mice. When macrophage was deleted with liposome-encapsulated clodronate in the wild type C56BL/6J mice, the density of vascular network was decreased and this reduction was associated with loss of angiogenic factors (PDGF) expression. Meanwhile, adipocytes function is also impaired in the adipose tissue of SIRT1^{-/-} mice as adiponectin and leptin expression was reduced dramatically. VEGF, Agarnase1 and IL-6 were decreased significantly on differentiated MEF in SIRT1^{-/-} mice. However, no significant defects above were observed in SIRT1^{+/+} mice.

Conclusion: The data suggests that SIRT1 may regulate angiogenesis in adipose tissue through its activity in macrophage and adipocyte in a gene-dose dependant way. SIRT1 "gene dose" influences angiogenesis in adipose tissue. Angiogenic defect occurs in SIRT1^{-/-}, but not SIRT1^{+/+} mice. Deficiency of adipocytes and macrophages in angiogenic factor expression contributes to the angiogenic defect in SIRT1^{-/-} adipose tissue. The observation supports a new mechanism of SIRT1 action in the regulation of vascular growth.

Immunosuppressive agents induce alterations in human subcutaneous adipose tissue gene expression and glucose and lipid metabolismM.J.R. Pereira^{1,2}, J. Palming¹, M. Rizell³, M. Gäbel³, M. Aureliano², E. Carvalho⁴, M.K. Svensson⁵, J.W. Eriksson⁶;¹The Lundberg Laboratory for Diabetes Research, University of Gothenburg, Sweden, ²Center for Marine Sciences, Faro, Portugal, ³Department of Surgery, University Hospital of Gothenburg, Sweden, ⁴CNC, University of Coimbra, Portugal, ⁵Department of Molecular and Clinical Medicine, University Hospital of Gothenburg, ⁶AstraZeneca R&D, Mölndal, Sweden.

Background and aims: Immunosuppressive agents (IA), such as cyclosporine (CsA), tacrolimus (FK) and rapamycin (Rap) can cause new-onset diabetes (NODAT) as well as dyslipidemia in solid organ-transplantation patients. The studies of the effects of IA in human adipocytes are few, and it is believed that it could be a good model to understand the effects of IA in humans. The aim of this study was to investigate whether IA could cause alterations on glucose and lipid metabolism as well as on gene expression in human subcutaneous adipose tissue.

Materials and methods: Abdominal subcutaneous adipose tissue was obtained from surgical and needle biopsies from healthy volunteers (24F/15M, 23–72 yrs, BMI: 21–36 kg/m²). Adipose tissue and isolated adipocytes were incubated in the absence and presence of IA: CsA and FK (0.1 µM) and Rap (0.01 µM). Basal and insulin-stimulated glucose uptake (n=18), lipolysis (n=13), signalling protein amount and phosphorylation (30 min, 3h and 20h, n=6) and gene expression (n=13) were assessed.

Results: It was observed that all three IA inhibited both basal: CsA 28%, FK 30% and Rap 18% (p<0.05) and insulin-stimulated: CsA 27%, FK 28% and Rap 26% (p<0.001) 14C-glucose uptake compared to controls. Rap decreased IRS2 protein levels and insulin-stimulated phosphorylation of PKB Ser473 by 20% (p<0.05) compared to control. A reduction in rictor-mTOR interaction was found after Rap treatment (35%, p=0.04). Following CsA and FK incubation the total expression and phosphorylation of initial proteins of the insulin signaling cascade: IR/IRS1-2/PKB/AS160, were not changed. Also, the protein level of GLUT4, or its gene expression was not changed, upon exposition to any of the IA. CsA, FK and Rap increased isoprenaline-stimulated lipolysis (30% p<0.01; 20% p<0.05 and 20% p<0.05, respectively) compared to control, but only Rap increased basal lipolysis (40% p<0.05). In addition, treatment with Rap was associated with increased perilipin and IL6 and a decrease of lipin1, leptin and the inflammatory mediator TNF-alpha gene expression (p<0.05) compared to control. Paradoxically, IRS2 gene expression was increased after Rap treatment (p<0.05). No effects of IA on IRS1, LPL, HSL and adiponectin gene expression were observed.

Conclusion: It was demonstrated for the first time that in human adipocytes CsA and FK at therapeutic concentrations inhibits both basal and insulin-stimulated glucose uptake, but did not change the initial steps of the insulin signaling cascade or GLUT4. Moreover, Rap may impair insulin action on glucose uptake by reducing IRS2 protein levels and AKT Ser473 phosphorylation in the human subcutaneous adipose tissue. All three IAs increased lipolysis but only Rap was found to alter gene expression of important lipolysis regulators and adipokines that may induce insulin resistance. These observed effects of IA in the adipose tissue could potentially contribute to the development of new-onset diabetes and dyslipidemia in solid organ-transplant patients.

Role of lipokines and oxysterols as novel adipose-derived lipid “hormones” linking adipose (dys)function and insulin resistanceG. Murdolo¹, C. Tortoioli¹, M. Piroddi¹, B. Canonico², F. Luchetti², L. Iuliano³, F. Galli¹;¹Dpt Internal Medicine, Perugia University, ²Dpt. of Earth, Life and Environmental, University of Urbino Carlo Bo, ³Dpt. of Medical Sciences and Biotechnology, Unit of Vascular Medicine, Sapienza University of Rome, Italy.

Background and aims: Experimental data suggest that lipokines (adipose-derived “lipid-hormones”) and oxysterols (oxidized derivatives of cholesterol) may play an important role in linking the adipose organ (dys)function with impaired glucose homeostasis. Yet, the role of these lipid hormones/oxi-

dation derivatives in human adipose tissue (AT) remains largely unexplored. Here we combined a “lipidomic” approach (gas chromatography-mass spectrometry) with the subcutaneous (SC) microdialysis technique to characterize the adipose-derived profile of fatty acids (FA) and oxysterols *in vivo*. Also, we tested the hypothesis that 7-ketocholesterol (7κ-C) and 4-hydroxynonenal (4-HNE), the more representative oxidation products of cholesterol and polyunsaturated fatty acids, respectively, may modulate the lineage-specific differentiation of adipose-derived stem cells (ASC).

Materials and methods: Abdominal SC, mesenteric (MES) and omental (OM) fat specimens were obtained from obese nondiabetic (OB) and type 2 diabetic (OBT2D) patients. Flow cytometry and western blot analysis were performed on isolated ASC and whole tissue specimens for cell sorting and oxidative stress evaluation, respectively.

Results: In AT interstitial fluid, abundant concentrations of oxysterols (ie, 7κ-C) and lipokines were found. The major FA in dialysate were palmitic (16:0, 27%), stearic (18:0, 23%), elaidic (18:1 *n*-9*t*, 20%) and linoleic (18:2 *n*-6, 14%) acid, which made about 85% of total FA. The profile of FA in plasma, showed higher oleic (18:1 *n*-9, 22 vs 1.4%) and linoleic (26 vs 14%), lower stearic (8 vs 23%) and similar palmitic (22 vs 27%) and palmitoleic (16:1, 1.6 vs 1.8) acid, as compared with interstitial fluid. The immunophenotype of isolated ASC revealed positivity for CD29, CD44, CD71, CD90 and CD106 (mesenchymal stem cell markers), with slight CD34 (endothelial stem cell marker), but negative CD135, CD11b, CD45 and HLA-DR (leukocyte and macrophage markers) expression. After incubation with 7κ-C at 10–100 µM, CD29/CD106/CD34-positive precursor cells from the SC, MES and OM fat depot showed a dose-dependent decrease in cell viability, while at levels resembling those found in dialysate (>1<10 µM) 7κ-C challenge virtually abolished adipogenic differentiation without affecting cell viability. In OBT2D patients, adipogenic differentiation (Oil Red O) of the SC precursor cells was further impaired, as compared with that of ASC from OB individuals. Accordingly, in the SC fat of OBT2D patients, the expression of 4-HNE was meaningfully increased when compared with that of OB subjects that, in turn, displayed more abundant 4-HNE expression in OM and MES than in SC fat depot, respectively. Finally, activation of the WNT-signaling pathway by 7κ-C and 4-HNE is under investigation.

Conclusion: Human AT emerges as a critical compartment for storage and secretion of lipokines and oxysterols, which, when in excess, may detrimentally affect the adipogenic differentiation of ASC. We thus suggest the adipose-derived lipid hormones and oxidized cholesterol derivatives as new players involved in adipose organ dysregulation and “diabetic” adiposopathy. Alterations in the corneal nerve plexus of diabetic NOD mice

M. Reichard¹, H. Weiss², M. Tiedge², R.F. Guthoff¹, O. Stachs¹, S. Baltrusch²;¹Department of Ophthalmology; ²Institute of Medical Biochemistry and Molecular Biology, University of Rostock, Germany.

Background and aims: Macro- and microangiopathy are serious long-term consequences of diabetes mellitus. Patients with type 1 diabetes mellitus have particularly a high risk to develop neuropathy. Engineering of in-vivo confocal laser scanning microscopy in recent years facilitate for the first time examination of the human cornea. Implementation of this innovative technique has provided direct evidence for distinct changes of the corneal nerves due to diabetes mellitus in humans. This raised the question whether corneal neuropathy directly correlates with hyperglycaemia. The NOD mouse is a well characterized animal model of type 1 diabetes mellitus. Therefore the aim of this study was to establish in-vivo visualization of corneal nerves in NOD mice by confocal laser scanning microscopy and to compare corneal innervations in diabetic and healthy animals.

Materials and methods: NOD mice were characterized by measuring auto-antibodies against insulin, blood glucose and HbA1c. For confocal laser scanning microscopy the animals were anesthetized and fixed to avoid movement. The eye was moistened with a carbomer gel and the cornea was visualized by single image acquisition or a z-layer image sequence by confocal laser scanning microscopy (HRTII + RCM, Heidelberg Engineering). Thereafter images were analysed using AutoQuant/AutoDeblur Software (Media Cybernetics).

Results: NOD mice with a high level of auto-antibodies against insulin at the age of 20 weeks were classified as diabetic. These animals had with 24 mmol/l and 10.5 % a significant higher blood glucose level and HbA1c value, respectively in comparison with healthy animals (5 mmol/l and 4%). Five healthy and diabetic mice each were examined by corneal confocal laser scanning microscopy. Quantification of the total number of nerves per image frame revealed a significant reduction in sub-basal nerves in diabetic NOD mice compared with their healthy littermates. Furthermore a reduction in the homogeneous linear texture of the nerves was observed in diabetic NOD mice. Deconvolution of a z-layer image sequence revealed a beaded structure of nerve bundles in healthy mice in a comparable manner as previously described in humans.

Conclusion: We could demonstrate for the first time in-vivo confocal laser scanning microscopy of mouse corneal nerves in healthy and diabetic NOD mice. It will be the challenge of a comprehensive study to elucidate correlations of hyperglycaemia and alterations in corneal nerves in terms of time response, reversibility and protection. This will pave the way to establish this non-invasive technique as an early diagnostic criterion of diabetes mellitus.

Autonomic neuropathy depresses circulating angiogenic cells

M. Albiero^{1,2}, L. Menegazzo^{1,2}, E. Boscaro¹, A. Avogaro^{1,2}, G.P. Fadini^{1,2};¹Department of Clinical and Experimental Medicine, University of Padova,²Venetian Institute of Molecular Medicine (VIMM), Padova, Italy.

Background and aims: Diabetic patients have reduced levels of circulating endothelial progenitor cells (EPCs), which may contribute to vascular complications. The mechanisms accounting for reduced EPCs in diabetes are incompletely understood and include a defective bone marrow mobilization. Experimental data indicate that bone marrow autonomic neuropathy hampers mobilization of EPCs to the bloodstream and precedes the development of retinopathy. We aimed to assess the association and causal relationship between cardiac autonomic neuropathy (CAN) in diabetes.

Materials and methods: We have enrolled 65 diabetic patients in an observational study. We determined the level of circulating CD34+ angiogenic cells. We collected anthropometric data and information on concomitant risk factors and diabetic complications. The patients were subjected to 4 CAN tests: orthostatic hypotension; valsalva maneuver; lying-to-standing; deep breathing. Patients were divided according to the number of altered CAN tests. Age specific threshold were used. To understand the causal relationship between autonomic denervation and alteration in angiogenic cells, we measured

CD34+Flk1+ endothelial progenitor cells (EPCs) in wild type C57Bl/6 mice (n=4) before and after treatment with the gangliotoxin 6-hydroxy-DOPA (6-OH-DOPA).

Results: Out of 65 diabetic patients included in the study, 39 had normal CAN tests, 14 had one pathologic CAN test and 12 had at least two pathologic CAN tests. Patients with 2+ pathologic CAN tests had a significant 40% reduction of circulating CD34+ cells (p=0.002). A linear inverse correlation was found between number of altered CAN tests and CD34+ cell level (r=-0.38; p<0.001). Significant correlations were also found between CD34+ cells and single CAN test indexes (deep breathing: r=0.32; p=0.006; lying-to-standing: r=0.41; p<0.001; Valsalva maneuver: r=0.34; p=0.003; orthostatic hypotension: r=-0.29; p=0.014). In mice, the level of circulating EPCs was significantly reduced by about 50% after pharmacologic induction of experimental autonomic neuropathy (35.6±15.5 vs 19.3±9.20 cells/millions of events, control vs 6-OH-DOPA, p=0.005).

Conclusion: Autonomic neuropathy in diabetic patients is strongly associated with depletion of circulating angiogenic cells. According to preliminary data in mice, this association may have a causal relationship.

Evaluation of the Neuropad[®] sudomotor function test as a screening tool for polyneuropathy in the elderly population with diabetes and prediabetes: the KORA F4 survey

D. Ziegler^{1,2}, N. Papanas¹, M. Heier³, W. Rathmann⁴, M. Scheer⁴,C. Meisinger³, KORA Study Group;¹Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf,²Department of Metabolic Diseases, University Hospital, Düsseldorf,³Institute of Epidemiology II, Helmholtz Zentrum München, Neuherberg,⁴Institute of Biometrics and Epidemiology, German Diabetes Center, Düsseldorf, Germany.

Background and aims: Neuropad[®] is a new indicator test for sudomotor dysfunction. This study aimed to examine the sensitivity and specificity of Neuropad[®] as a screening tool for distal symmetric polyneuropathy (DSPN) among elderly subjects with diabetes and pre-diabetes in the general population.

Materials and methods: The population-based KORA (Cooperative Health Research in the Region of Augsburg) S4 survey (1999–2001) included 2656 subjects aged 55–74 years, who were living in the region of Augsburg, Germany. Of these, 1653 participated and 1353 subjects without known diabetes had an oral glucose tolerance test (OGTT) at baseline. This cohort was re-examined between 2006 and 2008 (F4 survey) including 1129 subjects aged 61–82 years (mean±SD: 69.8±6.5 years). Of these, 940 subjects were available for re-examination after 189 subjects had been excluded due to relevant neurological and musculoskeletal diseases. Based on the previous diagnosis of diabetes or OGTT results in F4, 201 subjects had diabetes (148 with known diabetes, 53 with diabetes detected by OGTT) and 231 had pre-diabetes (WHO 1999 criteria). Neuropad[®] was applied on a callus-free area between the 1st and 2nd metatarsal head on the plantar aspect of the foot and the result was read at 10 minutes (normal: complete colour change from blue to pink; abnormal: no/incomplete colour change). DSPN was diagnosed by clinical neurological examination using the Michigan Neuropathy Screening Instrument (MNSI) and defined as an MNSI score >2.

Results: DSPN was diagnosed in 74 (36.8%) subjects with diabetes and in 72 (31.2%) persons with pre-diabetes, respectively. The sensitivity and negative predictive value (NPV) of Neuropad[®] for the diagnosis of DSPN were moderately high, reaching 75.7% and 71.9% in subjects with diabetes and 68.1% and 71.6% in those with pre-diabetes, respectively. In contrast, the specificity and positive predictive value (PPV) for the diagnosis of DSPN were relatively low, yielding only 36.2% and 40.9% in diabetic individuals and 36.5% and 32.7% in persons with pre-diabetes, respectively.

Conclusion: In the elderly general population, Neuropad[®] has reasonable sensitivity but rather low specificity for the diagnosis of DSPN. It is a useful simple and inexpensive tool to screen for and to exclude DSPN as desired, while its low specificity implies that a longer reading time merits consideration in older subjects with diabetes and pre-diabetes.

The modified LDI Flare technique demonstrates sub maximal stimulation of C-fibres with current methods and reveals abnormal C-fibre function in individuals with diabetes

P.R.J. Vas, G. Rayman;

The Diabetes Centre, Ipswich Hospital NHS Trust, Ipswich, UK.

Background and aims: Diabetic peripheral neuropathy (DPN) can affect at least 50% of individuals with diabetes and results in significant morbidity, mortality and healthcare costs. There is increasing evidence that small unmyelinated fibres which mediate pain and temperature (C-fibres) are damaged in early diabetes before clinical signs or electrophysiological changes arise. We have developed a non-invasive method of assessing C-fibre function involving skin heating to 44°C using a 1cm² probe and measuring the resultant flare area (LDIflare). We had chosen this temperature as temperatures between 42–44°C have been shown to stimulate maximal hyperaemia (LDImax), a marker of endothelial function, and therefore, we assumed were likely to also maximally stimulate C-fibre activation. In this study we have challenged our assumption by studying subjects at 44°C and 47°C. The latter method we have termed the modified LDIflare (mLDIflare) and the previous method the original LDIflare (oLDIflare).

Materials and methods: Our first study was in a group of healthy controls (HC, n=18, males=7 aged 40.3±11.2 years (mean±SD). Our second study included a group of individuals with diabetes and without clinical neuropathy (DN-, n=18) and a group with clinical neuropathy (DN+, n=10) and compared them to findings in HC. Mann-Whitney U test was used to compare the variables.

Results: In the first study of HC, LDImax was not different in the two methods (oLDImax= 811±179 PU, mLDImax = 845 ±157 PU, P=NS). In contrast mLDIflare produced a significantly bigger flare response (oLDIflare = 5.79±1.9 cm², mLDIflare = 11.2± 2.66 cm² (P<0.0001). Correlation between the two methods was r=0.81, P<0.0001). In the second study in DN- subjects the oLDIflare was significantly smaller compared with HC and DN-subjects (oLDIflare area: DN- = 4.44±0.93 cm² v HC=5.79±1.9 cm², and DN+ 1.58±0.15 cm²; P<0.0001 and P=0.01, respectively (Figure 1). The corresponding mLDIflares in DN- = 8.95±1.88 cm² (P<0.0001 compared to oLDIflare), and DN+ = 1.88±0.7 cm² p=NS compared to oLDIflare). The percentage increase in flare area in DN- was similar to HC (109±62% and 92±41% respectively, p=0.39) but was significantly lower in DN+ (10.5±12.1%, p<0.0001).

Conclusion: These results confirm that in healthy individuals 44°C induces maximal vasodilatation, and demonstrate that C-fibres are submaximally stimulated at this temperature. They also suggest that the nerve axon reflex pathway is an independent measure of C-fibre function and is independent of endothelial function. Although individuals with diabetes without neuropathy have impaired neurovascular responses they are able to augment C-fibre function similar to healthy controls, however this does not occur in the presence of clinical neuropathy.

Fig 1. Comparative oLDIflare and mLDIflare areas (cm²) in the 3 groups studied.

The neural correlates of central pain processing in diabetic neuropathy - a functional magnetic resonance imaging study

D. Selvarajah¹, J. Davies¹, A. Sankar¹, E. Cachia¹, I. Tracey², I. Wilkinson³, S. Tesfaye¹;¹Diabetes Research Unit, University of Sheffield, ²fMRIB, Oxford University,³Academic Unit of Radiology, University of Sheffield, UK.

Background and aims: Patients with painful diabetic neuropathy (DN) suffer with distressing and disabling symptoms. Unfortunately, current treatments for painful-DN are inadequate, partly as the development of new analgesics has been hindered by the poor translation of their efficacy from

animal studies to the human condition. There is thus a clear need to develop objective biomarkers of neuropathic pain in order to evaluate the efficacy of new therapies. The aim of this study was to investigate the brain's responses to acute painful stimuli to identify the neural correlates of central nociceptive processing in DN.

Materials and methods: 34 age and sex matched groups type 1 diabetes subjects (12 no-DN, 11 painful-DN and 11 painless-DN), 12 healthy volunteers (HV) and 12 disease control subjects with chemotherapy induced painful neuropathy (CIPN) underwent functional magnetic resonance imaging during noxious heat versus pain-free baseline thermal stimulation in a 'boxcar' paradigm. This was performed on the neuropathic site (dorsum of foot) and non-neuropathic site (anterior thigh). Images were analysed using SPM (www.fil.ion.ucl.ac.uk/SPM). Prior to scanning all subjects had detailed characterisation of peripheral neuropathy [NIS(LL)+7 tests] and pain phenotyping. Painful neuropathy subjects had severe neuropathic pain (Likert scale NRS > 4) below the knees.

Results: Painful stimuli delivered to the neuropathic foot resulted in significantly greater activation in the dorsolateral prefrontal cortex (DLPFC, Talairach coordinates -8, 0, 31mm, p<0.001 uncorrected; Figure B) and cingulate gyrus (-8,0,31mm, p<0.001; Figure A) in painful-DN compared to HV. Increased activation in these regions persisted during nociceptive stimulation of the non-neuropathic thigh location in painful-DN compared with painless-DN. In contrast, when compared to HV, CIPN subjects did not demonstrate a similar pattern of neuronal activation as seen in painful-DN. Subjects with painful-DN had greater activation of the paracentral gyrus (-10,-12,44mm, p<0.001) when compared with CIPN.

Conclusion: The prefrontal cortex is involved in processing of emotions and mood. Increased activation reflects the cognitive set of painful-DN with high prevalence of mood disorders. The cingulate gyrus processes the 'suffering' component of pain. Increased activation suggests greater emphasis on the affective dimension in acute pain processing in painful-DN not seen in the disease control group. The paracentral gyrus is involved in processing sensory signals from the lower limb. Together with the cingulate gyrus, these two regions may serve as objective neural correlates of pain in DN. Further validation studies are required to examine the utility of this technique to evaluate the efficacy of new therapies.

Predictors of peripheral neuropathy and effects of fenofibrate among 9,795 subjects with type 2 diabetes: the fenofibrate intervention and event lowering in diabetes (FIELD) study

A.C. Keech, J.K. Rajamani, J.D. Best, G. Hankey, M.W. Donoghoe, L. Li, A.J. Jenkins, R. Ting, T.M.E. Davis, P. Phillips, P. Barter;

c/o NHMRC Clinical Trials Centre, The University of Sydney, Camperdown, Sydney, Australia.

Background and aims: Peripheral neuropathy, a significant microvascular complication of diabetes, leads to impaired quality of life, and lower limb ulcer formation and amputation. The aim of this analysis was to explore characteristics associated with neuropathy and the effects on it of long-term treatment with the lipid-modifying drug, fenofibrate.

Materials and methods: 9,795 patients with type 2 diabetes mellitus were randomised to co-micronised fenofibrate 200 mg/day or matching placebo for 5 years. The presence of neuropathy symptoms was recorded at baseline and sensation tested using a standard 10-G monofilament, repeated at 2 years and study close. All non-traumatic lower limb amputations were recorded, and classified as major or minor. Risk models used exhaustive search methods in logistic regression.

Results: 17.2% (1689 of 9795) of participants had features of peripheral neuropathy at baseline (1125 had symptoms without abnormal monofilament;

564 had abnormal monofilament). Factors associated with onset of new neuropathy included age, diabetes duration, high HbA_{1c}, prior retinopathy, hypertriglyceridaemia, history of CVD, and height (all $p < 0.03$). The prevalence of an abnormal monofilament test at study close was significantly lower among those allocated to receive fenofibrate than placebo (6.9% versus 8.2%; RR 0.81 [95%CI 0.72–0.93, $p = 0.002$ adjusted for baseline, with significantly less new neuropathy with fenofibrate treatment, and significant reversal of baseline monofilament abnormality with treatment (RR=1.28, [95% CI 1.06–1.55], $p = 0.01$). Neuropathy was one of the strongest predictors of amputation, increasing the risk of a first amputation approximately sixteen-fold for those with both symptoms and an abnormal monofilament test at baseline ($P < 0.001$) in whom the number needed to treat (NNT) over 5 years to avoid a first on-study amputation with fenofibrate treatment was only 16.

Conclusion: Treatment with fenofibrate reduced overall monofilament abnormality as a marker of neuropathy and increased the reversal of pre-existing monofilament abnormality in type 2 diabetes, although the mechanisms remain unknown. These benefits could potentially explain the large 37% reduction seen in amputations with fenofibrate use in the FIELD study.

Effect of Roux-En-Y gastric bypass on beta cell function and glucose metabolism in type 2 diabetic and non-diabetic patients

S. Camastra¹, A. Gastaldelli², A. Mari³, B.D. Astiarraga¹, D. Ciociaro², E. Barsotti¹, E. Buzzigoli², S. Frascerra¹, M. Anselmino⁴, E. Muscelli¹, E. Ferrannini¹;

¹Department of Internal Medicine, University of Pisa, ²Institute of Clinical Physiology, CNR, Pisa, ³Institute of Biomedical Engineering, CNR, Padua,

⁴Bariatric Division, AOP, Pisa, Italy.

Background and aims: Roux-en-Y gastric bypass (RYGB) surgery leads to remission of diabetes (T2D) in a high percentage of cases; the mechanisms are not completely understood. While recent data suggest an effect of RYGB on beta cell function in T2D patients early after surgery, the long-term effects have not been investigated.

Materials and methods: We measured the metabolic response to a mixed meal (MMT) in 16 morbidly obese non-diabetic (M-Ob) and 13 morbidly obese T2D patients before (BMI=52±1 and 50±2 kg/m², respectively) and one year after RYGB (BMI=36±2 and 33±2, respectively, $p < 0.0001$); 7 normal-weight subjects (Ct, BMI=23±1) and 14 obese volunteers BMI-matched to postsurgery patients (Ob, BMI=34±1) served as controls. MMT was combined with the double tracer technique and mathematical modelling to measure β -cell glucose sensitivity (β -GS), rate of oral glucose appearance (RaO) and endogenous glucose production (EGP).

Results: In T2D, surgery normalised fasting plasma glucose (8.6±0.8 to 5.3±0.2 mM, $p = 0.005$) and HbA_{1c} levels (7.3±0.5 to 5.4±0.1%, $p < 0.01$). On the MMT, the postprandial plasma glucose and insulin secretion patterns were similar in T2D and M-Ob, with a rapid increase after ingestion of the meal followed by a sharp drop. In M-Ob, β -GS decreased slightly (from 125[63] to 91[19] pmol·min⁻¹·m⁻²·mM⁻¹, median[IQR], $p = 0.02$), but was still within the normal range ($p = \text{ns}$ vs Ct or Ob); in T2D, β -GS doubled (from 33[29] to 62[54] pmol·min⁻¹·m⁻²·mM⁻¹, $p = 0.05$) but did not normalize ($p < 0.05$ vs Ct or Ob). RaO patterns were similar in T2D and M-Ob, with a rapid increase after meal ingestion followed by a sharp drop, indicating rapid absorption of glucose; RaO area-under-curve was unchanged. In both surgical groups, the EGP time-course was the mirror image of Rao, the drop in Rao being synchronous with an increase in EGP. EGP area-under-curve increased in both M-Ob (from 1.57[0.80] to 2.1 [0.89] mmol·kg_{FEM}⁻¹·h⁻¹, $p = 0.008$) and T2D (from 1.38[1.22] to 2.26[1.4], $p = 0.05$) and in both was higher than in Ob or Ct ($p = 0.02$ for both). In both M-Ob and T2D, fasting plasma glucagon levels decreased but post-meal glucagon excursions were accentuated post-surgery.

Conclusion: Following RYGB-induced major weight loss, the glycaemic response to a mixed meal shows a biphasic, dumping-like, time-course, which is associated with augmented EGP and hyperglucagonaemia, presumably to counter late post-meal hypoglycaemia.

182

Improved glucose metabolism early after gastric bypass surgery relies primarily on enhanced insulin sensitivity

E. Švehlíková¹, S. Zahiragic¹, T.R. Pieber¹, A. Tuca¹, B.M. Obermayer-Pietsch¹, O. Freisinger², B. Ernst³, B. Wilms³, M. Thurnheer³, B. Schultes³;

¹Division of Endocrinology and Metabolism, Medical University of

Graz, ²Department of Surgery, Medical University of Graz, Austria,

³Interdisciplinary Obesity Center, Kantonsspital St. Gallen, Switzerland.

Background and aims: Gastric bypass surgery has been shown to resolve type 2 diabetes but the underlying mechanisms are incompletely understood. The aim of the study was to quantify changes in beta cell function and insulin sensitivity before and shortly after gastric bypass in type 2 diabetic (DM) patients and non-diabetic patients (non-DM) with severe obesity.

Materials and methods: Before and 8 to 21 days after the surgery, 20 DM patients (10 patients with diabetes duration ≥ 9 years) and 8 non-diabetic patients underwent an oral glucose tolerance test (OGTT) and a botnia clamp which combines an IVGTT with a subsequent hyperinsulinaemic-euglycaemic clamp. Established models were used to calculate various indices of glucose metabolism. During OGTT, glucagon-like peptide 1 (GLP-1) and glucagon time profiles were assessed.

Results: After surgery, a comparable decrease in body weight and BMI was achieved in the DM and non-DM group. HbA_{1c}, fasting glucose and 2h glucose response in the OGTT declined after surgery in DM (all $p < 0.05$). DM patients with a disease duration of ≥ 9 years showed a greater glucose AUC during OGTT than patients with a shorter diabetes duration before as well as after surgery (both $p < 0.05$) but a comparable improvement induced by the surgery. Among the OGTT insulin secretion indices, only the ratio AUC C-peptide/AUC glucose pointed to slightly improved insulin secretion in the DM patients (pre- vs. postoperative 0.37 ± 0.06 vs. 0.58 ± 0.08 ; $p < 0.01$), which overall remained substantially impaired when compared to the non-DM patients (pre- vs. postoperative 1.21 ± 0.06 vs. 1.44 ± 0.07). None of the insulin secretion indices differed between patients with a long or short diabetes duration. Indices of insulin sensitivity showed a marked improvement in DM patients (e.g. glucose disposal: 2.34 ± 0.42 vs. 4.11 ± 0.35 mg·kg⁻¹·min⁻¹; $p < 0.001$) which did not depend on the disease duration, whereas no such postoperative changes were observed in non-DM group. Plasma GLP-1 and glucagon concentrations showed a distinctly greater increase after the oral glucose load after than before surgery independently of the DM state (all $p < 0.05$).

Conclusion: The improvement in insulin sensitivity appears to be the main factor underlying the improvement in glucose metabolism shortly after gastric bypass surgery. Despite of a markedly enhanced GLP-1 response in OGTT there was only a mild improvement in insulin secretion which still remained impaired in comparison to non-DM patients. The unexpected enhanced rise in glucagon levels during the OGTT points to a substantial stimulatory effect of gastric bypass on alpha cell function.

Enhanced myocardial glucose uptake after bariatric surgery in morbidly obese subjects

J.C. Hannukainen¹, H.M. Immonen¹, M. Soinio², K.A. Virtanen¹, P. Salminen³, M. Helmiö³, T.T. Pham¹, V. Lepomäki¹, R. Parkkola⁴, P. Nuutila¹; ¹Turku PET Centre, University of Turku, ²Department of Medicine, Turku University Hospital, ³Department of Surgery, Turku University Hospital, ⁴Department of Radiology, Turku University Hospital, Finland.

Background and aims: Obesity and type 2 diabetes are associated with higher uptake and oxidation of fatty acids and insulin resistance, but insulin stimulated glucose uptake (GU) of the heart has been normal in patients with moderate obesity. The aim of this study was to investigate heart metabolism and function in morbidly obese subjects and evaluate the effects of bariatric surgery-induced weight loss in adult obese non-diabetic and diabetic patients.

Materials and methods: Eight non-diabetic (BMI 42.6 ± 3.5 kg/m²) and 15 diabetic or pre-diabetic obese patients (BMI 44.1 ± 4.1 kg/m²) were studied before and six months after a bariatric surgery and compared to ten healthy volunteers (BMI 23.7 ± 1.8 kg/m²). Heart GU was measured with fluorine 18-2-fluoro-2-deoxyglucose and positron emission tomography during euglycemic hyperinsulinemic clamp. Myocardial triglyceride content, cardiac structure and function were assessed with magnetic resonance imaging and magnetic resonance spectroscopy.

Results: Body weight and BMI decreased similarly after the bariatric surgery in the non-diabetic and the diabetic group (BMI - 20 ± 6 % in non-diabetics and - 25 ± 6 % in diabetics, $p < 0.001$ vs. baseline). OGTT was normalized in 10 out of 13 patients after the follow-up. Heart GU increased after the surgery (from 23.5 ± 8.9 to 34.6 ± 11.0 $\mu\text{mol}/100\text{g}/\text{min}$ in non-diabetic, $p = 0.02$, and from 23.4 ± 13.0 to 32.0 ± 10.1 $\mu\text{mol}/100\text{g}/\text{min}$, $p = 0.01$, in diabetic group). No group differences were observed in heart GU or myocardial triglyceride content before or after the bariatric surgery. Whole-body insulin mediated glucose uptake (M-value) was significantly impaired in both groups (non-diabetic 14.0 ± 7.0 and diabetic 11.8 ± 5.2 $\mu\text{mol}/\text{min}/\text{kg}$) and improved post-operatively by 81 ± 48 % and 119 ± 92 %, ($p < 0.001$ and $p = 0.001$, respectively) still remaining significantly lower compared to healthy controls (40.3 ± 9.5 $\mu\text{mol}/\text{min}/\text{kg}$) (both groups, $p < 0.001$). Heart GU tended to correlate with plasma free fatty acid concentration preoperatively ($p = 0.06$) but not with body adiposity, myocardial triglyceride content or M-value. The results of myocardial structure and function are under evaluation.

Conclusion: These results show that morbidly obese subjects have significant myocardial insulin resistance, which is improved similarly in morbidly obese non-diabetic and diabetic patients after bariatric surgery.

Short-term and longer-term metabolic effects of biliopancreatic diversion (BPD) in non-morbidly obese patients with type 2 diabetes mellitus

B.D. Astiarraga¹, S. Camastra¹, M. Nannipieri¹, E. Muscelli¹, S. Baldi^{1,2}, F. Papadia², G. Adami², N. Scopinaro², E. Ferrannini¹;

¹Department of Internal Medicine, University of Pisa, ²Department of Surgery, University of Genoa School of Medicine, Italy.

Introduction and aim: Bariatric surgery is known to lead to remission of T2DM in a large proportion of morbidly obese patients. Objective of this study was to investigate the metabolic effects of BPD in non-morbidly obese T2DM.

Subjects and methods: We studied 16 patients (56 ± 4 years, BMI range $26.9 - 33.1$ kg/m²) with T2DM (duration 15 ± 6 years, all on treatment with metformin+sulfonylureas and 10 also on insulin [mean dose = 30 IU/day] before, 2 months, and 1 year after BPD. Each study consisted of a euglycemic hyperinsulinemic (240 pmol·m⁻²·min⁻¹) clamp, a standard OGTT, and a 5-hour mixed meal (561 kcal: protein 16%, lipid 30%, carbohydrate 54%) test.

Results: Two months after surgery, BMI had decreased from 28.1 ± 2.3 to 24.6 ± 2.1 kg/m² ($p < 0.001$); at one year, BMI was 23.2 ± 1.8 ($p = 0.002$ vs baseline). HbA_{1c} decreased from 8.6 ± 1.3 % to 6.7 ± 0.9 % at 2 months to 6.0 ± 1.0 % at 1 year ($p = 0.0004$ and $p = 0.002$ respectively). Fasting plasma glucose dropped from 12.3 ± 1.8 to 8.4 ± 2.6 , and to 7.7 ± 2.1 mmol/l ($p = 0.05$ and $p = 0.01$ at 2 months and 1 year, respectively); 2-hour post OGTT plasma glucose levels fell from 22.1 ± 2.5 to 12.7 ± 3.1 to 12.6 ± 3.1 mmol/l ($p < 0.001$ for the trend). At 2 months, no patient was on oral antidiabetic treatment, 8 were on insulin alone (mean dose = 14 IU/day); at 1 year, 6 patients were on insulin alone (mean dose = 12 IU/day). Insulin sensitivity (as the M value) increased from 20.1 ± 3.4 $\mu\text{mol}/\text{min}^{-1}\text{kg}_{\text{FFM}}^{-1}$ at baseline to 34.2 ± 11.2 at 2 months ($p = 0.0007$). The latter value is significantly less than in 60 age- and BMI-matched nondiabetic controls (58.5 ± 22.9 $\mu\text{mol}/\text{min}^{-1}\text{kg}_{\text{FFM}}^{-1}$, $p < 0.001$). The M value at 1 year was unchanged vs 2 months (33.1 ± 4.1 , $p = \text{ns}$). On the mixed meal, the ratio of C-peptide to glucose incremental areas rose from 150 ± 55 to 298 pmol/mmol ($p < 0.01$), indicating a $\sim 100\%$ increase in β -cell response.

Conclusion: In non-morbidly obese patients with long-standing, poorly controlled T2DM, BPD is followed by a substantial amelioration in glycemic control due to major improvements in both insulin sensitivity and β -cell function despite relatively small weight loss. The improvement is evident early after surgery and is maintained in the longer term. Defects in both insulin sensitivity and β -cell, however, persist at one year.

185

Intestinal insulin resistance associated with obesity and type 2 diabetes

J. Mäkinen, A. Karmi, J.C. Hannukainen, H.M. Immonen, M. Soinio, L. Nelimarkka, P. Salminen, P. Nuutila; Turku PET Centre, Finland.

Background and aims: The role of the proximal intestine in the pathophysiology of type 2 diabetes mellitus has been subject to growing interest. The remarkable results of bariatric surgery in improving glucose tolerance in obese diabetics are not still fully explained. We hypothesized that intestinal insulin resistance is an important factor in the pathophysiology of DM2. Our aim was to quantitate non-invasively intestinal insulin-stimulated glucose uptake (GU) in obese before and after bariatric surgery.

Materials and methods: We recruited 21 obese patients (age 47.3 ± 9.4 years, BMI 43.2 ± 3.8 kg/m²) of whom 13 had DM2 or impaired glucose tolerance and 10 age-matched healthy subjects. (BMI 23.7 ± 1.8 kg/m²). Patients were studied before and six months after bariatric surgery (Roux-en-Y gastric bypass or sleeve gastrectomy). Skeletal muscle and intestinal GU were studied using [¹⁸F]fluoro-2-deoxyglucose and positron emission tomography (PET) during euglycemic hyperinsulinemia. Intestinal GU was measured in the descending duodenum, the jejunum and the colon using graphical analyses and MRI fusion images were used as the anatomical reference.

Results: Both duodenal (17.8 ± 12.1 vs. 34.3 ± 13.4 $\mu\text{mol}/\text{kg}/\text{min}$) and jejunal glucose uptake (12.6 ± 9.7 vs. 34.5 ± 17.6 $\mu\text{mol}/\text{kg}/\text{min}$) were significantly lower ($p < 0.005$) in the obese compared to the lean group, but no difference was found in ascending colon. Bariatric surgery improved GU in jejunum (to 20.1 ± 10.6 $\mu\text{mol}/\text{kg}/\text{min}$; $p < 0.005$). Postoperative GU in duodenum (16.9 ± 9.0 ; $p = 0.7$) and colon (16.3 ± 10.3 , NS) remained unchanged. Compared to the healthy group, diabetic and nondiabetic subjects had lower whole body glucose uptake before the operation (12.5 ± 5.3 and 13.3 ± 7.4 $\mu\text{mol}/\text{kg}/\text{min}$ vs.

40,3±9,5 $\mu\text{mol/kg/min}$, $p < 0,001$). Surgery improved whole body insulin sensitivity in both diabetic (to 23,7±8,7 $\mu\text{mol/kg/min}$, $p < 0,01$) and nondiabetic (to 22,1±8,5 $\mu\text{mol/kg/min}$, $p < 0,01$) subjects. Jejunal GU correlated with whole-body insulin sensitivity in all subjects preoperatively ($r = 0,64$, $p < 0,001$) and in the obese postoperatively ($r = 0,75$, $p < 0,001$). Increased postoperative skeletal muscle glucose uptake was associated with improved jejunal ($r = 0,56$, $p < 0,05$) and duodenal GU ($r = 0,68$, $p < 0,01$).

Conclusion: This study demonstrates that obese subjects with and without type 2 diabetes have significant insulin resistance in the proximal intestine. Jejunal GU is improved in line with whole-body and skeletal muscle insulin sensitivity after bariatric surgery and the recovery of diabetes. The findings suggest that intestinal insulin resistance is an important factor in DM2.

Jejunal GU correlates with whole body insulin sensitivity

Endobarrier™ duodenal-jejunal bypass liner rapidly improves diabetes parameters paralleled by increased postprandial GLP-1 and PYY levels in obese type 2 diabetic patients

C. de Jonge¹, F.J. Verdam¹, S.S. Rensen¹, R.P. Vincent², S.R. Bloom², M.A. Ghatti², W.A. Buurman¹, C.W. le Roux², N.D. Bouvy¹, J.W.M. Greve³; ¹Maastricht University Medical Centre, Netherlands, ²Hammersmith Hospital, Imperial College London, UK, ³Atrium Medical Centre Parkstad, Heerlen, Netherlands.

Background and aims: Excluding the proximal intestine from nutrients by malabsorptive bariatric surgical techniques improves Type 2 Diabetes (T2DM) within days. The gut peptides Glucagon-like peptide-1 (GLP-1) and Peptide YY (PYY) are thought to play a central role in this important improvement. Here, the effects of the EndoBarrier™ Duodenal-Jejunal Bypass Liner (DJBL), a new minimally invasive duodenal/jejunal bypass sleeve, on diabetes parameters and GLP-1 and PYY were investigated.

Materials and methods: 17 obese T2DM patients received the DJBL in combination with a low calorie diet for 24 weeks. Patients were studied prior to and one week after implantation, and prior to and 1 week after explantation. Blood was sampled before and 10, 20, 30, 60, 90 and 120 minutes after a liquid 500 kcal test meal. HbA_{1c}, glucose, insulin, GLP-1, and PYY concentrations were measured.

Results: At explantation, after 24 weeks, patients showed a mean loss of excess weight of 29.8±3.5% (mean±SEM) while HbA_{1c} had improved significantly from 8.4±0.2% to 7.0±0.2% ($p < 0.01$). Furthermore, anti-diabetic medication was lowered in most patients (16/17). Interestingly, within one week after implantation, fasting and AUC glucose concentrations were improved (11.4±0.5 mmol/L vs. 8.9±0.4 mmol/L and 1,999±88 vs. 1,535±53, both $p < 0.01$). In parallel, AUC PYY and AUC GLP-1 concentrations both increased (2,584±144 vs. 4,112±441 and 4,440±242 vs. 6,448±527, both $p < 0.01$). Both at the time of explantation, and one week thereafter, the glucose parameters, fasting and AUC glucose concentrations, remained significantly decreased while the concentrations of PYY and GLP-1 had returned to normal.

Conclusion: DJBL treatment resulted in significant weight reduction and rapid and long lasting improvement of T2DM. The observed changes in gut peptides shortly after implantation may be involved in the early improvement. These observations are in line with the so-called hindgut hypothesis, which attributes diabetic improvement, after exclusion of the proximal small

intestine, to increased secretion of gut peptides in reaction to presence of undigested nutrients in the distal gut. Other, as yet unrevealed, factors may underlie the sustained effect.

OP 32 Novel agents for type 2 diabetes

187

A randomised, double-blind, placebo- and active-controlled, dose-ranging study to determine the efficacy and safety of the novel GPR40 agonist TAK-875 in subjects with type 2 diabetes mellitus

P. Viswanathan¹, J. Marcink², C. Cao³, B. Xie³, M. Vakilynejad⁴, E. Leifke¹,

¹Clinical Science, ²Pharmacovigilance, ³Statistics, ⁴Pharmacology, Takeda Global Research & Development Center, Inc., Deerfield, USA.

Background and aims: TAK-875 is a selective GPR40 agonist and first in its class to reach clinical development for the treatment of type 2 diabetes mellitus (T2DM).

Materials and methods: A randomized, double-blind, placebo- and active (glimepiride) comparator-controlled, parallel-group, multicenter study was conducted to evaluate the efficacy, safety and tolerability of 5 dosages (ranging from 6.25 mg to 200 mg QD) of TAK-875 over 12 weeks in subjects with T2DM. The primary efficacy endpoint was change from baseline in A1C at week 12. Other endpoints included changes in A1C over time, FPG, plasma glucose post-OGTT, number of subjects rescued due to hyperglycemia and incidence of hypoglycemia.

Results: 426 subjects were randomized (~60 per group). All doses of TAK-875 showed significantly greater A1C reductions at week 12 than placebo (Figure 1). The magnitude of the decrease in A1C produced by TAK-875 ≥50mg was comparable to that with glimepiride at week 12. Compared to placebo, approximately twice as many subjects (33–48%) treated with TAK-875 ≥25 mg achieved HbA1c <7% at week 12, similar to the glimepiride response. Changes from baseline in FPG and 2-hr OGTT values observed with TAK-875 were consistent with changes in HbA1c. The incidence of hypoglycemia was significantly lower in all TAK-875 groups (2.3% of subjects) compared to glimepiride (16.1%) and similar to placebo (3.3%). Treatment-emergent AEs ranged from 43.5% to 61.3% and were highest with glimepiride. Discontinuations because of AEs were low (1.6–3.3%) and similar among all active treatment groups.

Conclusion: The study results provide evidence of good safety, tolerability and HbA1c lowering activity for TAK-875 and are consistent with its glucose dependent mechanism of action. They support further evaluation of this novel compound in the treatment of T2DM.

Orally administered GPR119 agonist PSN821 shows clinically significant glucose lowering and other potential cardiometabolic benefits in patients with type 2 diabetes

M.L. Goodman¹, J. Dow¹, A.A. van Vliet², A. Pleszko¹, J.A. Lockton¹;

¹Clinical Research, Prosidion, Oxford, UK, ²PRA International, Zuidlaren, Netherlands.

Background and aims: PSN821 is a potent, selective, orally-administered agonist of the GPR119 receptor expressed predominantly in the pancreas (β-cells) and GI tract (enteroendocrine cells) in humans. In preclinical animal disease models PSN821 has been shown to substantially lower blood glucose and also reduce body weight, potentially via modulation of the gut hormones GLP-1, GIP and PYY. This randomized, double-blind, placebo-controlled assessment evaluated the safety, tolerability, and pharmacodynamic effects of PSN821 in overweight/obese patients with T2DM.

Materials and methods: Three cohorts of patients (250mg PSN821 alone, or 250mg, 500mg PSN821 plus stable metformin therapy) were evaluated in addition to placebo controls. Pharmacodynamic response was assessed by measuring changes in plasma glucose both fasting (C_{pre}) and during a liquid meal (Ensure Plus) challenge (E_{max} and $RAUC_{0-5}$). In addition energy intake at test meal (EI), gut hormones (GLP-1, GIP, PYY), fasting lipid profiles, adiponectin, leptin and weight change were measured.

Results: After 14 days treatment with PSN821 fasting plasma glucose was lower in all actively treated groups (-2.0, -2.1, -2.3 mmol) compared to placebo. Following a liquid meal challenge glucose exposures were lower for all active treatments compared to both baseline and placebo:

Energy intake at test meal was substantially less than placebo at the higher dose (mean -6%, -8%, -40% respectively). Gut hormone profiles were highly variable: GLP-1 and GIP showed no marked difference from placebo after 14 days treatment, however PYY_{total} and PYY₃₋₃₆ appeared increased from day -1, both at Day 14 and compared to placebo at Day 1 and Day 14. For all PSN821 treatments total cholesterol, LDL and triglycerides appeared lower on Day 14 than Day -1, with mean changes being greater than placebo; no differences were observed for HDL in any group. Unequivocal decreases in serum leptin levels (mean -13%, -27%, -15% respectively) and increases in adiponectin (mean +13%, +5%, +18% respectively) were seen in all active treatment groups compared to placebo. Non-statistically significant changes in weight compared to placebo (-1.1, -0.4, -0.7kg respectively) were noted. PSN821 at all doses was well tolerated with a low incidence of gastrointestinal upset and without any adverse effects on labs, vital signs or ECG. There were no SAEs or discontinuations due to AEs.

Conclusion: In this small number of overweight/obese patients with T2DM, PSN821 was well tolerated and showed clear evidence of both fasting and post-prandial glucose lowering, either alone or in combination with metformin. The suppression of EI at higher doses suggests weight lowering potential and corresponding changes in PYY indicate a possible mechanism for this.

LY2599506, a novel glucokinase activator (GKA), improves fasting and postprandial glucose in patients with type 2 diabetes mellitusJ.M. Bue-Valleskey¹, K.B. Schneck¹, V.P. Sinha¹, E.T. Wondmagegnehu¹, C. Kapitza², J.W. Miller²;¹Eli Lilly and Company, Indianapolis, USA, ²Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany.

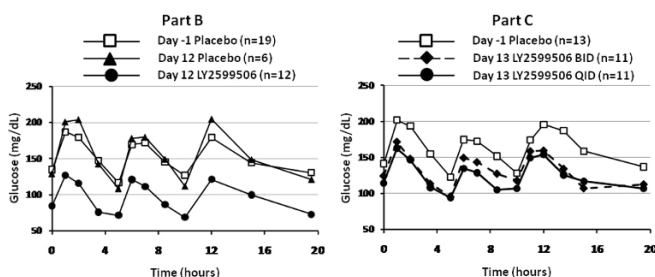

Background and aims: LY2599506 (licensed from Prosidion) is an orally-administered GKA. GKAs lower the plasma glucose threshold for insulin release and may modulate other hormonal and hepatic mechanisms of glucose homeostasis. The primary objective of this Phase 1 study was to assess the safety and tolerability of LY2599506 during multiple-dose administration to healthy subjects and T2DM. Based on previous clinical data, LY2599506 was expected to enhance glucose control for 1–4 hours after dosing; consequently, LY2599506 was given prior to each meal and at bedtime (four times a day [QID] dosing) to achieve glycemic control in both postprandial (PP) and post absorptive periods.

Materials and methods: This 3-part study used a single-blind design with randomized assignment to placebo or LY2599506 (Parts A and B) or study sequence (Part C). In Part A, healthy subjects (n=9) received ~50 mg LY2599506 or placebo QID for 7 days. In Part B, T2DM (n=18) underwent dose-titration of LY2599506 or placebo QID for 12 days; in Part C, T2DM (n=11) received twice-daily (BID) and QID LY2599506 dosing for 13 days each in a 2-period crossover design. Planned LY2599506 dose levels were 50, 100, 200, and 300 mg QID. Starting with 50 mg or 100 mg, doses were increased at 3 day intervals so that blood glucose (BG) thresholds of 60 mg/dL (Part B) and 80 mg/dL (Part C) were not exceeded. Standardized meals at breakfast, lunch, dinner, and bedtime were administered to characterize blood glucose, insulin, and glucagon responses.

Results: At baseline, mean HbA_{1c} in T2DM was 7.4%; mean diabetes duration was 7 years; and 80% were on stable metformin therapy. Mild or moderate hypoglycemia was the dose-limiting adverse event and was effectively managed with food/drink. No severe hypoglycemia occurred, even with dosing at bedtime. QID dosing of LY2599506 achieved a relatively flat 24-h exposure profile. Under inpatient conditions with dose reduction for BG <60 mg/dL (Part B), the maximum tolerated (non-hypoglycemic) dose of LY2599506 ranged from 50–1100 mg/day; under ambulatory conditions with dose reduction for BG <80 mg/dL (Part C), the maximum dose ranged from 60–530 mg/day. In part B, fasting BG after 12 days of treatment was significantly lower during treatment with LY (Placebo: 129 ± 26.6 mg/dL vs LY: 84.4 ± 15.7 mg/dL, p=0.0004) and significant reductions in 2-h PP BG were also observed after each of the main meals (Figure). In Part C, BID dosing was slightly less effective in controlling BG following lunch than QID dosing (Figure). Although absolute differences in PP insulin levels were not generally observed, the insulin/glucose ratios on Day 12 were increased at PP time points relative to placebo (Placebo: 0.36 ± 0.38 vs LY: 0.71 ± 0.33) which may suggest an improvement in beta cell function. No significant effects on glucagon were observed.

Conclusion: LY2599506 was well tolerated and improved glycemic control in T2DM patients.

Mean Glucose Profiles From Test Meal Assessments
Performed on Days -1 and 12 (Part B) or Days -1 and 13 (Part C)

Short-term treatment with glucagon receptor antagonist LY2409021 effectively reduces fasting blood glucose (FBG) and HbA_{1c} in patients with type 2 diabetes mellitus

M.J. Prince, P. Garhyan, E.J. Abu-Raddad, H. Fu, C.N. Lim, J.A. Pinaire, M.T. Loh, M.A. Deeg, R.P. Kelly; Eli Lilly and Company, Indianapolis, USA.

Background: Glucagon levels are elevated in many patients with type 2 diabetes mellitus (T2DM) and contribute to hyperglycemia. LY2409021 is a potent, selective glucagon receptor antagonist.

Materials and methods: This Phase 1, randomized, double-blind, placebo (PBO)-controlled study examined the safety, tolerability, pharmacokinetics (PK), and short-term (28-day) efficacy of once-daily doses of LY (5, 30, 60, or 90mg) in patients with T2DM treated with diet and exercise or metformin (N=47; mean FBG 148 mg/dL; HbA_{1c} 8.0%).

Results: Across LY dose levels, PK parameters t_{max} , $t_{1/2}$, and apparent clearance (CL_{ss}/F) ranged from 6 to 8 h, 56.1 to 61.9 h, and 0.263 to 0.345 L/h, respectively, and C_{max} increased in proportion to dose. Accumulation (R_a) ranged from 3.74 to 4.5. LY produced clinically significant reductions in FBG by Day 2; by Day 14, least squares (LS) mean changes from baseline vs. PBO were -25.74, -39.96, and -37.44 mg/dL (p < .01 for all) in the 30, 60, and 90mg dose groups, respectively. By Day 28, LS mean changes in HbA_{1c} were statistically significant vs. baseline in all treatment groups, including PBO (-0.49%; 90% confidence interval: -0.70 to -0.28), such that significant reductions vs. PBO were seen only at 60- and 90-mg LY, respectively: -0.53% (p=.0117); -0.43% (p=.0391). ED₅₀ for glucose-lowering was 5mg. Fasting glucagon significantly increased by 0.6-, 1.5-, 2.5-, and 4.2-fold vs. baseline across LY dose levels, and fasting active glucagon-like peptide-1 (GLP-1) by 59% at 90mg. Glucagon and GLP-1 returned to baseline levels during follow-up. No significant effects of LY on fasting or postprandial insulin and C-peptide were seen. LY was generally well tolerated. Hypoglycemia was infrequent and mild to moderate in intensity (4 events at 90mg; minimum glucose 62mg/dL). Reversible elevations in hepatic transaminases > 3x ULN were seen in 5 of 9 patients in the 90mg dose group, with no clinical signs or significant elevations in bilirubin or alkaline phosphatase.

Conclusion: The potent glucose-lowering observed during short-term treatment with LY supports the continued development of this glucagon receptor antagonist as a once-daily treatment for T2DM.

191

Efficacy and safety of the glucagon receptor antagonist, MK-0893, in combination with metformin or sitagliptin in patients with type 2 diabetes mellitus

S.S. Engel, R. Teng, R.J. Edwards, M.J. Davies, K.D. Kaufman, B.J. Goldstein; Merck Sharp & Dohme Corp., Whitehouse Station, USA.

Background and aims: Reduction in hepatic glucose production (HGP) is a key therapeutic goal in patients (pts) with type 2 diabetes (T2DM). Metformin (MET) lowers glucose, in part, by reducing HGP. Sitagliptin (SITA), by suppressing glucagon and enhancing insulin secretion, may also reduce HGP. Inhibition of glucagon action through blockade of the glucagon receptor may provide a complementary mechanism for further reduction in HGP and improvement in glycaemic control. MK-0893 is an oral, highly-selective glucagon receptor antagonist in development for the treatment of T2DM. The present study evaluated the efficacy and safety of combination therapy of MK-0893 with MET or SITA.

Methods: Pts with T2DM were eligible if, at screening, they were either not on an antihyperglycaemic agent (AHA) with an HbA_{1c} of 7.5–12%, or were on AHA monotherapy or low-dose combination therapy with an HbA_{1c} of 7–10%. After AHA wash-off and placebo run-in periods, eligible pts were randomised in a 1:1:1 ratio to double-blind treatment with MK-0893 40 mg qd + MET 1000 mg bid, MK-0893 40 mg qd + SITA 100 mg qd, or SITA 100 mg qd + MET 1000 mg bid. Change in 24-hr weighted mean glucose (WMG) from baseline after 4 weeks was the primary endpoint. Statistical comparisons focused on each of the MK-0893 groups relative to the SITA + MET group.

Results: At baseline, randomised pts (N=146, 61% males) had a mean age of 53 yrs, mean HbA_{1c} of 8.6%, and median duration of T2DM of 7 yrs. All treatment regimens provided substantial reduction in 24-hr WMG and fasting (FPG) and postprandial glucose at Week 4. Therapy with MK-0893 + MET demonstrated statistical superiority to SITA + MET in lowering 24-hr WMG and FPG over 4 weeks (p<0.001), while MK-0893 + SITA was significantly

less effective than SITA + MET (Table). No significant between-group differences were observed for fasting insulin, fasting C-peptide, or HOMA- β . HOMA-IR was reduced to a greater extent with MK-0893 + MET compared with SITA + MET. All treatments were generally well tolerated. A numerically higher incidence of adverse events of diarrhoea was observed in the MK-0893 + MET (10.2%) and SITA + MET (10.2%) groups compared with the MK-0893 + SITA group (0%). Mean changes in ALT levels with MK-0893 + MET, MK-0893 + SITA and SITA + MET were 4.3, -0.4, and -3.2 IU/ml, respectively; mean changes in AST levels were 1.51, 3.85, and -1.59, respectively. Total cholesterol and LDL-cholesterol were increased from baseline with MK-0893 + SITA (mean % change = 3.2% and 4.5%, respectively) relative to reductions with MK-0893 + MET (-0.6% and -5.7%, respectively) and SITA + MET (-5.5% and -7.7%, respectively).

Conclusion: Initial combination therapy of MK-0893 with MET or SITA provided substantial improvements in glycaemic control after 4 weeks. Treatment with MK-0893 in combination with MET or SITA was generally well tolerated. Relative to SITA + MET, small mean increases in hepatic enzymes and plasma lipids were observed with MK-0893 in combination with MET or SITA.

	MK-0893 40 mg qd + MET 1000 mg bid	MK-0893 40 mg qd + SITA 100 mg qd	SITA 100 mg qd + MET 1000 mg bid
Baseline 24-hr WMG, mmol/L	13.19 (3.07)	12.55 (3.27)	12.90 (3.36)

Safety and efficacy of oral chemokine receptor 2 antagonist CCX140-B in a phase 2 type 2 diabetes study

M. Hanefeld¹, E. Schell², I. Gouni-Berthold³, M. Melichar⁴, I. Vesela⁵, T. Sullivan⁶, S. Miao⁶, D. Johnson⁶, J.C. Jaen⁶, T.J. Schall⁶, P. Bekker⁶;

¹Center for Clinical Studies in Endocrinology and Metabolic Disorders, Dresden, ²Luedwigstr. 67, Nuremberg, ³Dept of Internal Medicine II, University of Cologne, Germany, ⁴Internal Medicine, Pardubice, ⁵Internal Medicine & Diabetes, Unicov, Czech Republic, ⁶ChemoCentryx, Inc, Mountain View, USA.

Background and aims: Monocyte chemoattractant protein-1 (MCP-1; also known as chemokine ligand 2, CCL2) and its chemokine receptor CCR2 are implicated in the development of insulin resistance in type 2 diabetes mellitus. CCX140-B is an oral, specific CCR2 antagonist shown previously to be safe and well tolerated in Phase 1 clinical trials. CCR2 antagonist treatment in diet-induced obese mice as well as *db/db* mice has shown significant improvement of glycemic parameters as early as 1 week of treatment.

Materials and methods: A 159-subject multinational, randomized, double-blind, placebo- and active-controlled Phase 2 clinical trial has been completed recently. Subjects had been on stable metformin treatment for at least 8 weeks prior to study entry, had HbA_{1c} of 6.5 to 10% and fasting plasma glucose (FPG) of 135 to 270 mg/dL. Randomized subjects received double-blind placebo QD (N=32), 5mg CCX140-B QD (N=32), 10mg CCX140-B QD (N=63), or open-label pioglitazone 30mg QD (N=32) for 4 weeks. Safety and tolerability were primary endpoints, and secondary endpoints included changes from baseline in glycemic parameters. The pharmacokinetic profile of CCX140 was also evaluated.

Results: Baseline characteristics, mean (SD), were: Age 59 (7) yrs, 64% male, BMI 32 (4) kg/m², median diabetes duration 5.8 yrs, HbA_{1c} 7.5 (0.8) %, FPG 170 (41) mg/dL. CCX140-B was well tolerated by study subjects. No serious adverse events were observed in the CCX140-B groups. There were no safety concerns regarding laboratory hematology, chemistry, or urinalysis. FPG showed a CCX140-B dose-dependent decrease through week 4. HbA_{1c} least-squares mean changes from baseline to week 4 for the placebo, 5 mg CCX140-B, 10 mg CCX140-B, and pioglitazone groups were -0.09%, -0.09%, -0.23% ($p=0.045$ vs. placebo), and -0.13% (NS vs. placebo), respectively. The percentage of subjects showing a decrease from baseline to Week 4 in HbA_{1c} was 58%, 51%, 82% ($p=0.045$ vs. placebo) and 77% (NS vs. placebo) for the placebo, 5 mg, 10 mg CCX140-B, and pioglitazone groups, respectively. Unlike other

CCR2 antagonists, no significant changes were seen in plasma MCP-1 or blood monocyte count with CCX140-B treatment. No significant changes in body weight or evidence of hemodilution or peripheral edema were observed with CCX140-B treatment. At steady state, measured at Day 22, mean (SD) trough plasma levels of CCX140 were 1370 (548) and 2450 (1050) ng/mL for the 5mg and 10mg CCX140-B groups, respectively.

Conclusion: A statistically significant decrease in HbA_{1c} and a higher percentage of HbA_{1c} responders were observed after only 4 weeks of treatment with CCX140-B 10mg QD compared to placebo. No detrimental effects were observed on plasma MCP-1 or blood monocyte levels, and once daily oral CCX140-B provided excellent blockade of blood leukocyte CCR2. The novel oral CCR2-specific antagonist CCX140-B was effective, safe and well tolerated in this study.

Characterisation of microRNA in sera as biomarkers for type 1 diabetes progression in newly diagnosed children

L.B. Nielsen¹, C. Wang², K. Sørensen³, C.H. Bang-Bertelsen⁴, M.-L.M. Andersen¹, L. Hansen¹, F. Pociot⁴, C.-Y. Zhang², H.B. Mortensen¹; ¹Pediatrics, Herlev Hospital & University of Copenhagen, Herlev, Denmark, ²School of Life Science, Nanjing University, China, ³University Department of Growth and Reproduction, Rigshospitalet University Copenhagen, ⁴Glostrup Hospital & University of Copenhagen, Glostrup, Denmark.

Background and aims: The use of serum/plasma samples as a non-invasive and easily accessible body fluid for detection of the miRNAs has shown to be of great potential in the clinic as a reliable way to detect cellular and physiological changes as cancer, pregnancy and sepsis. This study aim to identify specific key miRNAs and miRNA patterns usable as clinical biomarkers, which can be predictive for ongoing beta-cell function destruction and regeneration in children with newly diagnosed type 1 diabetes (T1D). Therefore, we have investigated miRNAs in fractionated serum samples from two cohorts of new-onset T1D children and age-matched controls by miRNA sequencing and validation by qRT-PCR.

Materials and methods: The International Hvidoere Cohort and the Danish Remission Cohort comprise 275 and 130 newly diagnosed children (0.2–16.8 years), respectively. The residual beta-cell function was estimated by a meal-stimulated C-peptide test 1, (3 for the Danish Cohort), 6 and 12 months after disease onset and blood samples for centrally determined HbA_{1c}, stimulated C-peptide, glucagon, incretin hormones, cytokines and immunology was taken. DNA was extracted for SNPs genotyping. In addition 151 healthy children (6.7–13.7 years), which were recruited from 2 public schools in the Copenhagen area, served as a control group. Pooled RNA samples (containing 5–10 µg RNA) from sera collected 1 month after diagnosis were sequenced on the Solexa sequencing platform (Illumina). The deep-sequencing data were analysed with bioinformatics and statistical tools and differentially expressed miRNAs were validated by qRT-PCR.

Results: By using Solexa sequencing 1,100 miRNAs were found to be expressed in serum samples from the three cohorts. 47 miRNAs met the criteria of copy number >100 and a 2-fold altered expression in both diabetes cohorts. Of these 26 miRNAs were selected for further validation by RT-qPCR in the individual samples. Among the 26 miRNAs we found several miRNAs already known to be linked to insulin production and glucose responsiveness (miR-124 and miR-200), apoptosis (miR-21) and beta-cell regulatory networks (miR-192 and miR-199a). Even more importantly we found several miRNAs with yet unidentified function related to T1D (e.g. miR-24, miR-25 and miR220).

Conclusion: This study demonstrates the feasibility of identifying miRNAs in serum that associate with newly diagnosed T1D. Further studies of the key miRNAs may help identify new pathways involved in the pathogenesis of beta-cell destruction in T1D.

Incidence of multiple autoimmune phenotypes among children at high risk for type 1 diabetes

M. Rewers, A. Perlman, K. Barriga, A. Steck, J. Norris, J.C. Hutton, G.S. Eisenbarth; University of Colorado Denver, Aurora, USA.

Background and aims: HLA-DR3,DQ2 and DR4,DQ8 haplotypes are associated with multiple autoimmune diseases. However, little is known concerning the overall autoimmunity burden among children with these HLA markers.

Materials and methods: The Diabetes Autoimmunity Study in the Young (DAISY) has followed for an average of 8 years 2542 children at risk for T1D, recruited by newborn screening for HLA DR3,DQ2 or DR4,DQ8, or as relatives of T1D patients. Participants were tested annually for autoantibodies to glutamic acid decarboxylase 65 (GAD), insulin (IAA), insulinoma associated antigen-2 (IA2) and transglutaminase (TG). The most recent sample was measured for zinc transporter 8 (ZnT8), thyroid peroxidase (TPO), 21-hydroxylase (21-OH) and cyclic citrullinated peptide (CCP); if positive, the entire subject sample series was tested. GAD, IAA, IA2 and ZnT8 are grouped as

islet autoantibodies (IA). Positivity on 2 or more consecutive tests defined the specific autoimmune phenotype. Standard clinical criteria defined autoimmune disease.

Results: By the age of 12 years, one in four children expressed an autoimmune phenotype: 23.8% (95% CI: 21.5–26.1) and 12.9% had more than one autoimmune phenotype. IA developed in 11.3% (9.6–12.9), TG in 10.8% (9.1–12.4), TPO in 7.0% (5.4–8.6), 21-OH in 0.5% (0.1–1), and CCP in 0.2% (0.0–0.5). Overall 5% of the children have developed at least one clinically confirmed disease: 69 T1D, 52 celiac disease, 9 hypothyroidism, 1 Addison's disease, and 2 rheumatoid arthritis. The HLA genotypes most strongly associated with autoimmune phenotypes were: DR3/4,DQ8 for T1D Relative Risk =2.8 (2.0–3.9), DR3/3 for TG 2.4 (1.5–3.8), and DR4/4,DQ8 for TPO 2.0 (1.1–3.5), adjusting for sex, ethnicity, and family history of T1D.

Conclusion: The high incidence of autoimmune phenotypes in children at genetic risk for T1D warrants a screening program and early intervention.

Optimising the tolerogenic potential of a 'vaccine' for type 1 diabetes by topical betamethasone therapy

M. Alhadj Ali^{1,2}, S. Thrower¹, S. Harris², S. Wong², C.M. Dayan^{1,2}; ¹Henry Wellcome Laboratories, University of Bristol, ²Centre for Endocrine & Diabetes Sciences, University of Cardiff, UK.

Background: Peptide immunotherapy has been shown to be a simple and effective method of restoring tolerance and reversing disease in animal models of type 1 diabetes. In humans, the intradermal route of peptide administration is convenient. It is highly important to administer the peptide into an environment in which antigen presenting cells such as dendritic cells are maintained in a tolerogenic state to maximize their potential of inducing tolerogenic responses. Use of the intradermal route has a specific advantage in peptide immunotherapy as dendritic cells are potentially accessible for peptide immunotherapy and local treatment with agents may be able to promote the induction of tolerance.

Aims: Our aim was to determine whether topical pre-treatment of the skin has the potential to promote a tolerogenic phenotype in epidermal dendritic cells.

Materials and methods: Healthy volunteers received no treatment (C) or one of 5 pre-treatment topical regimes twice/daily for 4 days followed by a 50 µl intradermal saline injection: no treatment (Sal), 0.05% Betamethasone (S), 50 mcg/mg Calcipotriol (D), 0.05% Betamethasone + Calcipotriol (S+D), 0.01% Tretinoin (A). 12–18 hours later, all subjects had a 10–15 mm suction blister raised at the site of treatment. Blister fluid was then withdrawn for the measurement of cytokine production. The blister roof was removed and epidermal cells isolated for study using 9-colour flow cytometry and for functional analysis in a Mixed Lymphocyte Reaction (MLR) using allogeneic PBMC.

Results: Epidermal cells comprised around 2% CD1a+ dendritic cells (EDC), which were 80–90% viable and induced a strong MLR response in control subjects (Sal).

DCs from S treated subjects showed a trend to reduced MLR proliferation less than Calcipotriol (P=0.03), and lower levels of TNF-α and MCP-1 in the

interstitial (blister) fluid in comparison with Calcipotriol Group ($P=0.01$, $P=0.002$ respectively). Levels of TNF- α and MCP-1 in the Steroid group were significantly lower than the levels in the saline group ($P=0.05$, $P=0.05$ respectively). There was also significant reduction in the levels of expression of the key costimulatory molecules, CD86 and CD83 with the Betamethasone topical therapy in comparison with the saline group ($P=0.04$, $P=0.04$ respectively). A trend to lower levels of expression of CD40, CD80 and ILT3 was seen with vitamin D. No significant changes were observed with vitamin A pretreatment in this dataset.

Conclusion: Pretreatment of the skin with steroid (Betamethasone) for 4 days appears to have significant effects on epidermal dendritic cell phenotype and cytokine milieu. Further functional studies are required to determine whether these changes will prove beneficial in tolerance induction in peptide immunotherapy.

41% in the last quartile, $p=0.013$) after adjustment for age and genetic risk. **Conclusion:** The rising incidence of type 1 diabetes in the UK between 1985–2002 was paralleled by changes in islet autoantibodies at diagnosis indicating broader reactivity against target epitopes, independent of changes in age at diagnosis and HLA class II genetic risk. This suggests that changes in the disease process may underlie recent increases in childhood diabetes. *Supported by: Diabetes UK*

Increases in number, prevalence and level of islet autoantibodies at diagnosis of childhood type 1 diabetes parallel the rising incidence: evidence for a changing disease process?

A.E. Long, K.M. Gillespie, P.J. Bingley, A.J.K. Williams;
School of Clinical Sciences, University of Bristol, UK.

Background and aims: The incidence of type 1 diabetes is increasing, and islet autoantibodies are important markers of immune activity. Our aim was to determine whether autoantibodies at diagnosis altered during a period of rapid increase in diabetes incidence.

Materials and methods: We studied 611 patients from the Oxford Region, UK with type 1 diabetes diagnosed before age 21 years (median 11.0 years) between 1985 and 2002. Sera were collected within 3 months of diagnosis (median 1 day). Autoantibodies to insulin (IAA), glutamic acid decarboxylase (GADA), islet antigen-2 (IA-2A), the juxta-membrane domain of IA-2 (JMA), the PTP region of IA-2 β (IA-2 β A) and zinc transporter 8 (ZnT8A) were determined by radioimmunoassay. Patients were divided into four groups on the basis of quartiles of date of diagnosis (Jul 1985–March 1990, April 1990–February 1994, February 1994–June 1997, and July 1997–February 2002). Logistic regression was used to determine whether autoantibody prevalence varied according to date of diagnosis after adjustment for age, gender and HLA class II genetic risk.

Results: The prevalence of IA-2A increased from 69% to 83% between the first and last date of diagnosis quartile (logistic regression, $p=0.025$), and prevalence of ZnT8A from 64% to 75% ($p=0.022$). This was mirrored by increased levels of IA-2A ($p=0.025$), ZnT8A ($p<0.01$). Amongst IA-2A positive patients, IA-2 β A levels also increased ($p<0.001$). IAA, GADA and JMA did not change with respect to date of diagnosis. The number of autoantibodies detected (in 422 patient samples collected within 2 weeks of diagnosis, based on IAA, GADA, IA-2A and ZnT8A) also increased ($p=0.02$), and patients in the more recent group were more likely to have all four autoantibodies (27% in the first quartile and

197

Mesenchymal stem-cells derived microvesicles modulate cellular immune response to islet antigen GAD in type 1 diabetes

E. Favaro, I. Miceli, M.C. Deregibus, V. Fonsato, F. Collino, M. Ventura, E. Camussi, C. Caorsi, M. Giovarelli, P. Cavallo Perin, M.M. Zanone, G. Camussi;

Department of Internal Medicine, University of Turin, Italy.

Background and aims: Mesenchymal stem cells (MSCs) exert an immunosuppressive effect on immune system and can abrogate *in vitro* the pro-inflammatory Th1 response to islet antigen GAD in type 1 diabetes by impairing the production of IFN- γ . The mechanism may involve paracrine factors. Microvesicles (MVs) released from MSCs may account for this paracrine mechanism through a horizontal transfer of messenger RNA and microRNA. In the present study we evaluated whether MSC-derived MVs exert immunomodulatory effect similar to that of MSCs on T cell responses against GAD in type 1 diabetes.

Materials and methods: Human MSCs were isolated and characterised and MVs were purified from supernatants of MSCs by differential ultracentrifugation. The size of MVs was determined by the Zetasizer Nano instrument and by electron microscopy. Moreover, on MVs, cytofluorimetric analyses was assessed to analyse adhesion molecules and gene array analyses was performed to detect their mRNA content (Illumina platform) and miRNA profile was evaluated by quantitative real time PCR (microRNA human panel early accesskit). Peripheral blood mononuclear cell (PBMCs) were obtained from 4 type 1 diabetic patients at disease onset with a positive IFN- γ response to GAD65 stimulation by ELISPOT assay (positive response SI \geq 3). PBMCs were pulsed with GAD65 and incubated with or without MV for 24h followed by IFN- γ ELISPOT. Levels of prostaglandin E $_2$ (PGE $_2$), TGF- β , IL-10, IFN- γ , IL-6, in supernatants were measured by ELISA.

Results: By cytofluorimetric analyses MVs MSC-derived were detected mainly below the forward scatter signal corresponding to 1- μ m beads. When determined by Zetasizer, the size of MVs was ranging from 80 nm to 1 μ m, with a mean value of 135 nm. Transmission as well as scanning electron microscopy performed on purified MVs showed their spheroid morphology and confirmed their size. Cytofluorimetric analyses showed the presence of several adhesion molecules known to be expressed on MSC plasma membrane such as CD44, CD29, α 4- and α 5- integrins and CD73, but not α 6-integrin. In addition, MVs did not express HLA-class I molecule at variance of the cells of origin. MVs obtained from MSCs contained mRNA and in particular mRNA related to immune regulation, such as Cytokine receptor-like factor 1 (CRLF1), Interleukin 1 receptor antagonist (IL1RN), Metallothionein 1X (MT1X). Incubation of PBMCs obtained from the four GAD-responder diabetic patients with MVs, resulted in a significant decrease in the number of IFN- γ spots (mean spots 28 ± 2.8 without MVs, mean spots 14 ± 6.7). Furthermore, levels of IFN- γ , IL-6, in supernatants of GAD65-pulsed PBMCs incubated with MVs were significantly decreased compare to GAD65-pulsed PBMCs alone. Levels of PGE $_2$, TGF- β and IL-10 were significantly increased compare to GAD65-pulsed PBMCs alone.

Conclusion: These results provide evident that MSC-derived microvesicle inhibited *in vitro* a pro-inflammatory Th1 response to an islet antigenic stimulus, in diabetic patients, possibly mediated by PGE $_2$ and TGF- β . MVs induce IL-10 secretion, suggesting a possible switch to an anti-inflammatory Th2 signalling of T cells.

GAD65Ab specific anti-idiotypic antibody prevents the onset of type 1 diabetes in NOD mice

X. Wang¹, C.S. Hampe², J. Yu¹;

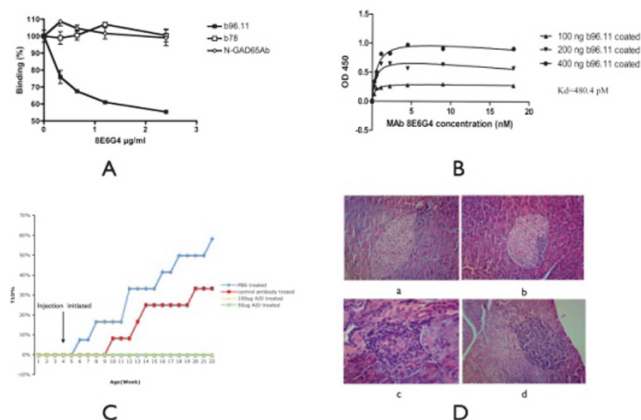

¹Department of Endocrinology, Jiangsu Province Hospital of TCM, Nanjing, China, ²Department of Medicine, University of Washington, Seattle, USA.

Background and aims: We previously found anti-idiotypic antibodies (AID) targeting human GAD65 auto-antibody (GAD65Ab) in the healthy population and their significantly decreased levels in patients with type 1 diabetes (T1D). Induction of GAD65Ab targeting AID by injection of human GAD65Ab b96.11 reduced morbidity of T1D in NOD mice. The aim of this study is to develop a monoclonal AID specifically binding to the antigen binding site of human GAD65Ab b96.11 for the prevention of T1D.

Materials and methods: The monoclonal GAD65Ab specific AID was developed by screening the hybridoma cells fused from the B lymphocytes of

Balb/c mice immunized with human GAD65Ab b96. The binding specific of the AID to the GAD65Ab b96.11 was characterized by ELISA, immunoprecipitation, and competing radioligand binding assay (RBA). The binding affinity of the AID to human GAD65Ab b96.11 was calculated by non-competitive ELISA. For *in vivo* study, female NOD mice at the age of 3–4 weeks were intraperitoneally injected with either 50 or 100 μ g of the monoclonal AID weekly. Control groups were injected with either PBS or non-related murine monoclonal antibody. Blood glucose was determined weekly by Abbott Optium Xceed glucometer. The onset of diabetes was defined as two consecutive blood glucose detected higher than 250mg/dL. For histopathological assay, pancreas of mice in each group was isolated and fixed in 4% paraformaldehyde and embedded in paraffin wax. Sections of 4- μ m were mounted on glass slides and stained with haematoxylin and eosin for histological analysis. **Results:** One monoclonal antibody, named 8E6G4, was screened out as the human GAD65Ab b96.11 specific AID. This AID specifically bound to b96.11 and blocked its interaction with GAD65, indicating the AID targets antigen binding site of b96.11. The dissociation constant of the AID to GAD65Ab b96.11 calculated by the non-competitive ELISA is 480.4pM. Our ongoing study in the NOD mice showed this monoclonal GAD65Ab specific AID, but not the control antibody, prevented the onset of T1D after 18-week treatment. Histopathological assay showed the AID reduced insulinitis in NOD mice.

Conclusion: Monoclonal antibody 8E6G4 is a human GAD65Ab b96.11 specific AID which has the potential to prevent T1D by reducing insulinitis.

A: Monoclonal antibody 8E6G4 specifically blocked binding of b96.11 to GAD65 in RBA: Binding of monoclonal antibodies b96.11 (black squares), b78 (white squares), and N-GAD65mAb (white circles) to radiolabeled GAD65 in the presence of the indicated concentrations of 8E6G4 was determined. Binding is reported as percent binding, binding of the respective antibody to radiolabeled GAD65 in the absence of 8E6G4 is set as 100%. We found that only binding of b96.11 to GAD65 was inhibited by 8E6G4, while both b78 and N-GAD65Ab were not affected by 8E6G4. These findings support that 8E6G4 is a b96.11 specific anti-idiotypic antibody, that binds to the antigen-binding region of b96.11; B: Dissociation constant of the AID 8E6G4 to b96.11 calculated by non-competitive ELISA is 480.4pM: binding of serially diluted AID (0.256–16.4nM) to different amount of b96.11 (1, 2, and 4ng/ μ l) coated in 96-well plate was analyzed by standard ELISA. The concentration of 8E6G4 and OD₄₅₀ were plotted to three hyperbolic curves and each K_d was calculated. The K_d was calculated average value of the following formula: $K_d = 2(\alpha K_d' - K_d)/(n-1)$, where $n = [b96.11]/[b96.11]_0$; C: Injection of the GAD65Ab specific monoclonal AID reduced morbidity of T1D in NOD mice in the 18-week intervention: Female NOD mice from 4-week age were weekly injected with 100 μ g GAD65Ab specific AID (yellow triangle), 50 μ g AID (green circle), 100 μ g control AID (red square) or PBS (blue diamond), onset of T1D was monitored by testing blood glucose weekly; D: GAD65Ab specific monoclonal AID reduced the insulinitis in NOD mice: a-d are representative image from mice treated with 100 μ g AID(a), 50 μ g AID(b), 100 μ g control antibody(c) and PBS(d).

OP 34 Hypoxia and remodelling of adipose tissue

199

Differentiation of human adipocytes at different oxygen levels results in increased adiponectin secretion but impaired adipocyte insulin signalling

S. Famulla, A. Horrigths, A. Cramer, H. Sell, J. Eckel;

Paul-Langerhans-Group, German Diabetes Center, Düsseldorf, Germany.

Background and aims: Obesity is characterized by a low grade inflammation of adipose tissue (AT) and dysregulation of AT secretory function of enlarged adipocytes. Hypoxia has been demonstrated to occur in AT of obese subjects and hypoxia treatment of adipocytes revealed dysregulation of adipocyte secretion with increase in inflammatory adipokines and reduction of adiponectin release. *In vitro* studies using adipocytes are mostly performed under normoxic conditions with a short-term exposure to strong hypoxia after differentiation. The aim of this study was to differentiate human primary adipocytes under physiological conditions of normal tissue oxygenation and to investigate its effect on adipocyte secretion and insulin signaling.

Materials and methods: Human primary adipocytes were differentiated under 5 %, 10 % and 21 % O₂ in an Xvivo hypoxic chamber. Conditioned medium (CM) and cell lysates were collected and analyzed by ELISA and Western Blotting. Fully differentiated adipocytes were treated with 100 nM insulin and insulin signaling was analyzed at the level of Akt phosphorylation. For analyzing the cross-talk between adipocytes and human skeletal muscle cells (hSkMC), hSkMC were incubated over night with the different CM and insulin signaling was investigated.

Results: Differentiation of adipocytes under 5 or 10 % O₂ resulted in unchanged adipocyte formation as demonstrated by lipid accumulation compared to 21 % O₂. However, analysis of adipocyte release revealed substantial differences in the secretion of several adipokines after differentiation at different O₂ concentrations. Adiponectin secretion was significantly elevated in CM of adipocytes differentiated under 5 and 10 % compared to 21 % O₂ (46.1 vs. 74.3 vs. 25.2 ng/ml), whereas reduced leptin levels under 10 % O₂ could be observed (21.7 vs. 14.7 vs. 27.9 pg/ml). Furthermore, release of the novel adipokine DPP-4 was elevated at 5 and 10 % compared to 21 % O₂ (2.1 vs. 3.2 vs. 1.3 ng/ml), whereas IL-6 amounts were reduced in CM at 5 %, but increased in CM of adipocytes differentiated at 10 % compared to 21 % O₂ (48.6 vs. 389.7 vs. 93.6 pg/ml). Analysis of insulin signaling showed a reduced stimulation of Akt phosphorylation by 30 to 40 % in adipocytes differentiated at 5 and 10 % compared to 21 % O₂. Expression analysis revealed an elevation in the expression level of the insulin receptor (IR)-β in adipocytes differentiated under 5 and 10 % compared to 21 % O₂ (2.3 vs. 1.6 fold). Additionally, incubation of hSkMC with CM from adipocytes differentiated under 5 and 21 % O₂ showed a substantial reduction in insulin-stimulated phosphorylation of Akt that was however comparable between both CM (43 % vs. 45 %).

Conclusion: We demonstrate that reduction in oxygen supply during differentiation of human primary adipocytes mimicking physiological tissue oxygen levels does not impair adipogenesis but leads to alterations in adipokine secretion. Especially the oxygen sensitive factor adiponectin shows a substantial elevated level in CM of adipocytes that were differentiated under more physiological concentrations. Furthermore, we observed impaired insulin signaling of adipocytes differentiated at 5 and 10 % O₂ although the expression of the insulin receptor is elevated. This study demonstrates that adipocyte secretion and signaling is highly oxygen sensitive illustrating hypoxia as an important factor in adipocyte biology that might be important in obesity-induced metabolic diseases.

Heme oxygenase-1 specifically modulates pro- and anti-adipogenic molecules to inhibit white adipose differentiation

J. Lindroos, T.-C. Zapf, M. Jeitler, A. Haschemi, S. Tauber, H. Esterbauer, O. Wagner, M. Bilban;

Department of Laboratory Medicine, Medical University of Vienna, Austria.

Background and aims: Adipocyte differentiation is a highly regulated process controlled by a complex signaling network. Mounting evidence suggests an essential role for Heme Oxygenase-1 (HO-1) in adipocyte generation and

function. However, the underlying mechanisms are currently unknown. Here, we aimed to investigate a potential mechanism by which HO-1 regulates adipogenesis.

Material and methods: Construction of transgenic mice was generated with the Cre-loxP system ultimately ablating HO-1 in adipocytes *in vivo*. Transgenic cell lines were made for studying constitutive stable HO-1 knock-down or overexpression in 3T3-L1 preadipocytes. Adipocyte differentiation studies were performed on isolated stromal vascular fractions from transgenic mice (containing preadipocytes) and 3T3-L1 cells.

Results: HO-1 is expressed in 3T3-L1 preadipocytes and declines during initial differentiation. Overexpression of HO-1 in 3T3-L1 cells prevents adipogenesis, whereas shRNA-mediated reduction of HO-1, promotes differentiation, as shown by increased lipid accumulation and elevated expression of adipogenic transcription factors PPARγ, CEBPα, KLF-15 and adipocyte marker genes aP2 and Adiponectin. HO-1 seems specific for white adipose tissue differentiation as knockdown of HO-1 did not affect brown adipocyte (HIB-1B) differentiation. Our findings with 3T3-L1 cells were substantiated with HO-1 deleted preadipocytes isolated from HO-1loxP/loxP mice: Adeno-Cre virus mediated excision of HO-1 *in vitro*, followed by differentiation resulted in enhanced accumulation of neutral lipids, as compared to HO-1loxP/loxP preadipocytes infected with Adeno-GFP virus. GeneChip comparisons of control- and HO-1 overexpressing 3T3-L1 cells induced for differentiation over a time course revealed several genes modulated by HO-1 including transcription factors, signaling proteins, as well as unknown genes. Some of these genes are now being investigated in functional assays as potential mediators of the anti-adipogenic effects of HO-1.

Conclusion: Collectively, our data demonstrate an inhibitory function of HO-1 in (white) adipocyte differentiation via specific modulation of pro-adipogenic and anti-adipogenic molecules.

The canonical Wnt activator, WISP 2, is upregulated in hypertrophic obesity and prevents stem cell commitment and adipocyte differentiation

J.R. Grünberg, A. Hammarstedt, L. Jenn Dahl, S. Hedjazifar, U. Smith;

Molecular and Clinical Medicine/Diabetes, Göteborg, Sweden.

Background and aims: The rapidly escalating prevalence of obesity is the major driver of the ongoing global epidemic of type 2 diabetes. Recent evidence indicates that an inability to normally store excess lipids in the subcutaneous adipose tissue leads to ectopic fat accumulation with insulin resistance and the associated dysmetabolic state. This, in turn, is a likely consequence of a reduced ability to recruit and differentiate new adipose cells leading to hypertrophic obesity. We have recently found that individuals with a genetic predisposition for type 2 diabetes, but not for obesity, are prone to develop hypertrophic obesity following small increases in body weight. This suggests that signaling pathways regulating mesenchymal stem cell commitment and/or preadipocyte differentiation are dysregulated in hypertrophic obesity. The canonical Wnt pathway is a key regulator of precursor cell differentiation to adipose cells. We have found that this pathway is upregulated in hypertrophic obesity and that Wnt-inducible secreted protein 2 (WISP 2) is a mediator of this pathway. We here examined the effect of WISP 2 on human mesenchymal stem cell (hMSC) commitment and differentiation and also if fully differentiated adipose cells are target cells for this secreted protein.

Materials and methods: hMSC were cultured with established protocols and induction of adipogenesis was characterized in the presence or absence of WISP 2 or the canonical Wnt ligand Wnt 3a after 12 and 21 days. 3T3-L1 cells were differentiated to adipose cells and then grown under basal conditions or in the presence of WISP 2 or Wnt 3a for 4 days. RNA and protein were harvested and gene expression measured with qPCR.

Results: WISP 2, like Wnt 3a, prevented hMSC commitment and differentiation to adipocytes measured both in terms of lipid accumulation and gene expression of typical adipocyte markers at both time points; C/EBPα (12d, p<0.01; 21d, p<0.01), FABP4 (12d, p<0.01; 21d, p<0.05), Adiponectin (12d, p<0.001; 21d, p=0.07), GLUT4 (12d, p<0.05; 21d, p<0.01). These effects were similar to those seen with Wnt 3a. Thus, these findings are consistent with WISP 2 as a mediator of the canonical Wnt pathway and an inhibitor of stem cell commitment and adipogenesis. We also examined if differentiated adipose cells are targets for Wnt activation by culturing mature 3T3-L1 adipocytes with WISP 2 or Wnt 3a for 4 days. WISP 2 induced a de-differentiation of the adipose cells measured as expression of adipogenic markers including C/EBPα (p<0.05), GLUT4 (p<0.05) and LPL (p<0.05), similar to the effects of Wnt 3a which is in agreement with our previous work. This downregulation of the adipose

cell phenotype impairs the ability of the cells to accumulate and store lipids. **Conclusion:** These results show that WISP 2, like Wnt 3a, inhibits both commitment and differentiation of adipose precursor cells to the mature adipose phenotype which, in turn, also prevents the cells from storing excess lipids and to secrete adipokines which promote insulin sensitivity like adiponectin. Furthermore, fully differentiated adipose cells undergo de-differentiation which also makes these cells targets for the Wnt pathway. Since WISP 2 inhibits PPAR γ and is upregulated in the adipose tissue in hypertrophic obesity, the present findings support this molecule as an important factor behind the metabolic complications of obesity and the Metabolic Syndrome.

Nutritional reversibility of human adipose tissue hypoxia and fibrosis

K. Kos¹, N. Franck², M. Jernas³, F.H. Nystrom², L.M.S. Carlsson³

¹Institute of Biological and Clinical Sciences, Peninsula College of Medicine and Dentistry, University of Exeter, UK, ²Department of Medical and Health Sciences, Division of Cardiovascular Medicine, Linköping University,

³Department of Molecular and Clinical Medicine, The Sahlgrenska Academy, University of Gothenburg, Sweden.

Background and aim of the study: Adipose tissue (AT) of obese subjects is known to be hypoxic, fibrosed and inflamed which contributes to metabolic dysfunction including diabetes. Collagen VI α III and the metalloproteinase MMP14 which is involved in collagen breakdown have previously been associated with the pathogenesis of diabetes. However, little is known about whether hypoxia and the fibrosis-related extracellular matrix changes (ECM) in adipose tissue (AT) are reversible by caloric restriction. The aim of this study was to examine hypoxia and fibrosis markers, collagens and collagenases in abdominal subcutaneous AT (SCAT) of subjects 1) before and after a very-low-calorie diet (VLCD) and subsequent re-feeding and 2) after fast food based hyper-alimentation induced weight gain.

Materials and methods: For the VLCD study, 24 obese subjects (BMI=37.6 \pm 4.9 kg/m²) underwent a 450 kcal/day based diet for 16 weeks (wks) followed by 2 wks of food reintroduction. Six lean subjects (BMI=21.4 \pm 2.5 kg/m²) underwent a fast food based diet for 4 wks. SCAT-biopsies were performed at 0, 8, 16 wks of caloric restriction by VLCD and at 2 wks after re-feeding. In the hyperalimantation group, biopsies were taken at 0 and 8 wks. ECM components and fibrosis regulators (16 collagens, fibronectin, TGF- β and MMPs) were studied alongside the hypoxia marker HIF-1 α using DNA microarray technology.

Results: With VLCD subjects lost 28 \pm 3.7 kg of weight and weight did not change in the period of food reintroduction. The mean weight gain in the hyperalimantation study was 7.2 \pm 1.6 kg. After VLCD induced weight loss there was no change in collagen Ia1 and Ia2 gene expression, however, within 2 wks of re-feeding, collagen expression increased (42%, p <0.01 and 29%, p <0.001 respectively) responded similar to hyper-alimentation in which collagen Ia1 and Ia2 were also up-regulated by 39% (p =0.01) and 48% (p <0.05) respectively. Collagen VI α 3 expression increased after VLCD (18%, p <0.001) but not significantly with hyper-alimentation and did not respond to re-feeding. With VLCD fibronectin decreased (36%, p <0.001), MMP14 increased (19%, p <0.001), and TGF- β and HIF-1 α remained unchanged; and as expected TGF- β , fibronectin and HIF-1 α increased with hyper-alimentation (p <0.01). In the period of food reintroduction only fibronectin decreased further (15%, p <0.001) whilst TGF- β and HIF-1 α and MMP14 remained unchanged.

Conclusion: Diet induced weight loss fails to reduce expression of the fibrosis inducing growth factor TGF- β , collagen VI α III and the hypoxia responsive gene HIF-1 α . The expression of collagen 1, the most abundant collagen in AT, continues to be up-regulated during weight loss and is hyper-responsive to the nutritional challenge of re-feeding with rapid up-regulation even before weight regain occurs. Whilst metalloproteinases may in part balance increased collagen production with increased collagen turnover during weight loss, the period of refeeding may be prone to an imbalance and subsequent dysfunction. Cyclical dieting also known as yo-yo dieting may thus prime SCAT towards fibrosis and to associated unfavourable metabolic consequences.

Dual effects of sphingosine 1-phosphate (S1P) on proliferation of mature adipocytes

K. Kajita, I. Mori, K. Fujioka, T. Hanamoto, T. Ikeda, H. Okada, T. Usui, N. Takahashi, Y. Uno, H. Morita, T. Ishizuka;
General Internal Medicine, Gifu University Graduate School of Medicine, Japan.

Background and aims: We have reported that mature adipocytes proliferate regulated with proliferin (PLF) in the last scientific session. 5-Bromo-2'-deoxyuridine (BrdU), a thymidine analog, incorporation, as well as expression of proliferating cell nuclear antigen (PCNA), was observed in mature adipocytes isolated from Wistar rats using collagenase digestion. In addition, isolated mature adipocytes were cultured with ceiling culture method, which revealed the population exhibiting dramatically replicating ability. Furthermore, dividing nuclei and centrosomes were identified with immunocytochemical staining using anti- γ -tubulin antibody. On the other hand, increased cell number, which was assessed with hemocytometer and MTT assay, BrdU incorporation and expression of PCNA were detected in fully differentiated 3T3-L1 adipocytes. Cell cycle was clearly recognized with flow cytometry in mature 3T3-L1 adipocytes. As reported previously, we took note of PLF as a growth factor in adipocytes. Gene silencing with siRNA, as well as adding anti-PLF antibody to the culture medium, suppressed cell proliferation in mature 3T3-L1 adipocytes proliferation. Considering the fact that PLF signaling is sensitive to pertussis toxin, we speculated the involvement of S1P in mature adipocyte proliferation. Recent research identified G protein-coupled five S1P receptors which were named S1P₁-S1P₅. Therefore, we evaluated the effect of S1P and inhibition of S1P₁ and S1P₂ on mature adipocytes proliferation.

Materials and methods: Effects of 1 μ M S1P, 10 μ M FTY-720, S1P₁ agonist, and 10 μ M JTE-013, a specific S1P₂ antagonist, on mature 3T3-L1 adipocytes proliferation were measured with BrdU incorporation. We also assessed the impacts of gene silencing of S1P₁ and S1P₂ with siRNA. Moreover, Effects of intraperitoneal injection with JTE-013 (2mg/kg) or FTY-720 (4mg/kg) on mature adipocytes were examined. Animal care and experimental procedures were performed under the approval of the Animal Care Committees of our University.

Results: Treatment with S1P increased BrdU incorporation, while gene silencing S1P₁ with siRNA reduced it. Inhibiting S1P₂ with JTE-013 or knock-down of S1P₂ with siRNA increased it in mature 3T3-L1 adipocytes. Treatment with FTY-720 increased BrdU incorporation in mature 3T3-L1 adipocytes. Taking together, these results indicate S1P₁ and S1P₂ act oppositely on mature adipocyte proliferation, whereas proliferating effect is predominant. Administration of JTE-013 or FTY-720 increased the expression of PCNA in isolated mature adipocytes from epididymal fat of C57/Black mice. Interestingly, treatment with JTE-013 for 2w resulted in suppressed body weight increase and the tendency to lower plasma glucose level in ob/ob mice. These results suggest that accelerated cell proliferation in mature adipocytes might lead to improvement of obesity and diabetes.

Conclusion: S1P regulates mature adipocytes proliferation, which influences glucose and lipid metabolism in whole body.

204

The adipogenic potential of human adipose tissue precursor cells is regulated in a fat depot- and BMI-dependent manner

S. Perrini¹, A. Cignarelli¹, P. Nigro¹, M. Barbaro¹, A. Peschechera¹, R. Ficarella¹, A. Natalicchio¹, M. De Fazio², F. Puglisi², L. Laviola¹, F. Giorgino¹

¹Endocrinology & Metabolism, Department of Emergency and Organ Transplantation, ²General Surgery and Liver Transplantation, Department of Emergency and Organ Transplantation, University of Bari, Italy.

Background and aims: An impaired lipo-/adipogenic capacity of human adipose stem cells (hASCs) may contribute to abdominal obesity and the related metabolic abnormalities. The aim of this work was to investigate whether obesity is associated with changes in the adipogenic potential of hASCs from the subcutaneous (SC) and visceral (V) adipose tissues.

Materials and methods: hASCs were isolated from paired SC and V fat biopsies, obtained from 10 lean (BMI 24.1 \pm 2.3 kg/m²) and 10 obese (BMI 37.4 \pm 3.2 kg/m²) subjects. Cells were differentiated in vitro in the presence of insulin and other adipogenic inducers, and adipogenesis was evaluated by analyzing the lipid deposition by Oil-Red-O staining, lipid droplet area by a dedicated image processing software, and gene expression by qRT-PCR.

Results: In lean subjects, the proportion of terminally differentiated adipocytes derived from SC hASC was significantly higher compared to that from V hASC, along with the estimated lipid droplet size, lipid staining intensity, and mRNA expression levels of PPAR γ 2 and GLUT4 ($p<0.05$). When SC hASC from lean and obese subjects were induced to differentiate comparatively, no significant differences in the proportion of mature adipocytes or PPAR γ 2/GLUT4 expression were detected, even though the fraction of adipose cells with large lipid droplets was higher in obese SC compared with lean SC cell cultures ($p<0.05$). By contrast, a markedly greater number of mature adipocytes, along with larger lipid droplets, and higher PPAR γ 2 and GLUT4 mRNA levels were observed in cultures derived from obese V as compared to lean V hASCs ($p<0.05$). Furthermore, insulin (10–100 nM) increased Akt phosphorylation to a greater extent in obese V as compared to lean V hASCs ($p<0.05$), whereas no differences in ERK-1/2 activation were observed.

Conclusion: Therefore, fat precursor cells isolated specifically from the V depot of individuals with elevated BMI possess an enhanced intrinsic adipogenic potential, which is due, at least in part, to higher responsiveness of Akt to insulin stimulation.

13-year post-trial follow-up of structured personal care for patients with type 2 diabetes in general practice

L.J. Hansen¹, V. Siersma¹, J. Hviid Hornnes¹, H. Beck-Nielsen², N. de Fine Olivarius¹

¹Department of Public Health, University of Copenhagen, The Research Unit for General Practice and Section of General Practice, Copenhagen,

²Medical Department M, Odense University Hospital, Denmark.

Background and aims: In primary care, quality of diabetes care continues to be suboptimal. This 13-year post-trial study assessed the long-term effects of 6 years of structured personal diabetes care from diagnosis on mortality as well as cardiovascular and microvascular complications. **Materials and methods:** The study, Diabetes care in general practice, is a pragmatic, open, controlled trial with randomization of practices to structured personal care or routine care. In 1989–91, 474 volunteering Danish general practitioners (GPs) included 1263 patients with newly diagnosed type 2 diabetes. A further 106 intervention patients were included during the third year for the register-based follow-up only. The intervention included regular follow-up and individualized goal-setting supported by prompting of GPs, clinical guidelines, feedback, and education for GPs. Clinical follow-up was done 8 years after cessation of 6 years of intervention for 475 (86.2%) of 551 surviving of the 1263 patients. Predefined outcomes were all cause mortality and incidence of diabetic retinopathy, microalbuminuria, myocardial infarction, and stroke. Comparisons of the clinical observations between survivors in the intervention and routine care group were made using χ^2 -test for categorical variables and Wilcoxon non-parametric test for continuous variables. A register-based follow-up until death or censoring at 31 December 2008 with outcomes as in UK Prospective Diabetes Study included data from a further 5 years. Time from diagnosis to death or incident outcomes was analyzed with log-rank tests and Cox regression models (SAS PROC PHREG). All endpoints were analyzed according to the intention-to-treat principle.

Results: At clinical post-trial follow-up, relative risk reductions for diabetic retinopathy (25%, $P=0.044$) and microalbuminuria (28%, $P=0.023$) were observed. During 13 years of post-trial follow-up, risk reductions for myocardial infarction (18%, $P=0.038$) and any diabetes-related endpoint (15%, $P=0.029$) emerged.

Conclusion: These results indicate that individualized treatment goals as promoted by our multifaceted structured diabetes care program is a realistic and efficient alternative to using strict targets to treat patients in order to lower the risk of diabetic complications in the general population of type 2 diabetic patients.

Clinical Trial Registration Number: NCT01074762 (ClinicalTrials.gov)

The National Diabetes Inpatient Audit 2010 (NaDIA) reveals concerns about inpatient care in English hospitals

G. Rayman¹, C. Taylor¹, R. Malik², N. Holman³, B. Young⁴, A. Morton⁵, R. Hillson⁶

¹The Diabetes Centre, Ipswich, ²King's College Hospital, London, ³Yorkshire and Humber Public Health Observatory, York, ⁴Salford Royal Hospital, ⁵NHS Diabetes, Newcastle Upon Tyne, UK, ⁶Department of Health, London, UK.

Background and aims: The prevalence of diabetes amongst people in hospital and the frequency of insulin use in this group are increasing in the United Kingdom. Surveys have revealed unacceptable inadequacies of inpatient diabetes care. The National Diabetes Inpatient Diabetes Audit (NaDIA) is a snap shot audit of bedside care inpatients conducted in a single day in 93% of English hospitals in November 2010. It aims to investigate and raise awareness of deficiencies in inpatient diabetes care as well as to drive and measure improvements in care overtime.

Materials and methods: 206 NHS hospitals, in 169 Trusts representing 93% of all Acute Trust in England took part. Bedside data was collected from 12,191 patients and 4745 completed a patient questionnaire.

Results: The Burden of Inpatient Diabetes People with diabetes accounted for 15.0% of audited beds. People with diabetes in hospital were older: Median age of 75 yrs compared to 68 yrs for all inpatients; People with diabetes have substantially longer length of stay: 8 nights compared with 5 nights for all ad-

missions; Nearly 40% were insulin treated. Delivery of diabetes care: Diabetes inpatient specialist input is low: 31.0%, 29.8% and 26.8% of units had no inpatient diabetes specialist nurses, diabetes dietetic or inpatient podiatry service respectively; Diabetes patients rarely see diabetes specialists: Few were under a diabetes consultant (9%) and 69.5% had not been seen by a member of the diabetes team. People with diabetes on insulin had poor glucose control: People with type 1 diabetes had 'good glucose days' (appropriate frequency of testing and values of 4–11 mmol/l) only one third of the time compared to just over half the time for patients with type 2 diabetes. There were significant issues concerning the use of insulin infusions: • 7.6% of insulin infusions were considered inappropriate • 9.9% of insulin infusions exceeded seven days; 12.0% were considered inappropriately long • In 25.8% the transfer to sub-cutaneous insulin was not managed appropriately. Medication errors were common and associated with poorer outcomes: • 26.0% of charts had prescription errors and 20.0% one or more medication management errors • Patients with medication errors had twice the rate of severe hypoglycaemia (18.1 vs 7.9%) • 0.4% (44) developed ketoacidosis and 2.4% severe hypoglycaemia (injectable treatment required) There are concerns about the prevention and management of diabetic foot disease • 21.4% of the units did not have access to a Multi-Disciplinary Footcare Team • Only 27.5% of patients had their feet examined • 2.2% developed a new foot complication during their stay

Conclusion: This unique snapshot audit reveals considerable concern about the care of inpatients with diabetes in most hospitals in England. The audit has now been adopted by the NHS as a driver for change to be repeated on an annual basis.

207

Evaluating benchmarking to optimise management of type 2 diabetes patients: the final OPTIMISE study data for HbA_{1c}, LDL-cholesterol and systolic blood pressure in Belgium

A. Matthys¹, M.P. Hermans², E. Muls³, F. Nobels⁴, G. Krzentowski⁵, N. Claes⁶; ¹AstraZeneca, Brussels, ²UCL St-Luc, Brussels, ³UZ Gasthuisberg, Leuven, ⁴OLV Ziekenhuis, Aalst, ⁵CHU Charleroi, ⁶University of Hasselt, Diepenbeek, Belgium.

Background and aims: Type 2 diabetes is frequently associated with micro- and macrovascular complications which markedly impact on survival, quality of life and health care costs. Standards of care that include provision of effective drug therapies combined with lifestyle interventions reduce such burden and contribute to improved quality of care. Benchmarking incorporates two-sided feedback of physician's individual performance graded alongside the current mean achievement of a peer group, as well as patient's target attainment. This study aimed at assessing the effect of benchmarking on quality of care in type 2 diabetes outpatients over a 12-month period.

Materials and methods: Belgium is one among 6 European countries (BE, GR, LU, PT, SP, UK) participating in the non-interventional, observational OPTIMISE study. Physicians were randomly assigned using a cluster randomisation procedure to either a benchmarking group or control group. The primary endpoint was the percentage of patients achieving preset targets according to European guidelines (2007) for HbA_{1c} (<7%), low-density lipoprotein cholesterol (LDL-C <80 mg/dl Belgium, <100 mg/dl all other countries) and systolic blood pressure (SBP <130 mmHg). Follow-up (FU) markers of preventive screening, such as dietary counselling, smoking habits, physical activity, were also evaluated as secondary targets. The results presented here represent the Belgian final data.

Results: 95 GPs with 1142 patients were randomized to the intervention group and 95 GPs with 1036 patients to the control group. Both groups were highly-comparable regarding all baseline demographic and diabetes-related parameters. 65.0% (1414/2177) of patients were taking lipid-lowering drugs (predominantly statins: 93.4%, 1321/1414), 94.6% (2053/2174) were taking glucose-lowering medication(s), mainly biguanides (77.8%, 1599/2056), and 77.4% (1685/2178) were taking antihypertensives with a majority of patients (67.8%, 1143/1685) taking ≥2 medication classes. The frequency of patients achieving LDL-C target after 12 months FU was increased by benchmarking vs. control (41.1%, 392/953 vs. 35.3%, 319/900; p=0.011). A greater proportion of patients overall had high-density lipoprotein and total cholesterol levels considered excellent (reached target) in both groups after 12 months FU. The frequency of patients reaching SBP target was increased by benchmarking (41.7%, 332/797 vs. 30.5%, 214/701; p=0.003) but there was no significant difference in target HbA_{1c} attainment (62.1%, 605/975 vs. 63.8%, 594/931). The number of patients achieving all 3 targets (LDL-C, HbA_{1c}, SBP) increased after 12 months FU, and was higher (+75%) in the benchmarking group (8.6%, 84/975 vs. 4.9%, 46/931; p=0.001).

Conclusion: The final Belgian results of the OPTIMISE study indicate that benchmarking positively impacts combined target attainment for three major cardiovascular variables (SBP, HbA_{1c} and LDL-C) in type 2 diabetes mellitus patients. However, despite many patients being treated for these cardiovascular variables, the rate of control for LDL-C, SBP and HbA_{1c} remains sub-optimal.

DiabetesE: Assessing progress in implementing national guidance on improving patient experience

B. Wright, K. Moore, H. Seymour; Innove, Manchester, UK.

Background and aims: DiabetesE is an online self assessment tool which measures and benchmarks the quality of diabetes service provision and provides prioritised recommendations for service improvement. It aims to provide a means for encouraging and monitoring specialist diabetes teams' progress in implementing national guidance on improving patient experience.

Materials and methods: During 2010, assisted by an expert reference group of service users, clinicians and managers, a new DiabetesE questionnaire for specialist diabetes teams was developed, piloted and launched. Questions are grouped into 12 modules, including one called Patient Experience. This comprises 23 questions covering the provision, content and quality of structured education, care planning and user feedback, all based on national policy and guidance. A weighting and scoring system is applied to all modules and questions, enabling the automatic generation of scores and of prioritised recommendations for making service improvement. Users can update their answers and obtain revised scores and recommendations as soon as they have made changes to their services.

Results: Between the launch of the questionnaire in November 2010 and 31st January 2011, 97 specialist diabetes teams (community and hospital based) completed the Patient Experience module. The mean score was 71%, 91% of teams scored over 50% and 4% scored over 90%. Responses to questions relating to the NHS Operating Framework 2011/12 requirement that Primary Care Trusts should commission structured patient education to support people with diabetes show that 67% of participating teams offer structured education to people newly diagnosed with Type 1 diabetes and 82% offer ongoing education to people with diabetes under their care. In addition, 65% of teams provide structured education for people using insulin pump therapy, 81% of teams' patient education programmes have written, evidence based, structured curricula, and 86% of these programmes have specific aims and learning objectives. 60% of teams said that patient education programmes are assessed by independent assessors to ensure sustained quality and consistency but only 42% said that the education programmes have enough places to reflect the number of people newly diagnosed with diabetes. Responses to questions about the policy requirement to provide personalised care and care planning show that only 61% of participating specialist teams agree personal care plans with people newly diagnosed with diabetes. In addition, care plans are updated by just 51% of teams and a copy of the care plan is given to the patient by only 57%. Answers to questions about the need for services to regularly survey patients and seek their views to help improve patient experience reveal that whilst 73% of participating specialist teams actively survey people with diabetes about their experience of using the diabetes service, only 35% feed survey results back to patients and just 48% can demonstrate that they act on the results of patient surveys.

Conclusion: Although there is widespread provision of structured education and the majority of teams undertake patient experience surveys, there is considerable room for improvement to ensure that education programmes have the capacity to meet demand, patients are involved in care planning and are given feedback on the outcomes of surveys, and services act on the results of patient surveys. Ongoing use of DiabetesE will enable specialist teams to continually monitor their progress in implementing guidance on enhancing patient experience.

Primary care providers: the key to improvement in diabetes care nationwide in Israel

M. Goldfracht¹, D. Levin², O. Peled³, I. Poraz⁴, E. Stern⁵, C. Key⁶, N. Lieberman⁷, O. Jacobson⁸, J. Dreier⁹;

¹Quality Improvement Department, Medicine Section, Community Division,

²Health Education and Promotion Department, Community Division, ³Head

Nurse Office, ⁴Chief Dietitian, Medicine Section, Community Division,

⁵Jaffa Diabetes Clinic, Tel-Aviv Jaffa District, ⁶Nursing Section, Community

Division, ⁷Medicine Section, Community Division, ⁸Community Division,

⁹Head Physician's Office, Clalit Health Services, Tel-Aviv, Israel.

Background and aims: Clalit Health Services (CHS) is the largest health maintenance organization (HMO) in Israel, provides healthcare for 4 million citizens, 53% of the Israeli population, and 72% of patients with diabetes in Israel. Since 1995, the responsibility for management of diabetes was placed in primary care services. This study describes CHS's program "Diabetes in the Community" for improving diabetes care for all diabetes patients (300,000), insured by CHS nationwide.

Materials and methods: CHS operates 1,150 primary care clinics- all computerized since 2001, employing 4,000 general practitioners and family physicians, and 2,050 nurses. Multifaceted interventions were directed towards primary care providers and included an educational approach, registries, clinical pathways, care quality indicators, computerized reminders, patient empowerment and feedback. The quality of diabetes care was evaluated using diabetes-specific indicators. Initially, in 1995, performance was documented and evaluated manually. Computerized quality indicators for the entire diabetes patient load were available as of 2001, from which time data were collected by a computerized central system for all patients and were analyzed by SPSS for Windows, with the chi-square test for detecting statistical significance in categorical variables.

Results: The prevalence of diabetes, as reported to the registry, increased from 20.2/1000 in 1995 to 63.7/1000 in 2007. Annual performance of HbA_{1c} test rose from 22% in 1995 to 88% in 2007. LDL cholesterol test increased respectively from 23% to 89%, and microalbumin testing rose from 10% to 69% ($p<0.0001$ for all comparisons). The proportion of patients with HbA_{1c} $\leq 7\%$ rose from 10% in 1995 to 53% in 2007, while the proportion of patients with HbA_{1c} $> 9\%$ decreased from 40% to 13% ($p<0.0001$). The rate of LDL cholesterol ≤ 100 mg/dl rose from 26% in 2001 to 59% in 2007 ($p<0.0001$).

Conclusion: Primary care has a major role in diabetes care; charging it with the responsibility for diabetes care can lead to improvement of follow up and management of diabetes nationwide.

Performance of follow-up and control, Clalit Health Services diabetes patients, 1995–2007.

Indicator	1995	1997	1999	2001	2003	2005	2006	2007

Changes in diabetes therapy and the quality of diabetes care in patients with type 1 diabetes 1989 to 2010: the JEVIN-Trial

T. Heller¹, C. Kloos¹, I.S. Ross², G. Wolf¹, U.A. Müller¹;

¹Internal Medicine III, University Hospital Jena, Germany, ²Laboratory Medicine, University of Aberdeen, UK.

Background and aims: The JEVIN-Trial started in 1989/90 as a cross-sectional survey on the quality of diabetes care of insulin treated diabetes patients ($n=190$; age 16–60y.) who were registered in Jena. The cohort was examined every 5 years. In 2004/05 and 2009/10 the follow up was continued only for patients with type 1 diabetes. Since the beginning of the trial enormous changes in social structure and medical care and therapy have occurred. The

health care system was decentralized in 1989/90 and structured treatment, as well as teaching programmes for intensified insulin therapy were established. After 1995 privately run diabetes specialized out-patient care was established, human insulin replaced animal insulin, insulin analogues were introduced, use of insulin pump increased and Point-of-Care-Testing diagnostic with multiple daily blood glucose controls became standard. The aim was to analyze changes in diabetes therapy and quality of diabetes care in a closed population of patients with type 1 diabetes in a period of 20 years.

Materials and methods: Of 131 patients with type 1 diabetes examined in 1989/90, 104 (79.4%) patients could be detected in 2009/10, 23 (17.6%) had deceased, 13 (9.9%) refused to participate. 68 (84%) patients were examined: age 59.4y; women 35.3%, diabetes duration 36y, BMI 26.6kg/m², blood pressure 144/82mmHg. Mean A1c-values are DCCT adjusted (normal mean 5.05%).

Results: 98% of the patients used conventional insulin therapy in 1989/90, after 2004/05 all patients used basal/bolus insulin regimes or insulin pump therapy. The frequency of blood glucose self-monitoring increased from 2.5/week in 1989 to 35/week in 2010 ($p<0.001$). In 1989/90 only animal insulin therapy was used, in 2000 78.6% had human insulin, 11.9% human- + analogue insulin, 9.5% animal- + human- + analogue insulin. In 2010 analogue insulin was used in 37.3%, human insulin in 35.8%, human- + analogue insulin in 26.9%. A1c-values in 1989 were 7.5% ($n=63$), 1995 8.4% ($n=52$), 2000 7.5% ($n=42$), 2005 7.7% ($n=48$) and 2010 6.9% ($n=67$). The increase in A1c from 1989 to 1995 ($p=0.007$) and the decrease from 1995 to 2000 ($p<0.001$) as well as from 1989 to 2010 ($p=0.008$) are significant, but not the A1c-values from 1989 to 2005. The prevalence of retinopathy was 69%, peripheral neuropathy 51% and albuminuria 39%.

Conclusion: During the follow-up of the long term study from 1989 to 2010 the political and social setting was completely turned over and the structure of diabetes treatment and therapy in patients with diabetes type 1 changed enormously. Centralized diabetes care and conventional therapy with animal insulin was replaced by decentralized diabetes care and intensified therapy with analogue- and human insulin. In spite of all changes, the quality of diabetes care remained remarkably good and stable. After a temporary deterioration until 1995, the initial quality of care was obtained again after 10 years and even exceeded after 20 years.

Effects of diet and diet plus physical activity on psychological outcomes in newly diagnosed type 2 diabetes mellitus: results of a randomised controlled trial

I. Bennett-Britton¹, A. Kingsly², P. White², N.A. Jackson¹, M.Z. Chen¹, R.C. Andrews¹;

¹Early ACTID Office, Joint Clinical Research Unit, University of Bristol,

²Department of Mathematical Sciences, University of the West of England, Bristol, UK.

Background and aims: The Early Activity in Diabetes (Early ACTID) Trial showed that both dietary and dietary plus activity interventions based on Motivational Interviewing improved glycaemic control, weight loss and reduced medication use over 12 months when compared to usual care in patients with newly type 2 diabetes mellitus (T2DM). Dietary advice alone was as effective as diet plus activity over this period. Few studies have reported the effect of diet and exercise on psychological outcomes, particularly soon after diagnosis or compared the benefits of increased physical activity over and above intensive dietary support on these outcomes. Here we aimed to determine the effect of increased physical activity on the psychological outcomes over that produced by intensified dietary intervention or usual care in individuals with newly diagnosed T2DM.

Materials and methods: 593 individuals, aged 60±10 yrs and 197±58 days from diagnosis were randomly assigned in a 2:5:5 ratio to receive usual care (UC, n=99; initial dietary consultation and 6 monthly follow-up), dietary (D, n=248; 3 monthly dietary consultation with monthly nurse support) or dietary plus activity (DA, n=246; equal contact time as D but with addition of a pedometer based exercise programme). The Diener's Satisfaction with Life Scale, EQ-5D scale, Diabetes Treatment Satisfaction and Brief Illness Perception Questionnaires were completed at baseline, 6 and 12 months.

Results: At baseline there were no statistically significant differences in illness perception, treatment satisfaction or EQ-5D between the three groups. Patients in UC had a lower Diener's score than D (22±7 vs 24±6 p=0.001), and DA (22±7 vs 24±7, p = 0.006) at baseline, but there were no differences between D and DA. UC only saw an improvement in their understanding (6.7±2.3 vs 7.4±2.1, p=0.012), expectation of disease continuation (9.0±2.2 vs 9.5 ± 1.9, p=0.028) and concern of their illness (5.3±3.0 vs 4.7±3.2, p=0.018) across the 12 months. D increased their understanding (6.9±2.4 vs 8.0±1.8, p <0.001), became less concerned (5.7±3.0 vs 5.1±3.0, p=0.005) and felt more in control of their illness (7.1±2.3 vs 7.6±2.0, p=0.002) over the 12 months. Satisfaction with treatment (29±6 vs 32±4, p<0.001) and self reported health scores (73±17 vs 76±16, p=0.007) also improved. DA showed similar improvements to D with the exception of their health scores which did not improve (74±16 vs 76±16, p=0.115). Neither intervention groups showed improvements in satisfaction with life. At 12 months, D and DA, compared to UC, felt in greater control of their illness (7.6±2.0 (D) vs 6.7±2.5 (UC), p=0.002; 7.6±2.0 (DA) vs 6.7±2.5 (UC), p <0.001), were more satisfied with their diabetes treatment (32±4 (D) vs 31±5 (UC), p=0.002; 32±4 (DA) vs 31±5 (UC), p <0.001) and had higher self reported health scores (76±16 (D) vs 71±17 (UC), p=0.047; 76±16 (DA) vs 71±17 (UC), p=0.013). No differences in any of the measures were seen at 12 months between D and DA.

Conclusion: D and DA programmes introduced soon after diagnosis of T2DM help patients to understand and feel more in control of their illness, as well as improving their satisfaction with treatment and health status. They do not however improve satisfaction with life and adding activity to a diet programme seems to confer no additional benefit.

Higher number of stressful life events in families of children with type 1 diabetes mellitus onset under 5 years of age than in families of healthy controls

B.M. Zdunczyk¹, A. Szypowska²;

¹Clinical Pediatric Hospital, Warsaw, ²Department of Pediatrics, Medical University of Warsaw, Poland.

Background and aims: Recent years show the worldwide increase in incidence of T1DM in every age group. There hasn't been found one good explanation

why the biggest increase is seen in children at the age 0-4 old. Stress is one of factors seen as contributing to T1DM development. The aim of this study was to assess the incidence rate of serious life events in families of children with T1DM prior to diabetes onset and examine if there is a difference in occurrence of such events depending on the age of a child at T1DM recognition in comparison with families of children in general population.

Materials and methods: The study was carried out from November 2008 to June 2010. There were included 822 families: 347 parents of children with T1DM and 475 parents of children without diabetes. Participants with T1DM were divided into two groups depending on the age of diabetes diagnosis: parents of 123 parents of children (67 girls, 56 boys) with T1DM onset at the age 5 years while the control group consisted of parents of 124 children (64 girls, 60 boys), at the age 0-5 years, and parents of 350 children (172 girls, 178 boys) at the age 6-17 years. Parents of children with T1DM completed a questionnaire on stressful events during the routine control visit, parents in control group - during the parents meeting. The questionnaire contained a hierarchical list of stressful events which may cause Posttraumatic Stress Disorder.

Results: Families of children with T1DM onset <5ys had experienced serious life events before diabetes diagnosis significantly more often than control subjects 57/66 vs. 38/86 respectively, $\chi^2=6.43$, $p=0.011$. There was no difference in the number of families of children with T1DM recognized 5ys affected with serious life event 57/66 vs. 108/116 respectively, $\chi^2=0.94$, $p=0.369$, and between children with T1DM recognized >5ys and controls 108/116 vs. 173/177 respectively, $\chi^2=0.303$, $p=0.608$. Results of multiple logistic regression analysis of serious life events in families of children with diabetes onset at < 5 years of age showed that 2 events were significantly associated with diabetes: divorce (OR 3.31 95%CI 3.51to21.4, $p=0.002$) and serious accidents (OR 2.21 95%CI 1.02to81.92, $p=0.048$).

Conclusion: Children with diabetes recognized < 5ys were affected more often with serious life events before diabetes diagnosis than their healthy peers which highlights the possible association between stress in families and the development of type 1 diabetes in the youngest children. Especially parental loss due to divorce may be a factor in the development of diabetes. Further prospective studies should be carried out to expand understanding of involved mechanisms.

213

The course of depression in primary care patients with type 2 diabetes: results from the DiaDDZoB study

G. Neefs, F. Pouwer, J. Denollet, V. Pop; Tilburg University, Netherlands.

Background and aims: Compared to controls without diabetes, the risk of depression is doubled in individuals with type 2 diabetes, affecting approximately one in every five patients. Despite a growing body of literature demonstrating the health risks of depression in this patient group, the course of depression has received relatively little attention. Therefore, the main aim of the present study was to examine the incidence and recurrence/persistence of depression in primary care patients with type 2 diabetes and to identify significant predictors of these course patterns.

Materials and methods: A cohort of 2460 primary care patients with type 2 diabetes was assessed for demographic, clinical and psychological factors, including symptoms of depression, in 2005 (baseline) and followed-up in 2007 (M_1) and 2008 (M_2). Incidence and recurrence/persistence of depression were defined using data from these three separate assessments, with a score of ≥ 12 on the Edinburgh Depression Scale (EDS) indicating depression. Stepwise logistic regression analyses were used to determine whether incident and recurrent/persistent depression could be predicted by means of baseline (1) demographics (female sex, age, being single, low education); (2) medical co-morbidities (prior cardiovascular disease, the presence of microvascular complications, a history of other co-morbid conditions); (3) stressful life events, self-reported history of depression (only for recurrence/persistence).

Results: Prevalence rates of depression were 12%, 14% and 16% at baseline, M_1 and M_2 , respectively. A total of 2124 patients completed the EDS at one or more assessments, with 21% reporting an EDS-score of ≥ 12 at least once (any depression). Compared with men, women were more likely to be depressed at any moment during the study (28%, $n = 303$ versus 15%, $n = 152$; $p < 0.001$). In the subgroup with no self-reported history of depression and no baseline depression ($n=1675$), incident depression at M_1 or M_2 was present in 171 individuals (10%), with a higher rate for women (13%, $n = 109$ versus 7%, $n = 62$; $p < 0.001$). As for recurrent/persistent depression, 46% of the 222 patients who were depressed at baseline also met the criterion for depression

at M_1 and/or M_2 . Recurrence rates were similar for female and male patients (48%, $n = 72$ versus 42%, $n = 30$; $p = 0.458$). Female sex (OR 2.35, 95% CI 1.45–3.81), low education (OR 1.87, 1.10–3.16), microvascular disease (OR 1.78, 1.13–2.79), other co-morbid conditions (OR 1.67, 1.06–2.62) and stressful life events (OR 1.70, 1.09–2.67) were all positively associated with incident depression, while the cardiovascular co-morbidities increased the odds of depression by 28%, but did not reach statistical significance ($p = 0.300$; $n = 971$). Low education level was the only significant predictor of recurrent/persistent depression (OR = 2.69, 95% CI 1.01–7.15; $n = 133$).

Conclusion: Depression is common in primary care patients with type 2 diabetes and often presents as a chronic condition. As recognition rates of depression are generally low while effective antidepressant treatments are available, monitoring of emotional well-being seems warranted, but should be embedded in collaborative care approaches.

214

Atlantic DIP: Diabetes in Pregnancy: a comparative study of stress and wellbeing in women with established diabetes, gestational diabetes, and those without diabetes

K. Lydon¹, B. McGuire², L.A. Owens¹, K. Sarma², G. Avalos¹, L. Carmody¹, C. O' Connor¹, L. Nestor¹, F. Dunne¹

¹Department of Medicine, National University of Ireland, Galway, ²School of Psychology, National University of Ireland, Galway, Ireland.

Background and aims: Diabetes in pregnancy increases the risk of maternal and perinatal morbidity and mortality. The experience of diabetes during pregnancy may be a significant source of stress, both because of the impact of the illness and associated treatments on the expectant mother and because of concern about the impact on the unborn child. In order to examine stress associated with diabetes during pregnancy, we carried out a prospective study in women with pre-existing (Type 1 or Type 2) Diabetes (PDM), Gestational Diabetes Mellitus (GDM), and non-diabetic pregnant controls (NDM).

Materials and methods: The participants were 210 pregnant women - 25 with pre-existing diabetes (PDM), 77 with GDM and 108 healthy controls (NDM). All were attending antenatal services in six health care centres in Ireland. We measured stress and wellbeing with several standardised psychological questionnaires including The Pregnancy Experience Scale; The Depression Anxiety Stress Scale; the Multidimensional Perceived Social Support Scale; the Illness Perception Questionnaire-Diabetes; the Diabetes Self-Efficacy Scale; the SF-8 and the Problem Areas in Diabetes Scale. We hypothesized that diabetic women would report higher levels of stress than healthy controls and we also hypothesized that social support may confer a protective role.

Results: We found a non-significant trend of increased stress and lower quality of life among diabetic women compared to non-diabetic controls. Women with PDM perceived their illness as having a higher impact on their lives than those with GDM ($p < 0.0001$). However, women with pre-existing diabetes also reported significantly greater self-efficacy in relation to their diabetes management compared to their gestational diabetes counterparts ($p < 0.05$). The results of the remaining questionnaires demonstrate a general trend towards higher distress in diabetic women compared to controls. The healthy controls reported higher perceived social support which may confer a protective role against psychological stress.

Conclusion: These preliminary results suggest that pregnant diabetic women perceive themselves as having a lower quality of life and higher levels of stress in pregnancy, especially women with pre-existing diabetes. This may indicate a need for psychological support in these patients. However, further research is required.

215

Comparing the effect of 2 different methods of follow-up after structured group education on psychosocial measures in patients with type 1 diabetes: the Irish DAFNE Study

M. O'Hara¹, S.F. Dinneen^{1,2}, J. Newell^{3,4}, N. Coffey⁴, M. Byrne⁵, DAFNE Study Group;

¹Endocrinology and Diabetes Centre, University Hospital Galway, ²Medicine, ³HRB Clinical Research Facility, ⁴Mathematics, Statistics and Applied Mathematics, ⁵Psychology, NUI Galway, Ireland.

Background and aims: This study compared group follow-up (intervention) with individual clinic follow-up (control) after delivery of the Dose Adjustment for Normal Eating (DAFNE) education programme to 437 participants

with type 1 diabetes. Psychosocial measures were included as secondary outcomes in this cluster randomised controlled trial. Group follow-up did not impact on the primary outcome, change in HbA_{1c} over time. Rates of severe hypoglycaemia did not differ significantly between intervention and control groups but there was a significant improvement in rates of severe hypoglycaemia over time.

Materials and methods: Hospital Anxiety and Depression Scale (HADS), Problem Areas in Diabetes (PAID), and Diabetes-Specific Quality of Life Scale (DSQOLS) were used to assess psychosocial outcomes at baseline and at 6, 12 and 18 months post-DAFNE. HADS measures mood disorder in particular anxiety and depression. PAID assesses diabetes-related distress. A validated English language version of DSQOLS was used to measure quality of life. The instrument has 4 subscales, Social Aspects, Fear of Hypoglycaemia, Dietary Restrictions and Physical Complaints as well as an overall quality of life (QoL) score.

Results: Participants in both the group follow-up ($n = 216$) and the individual follow-up ($n = 221$) arm of the study reported a mean reduction in anxiety (HADS-Anxiety, -0.53, $p < 0.001$), in depression (HADS-Depression, -0.44, $p < 0.001$), in diabetes-related distress (PAID, -9.41, $p < 0.001$) and a mean increase in overall QoL (DSQOLS, 9.23, $p < 0.001$) respectively from baseline to 18 months. There was no significant difference between groups for any of the measures (HADS-Anxiety, 0.13, $p = 0.43$; HADS-Depression, 0.13, $p = 0.37$; PAID, 1.55, $p = 0.12$; DSQOLS, -1.95, $p = 0.08$). A mean improvement in both groups was also observed for each of the DSQOLS subscales with Social Aspects, Fear of Hypoglycaemia and Physical Complaints improving on average by over 7%, Dietary Restrictions improved on average by over 17% in both groups. Similar to the other psychosocial measures there was no treatment effect between groups.

Conclusion: All the measures reported improvements post-DAFNE, these initial improvements were maintained in quality of life, depression, anxiety and diabetes-related distress after 18 months. DAFNE aims to give people the skills necessary to efficiently match the correct insulin doses to the amount of carbohydrate eaten while emphasising dietary freedom and flexibility. This may account for the Dietary Restrictions subscale on average showing the greatest improvement over time. While this trial confirms that DAFNE improves initial psychosocial outcomes and helps maintain them over 18 months, it also shows that structured group follow-up provides no additional benefit over traditional one-to-one clinic visits.

Widespread decreased white matter tract integrity in type 1 diabetes mellitus patients with microangiopathy and its relation to cognitive functions and disease variables

E. van Duinkerken^{1,2}, P.J.W. Pouwels³, R.G. Ijzerman¹, F. Barkhof⁴, M. Klein², F.J. Snoek², M. Diamant¹;

¹Diabetes Center / Department of Internal Medicine, ²Department of Medical Psychology, ³Department of Physics and Medical Technology, ⁴Department of Radiology, VU University Medical Centre, Amsterdam, Netherlands.

Background and aims: Type 1 diabetes mellitus (T1DM) is associated with brain volume loss and cognitive changes predominantly found in domains concerning information processing speed. A recent study, in a small sample, showed focal loss of white matter tract integrity in parts of the corpus callosum in T1DM patients relative to controls. This is of interest as loss of white matter tracts may result in loss of processing speed. Therefore, we aimed to identify changes in tract integrity in a large group of T1DM patients with and without microangiopathy and controls and determine its relationship with disease variables and cognitive functions.

Materials and methods: Forty-eight T1DM patients with and 52 patient without microangiopathy and 49 controls underwent MRI, including diffusion tensor imaging (DTI) with 60 directions of encoding. Using the diffusion toolbox and tract-based-spatial-statistics (TBSS), part of FSL4.1 software, we calculated fractional anisotropy (FA), as a marker of tract integrity. Cognitive functions were assessed using an elaborate cognitive test-battery. Analyses were corrected for age, gender, depressive symptoms and multiple comparisons.

Results: T1DM patients with microangiopathy were significantly older, had higher HbA_{1c} levels and depression scores compared to their counterparts and controls (all $P < 0.05$). Decreased FA was found in T1DM patients with microangiopathy relative to patients without microangiopathy and controls,

and was widespread, most notably in the bilateral inferior fronto-occipital fasciculus (IFO), corticospinal tracts, parts of the corpus callosum, cingulate gyrus, and in parts of the left temporal cingulate tract, whereas patients without microangiopathy showed a small, but statistically significant, decrease in FA in the frontal part of the brain compared to controls. As the left IFO showed the most consistent decrease in integrity in T1DM patients compared to controls we selected the mean FA-value of this tract for each participant, to determine correlations between FA of the left IFO, disease variables and cognitive functions. In the total population of T1DM patients, the mean FA-value of the left IFO correlated negatively with disease duration ($r=-0.338$) and albumin-to-creatinine ratio (ACR) ($r=-0.287$) and positively with general cognitive ability ($r=0.258$), information processing speed ($r=0.281$), executive functions ($r=0.280$) and attention ($r=0.301$) (all $P<0.01$).

Conclusion: T1DM patients with microangiopathy showed notable and widespread decreases in white matter integrity compared to controls and patients without microangiopathy, most pronounced in the left IFO and corticospinal tracts. In the T1DM patients, a reduced integrity of the IFO was associated with worse cognitive performance, longer disease duration and higher ACR levels. Longitudinal follow-up should identify possible mechanisms involved in decreasing FA and its relation to cognitive functional changes over time.

The relationship between distribution of body mass index and all fatal and non-fatal cancers combined: the FINRISK study

X. Song, Q. Qiao;

Hjelt Institute, University of Helsinki, Finland.

Background and aims: Although a high body mass index (BMI) has been well recognised to be associated with increased risk of all-cause mortality, fatal and non-fatal cardiovascular disease (CVD), its role as a risk factor for cancer events including fatal or non-fatal cancers remains controversial. The objective of this study was to investigate the relationship between BMI and cancer events based on the FINRISK study.

Materials and methods: We examined the association between cohort-specific BMI decile and cancer events in a prospective cohort study among 26 690 Finns aged 24–74 years, free of CVD, diabetes or cancer at enrollment. Multivariate-adjusted hazard ratios and 95% confidence intervals for cancer events were estimated using Cox proportional hazard analysis compared to the lowest BMI decile.

Results: During a mean follow-up of 15.9 years, 2 729 all fatal and non-fatal cancers combined occurred, including 880 fatal cancers and 2 611 non-fatal cancers. Crude risk (/1000 person-year) for all fatal and non-fatal cancers combined increased with increasing cohort-specific BMI decile, from 4.20 in the lowest BMI decile to 8.81 in the highest BMI decile in men and from 4.68 to 8.61 in women, respectively (P for linear trend both <0.001) (Figure 1). However, the linear relationship disappeared and HRs were not significant both in men and women, compared with the lowest BMI decile after adjusting for age, area, smoking status, leisure time physical activity, educational level, household income, alcohol consumption, daily intake of vegetable and fruit. The negative relationship remained after exclusion of fatal and non-fatal cancers combined occurring during the first five years of follow-up. Furthermore, the results for fatal or non-fatal cancers were similar.

Conclusion: Elevated BMI didn't increase the risk of cancer events after accounting for confoundings.

Figure 1 Crude events rate/1000 person-year (PY) (open circles), hazard ratio (solid diamonds) and 95% confidence interval (95% CI) (vertical bars) for all fatal and non-fatal cancers combined by deciles of cohort-specific body mass index (BMI) among men and women in FINRISK study adjusted for all confoundings at baseline. The lowest decile of cohort-specific BMI served as a referent group.

Time-varying risk of breast cancer after onset of type 2 diabetes: evidence of detection bias in post-menopausal women

S.L. Bowker¹, K. Richardson², C.A. Marra¹, J.A. Johnson¹;

¹School of Public Health, University of Alberta, Edmonton, ²University of British Columbia, Vancouver, Canada.

Background and aims: There is evidence of a modestly elevated risk of breast cancer in women with type 2 diabetes. However, it is unclear whether this risk is related to a potential detection bias surrounding diabetes onset, and if it is limited to post-menopausal women. Our objective was to examine the risk of breast cancer in pre- and post-menopausal women with incident type 2 diabetes during earlier and later time windows following diabetes onset.

Materials and methods: This was a population-based retrospective cohort study, using linked health databases from British Columbia, Canada. From 1996–2006, we identified incident diabetes and non-diabetes cohorts of women, matched on age and index year. Following a minimum two-year cancer washout period, first breast cancers were identified prospectively in both cohorts, via linkage to the British Columbia Cancer Agency database, with follow-up until death, departure from the province, or March 31, 2006. Cox regression analyses were used to estimate the hazard ratios (HR) and 95% confidence intervals (CI) for the association between incident diabetes and breast cancer, adjusting for age, socioeconomic status, and frequency of physician visits in the two years prior to cohort index. We stratified this analysis, using age as a proxy, for pre- (<55 years) and post-menopausal (≥55 years) status. We examined this relationship in earlier (0–3 months) and later (3 months–10 years) time windows after diabetes onset.

Results: There were 84,506 women in each of the diabetes and matched non-diabetes cohorts and the mean (SD) age was 61.8 (14.2) years. Mean (SD) follow-up was 4.4 (2.9) and 4.5 (2.9) years for the diabetes and non-diabetes cohorts, respectively. Over the full follow-up period, breast cancer incidence rates (per 1,000 person-years) were 1.83 (95%CI: 1.61–2.08) and 1.92 (95%CI: 1.68–2.21) for pre-menopausal women with and without type 2 diabetes, and 4.02 (95%CI: 3.77–4.29) and 3.89 (95%CI: 3.62–4.19) for post-menopausal women with and without type 2 diabetes, respectively. In the first 3 months following diabetes onset, the HRs for breast cancer were 0.95 (95%CI: 0.48–1.86; $p=0.88$) and 1.31 (95%CI: 0.92–1.86; $p=0.14$) in pre- and post-menopausal women with type 2 diabetes, respectively, compared to women without type 2 diabetes. In the later time window of 3 months to 10 years following diabetes index, the risks of breast cancer were 0.92 (95%CI: 0.75–1.13; $p=0.45$) and 1.00 (95%CI: 0.90–1.11; $p=0.93$) in pre- and post-menopausal women with type 2 diabetes, respectively.

Conclusion: Our findings suggest a trend towards an increased risk of breast cancer in post-menopausal women with type 2 diabetes, but only in the time period immediately following diabetes onset. These observations suggest previous reports of an increased risk of breast cancer in women with diabetes may have been over-estimated due to detection bias at the time of diabetes onset.

The influence of glucose-lowering therapies on cancer specific mortality in type 2 diabetes

S. Ioacara¹, C. Guja¹, C. Ionescu-Tirgoviste¹, S. Fica², S. Sabau³, S. Radu¹, M. Anghel¹, C. Tiu⁴;

¹I. Pavel Outpatient Clinic, Bucharest, ²ELIAS Hospital, Bucharest, Romania,

³Tokai University, Sapporo, Japan, ⁴University Hospital, Bucharest, Romania.

Background and aims: Following the general concern regarding the association between various diabetes treatments and cancer risk, the present study evaluated the cancer specific mortality in patients with type 2 diabetes.

Materials and methods: All type 2 diabetes patients residing in a major urban area, with onset over 40 years and receiving diabetes treatment were

included at the moment of their first diabetes outpatient visit from 1st January to 31st December 2001. All patients were followed-up for death of any cause until 31st December 2009 by crosslinking with the National Institute of Statistics mortality database, with a virtually 100% cover-up. Mortality data for the general population was obtained from the same source. Death related data was based on death certificate. Demographics and diabetes history were obtained from the Regional Diabetes Registry and patient files. Antidiabetic prescriptions for baseline and follow-up period, including the dose were available from local pharmacies or prescribing institutions. Glitazones, GLP-1 analogues, DPP4 inhibitors and basal insulin analogues were not marketed in 2001. A total of 21473 subjects (45.1% males) were divided into four groups according to whether they received monotherapy with biguanides (BIG, $n=4123$, 19.2%), insulin secretagogues (SEC, $n=8008$, 37.3%), combined oral therapy (COM, $n=7345$, 34.2%), or insulin (INS, $n=1997$, 9.3%) at baseline. Adjusted Cox proportional hazard models and other (non)parametric tests were used for statistics.

Results: At baseline, mean age was 64.06 ± 9.75 years and mean diabetes duration 5.89 ± 6.36 years. Mean follow-up was 7.4 ± 2.42 years (158808.2 person-years). Overall, unadjusted all-cause mortality was 43.4/1000 person-years (6893 deaths); cancer mortality was 7.25/1000 person-years (1152 deaths). The major types of cancers were: pulmonary ($n=179$, 15.5%), colorectal ($n=175$, 15.2%), pancreatic ($n=114$, 9.9%), liver ($n=109$, 9.5%), breast ($n=102$, 8.9%) and prostate ($n=59$, 5.1%). All-cause and cancer specific mortality rates in the general population were 11.18/1000 and 2.05/1000 subjects respectively. Age adjusted cancer mortality rates for 1000 person-years were calculated using the general population as reference: overall 2.76 (CI95% 2.6–2.92), BIG 2.15 (CI95% 1.83–2.47), COM 2.23 (CI95% 1.99–2.47), SEC 3.22 (CI95% 2.94–3.5) and INS 4.12 (CI95% 3.39–4.85). Comparing with MET, the adjusted HR for cancer mortality was 1.08 (CI95% 0.9–1.3, $p=0.38$) for COM, 1.47 (CI95% 1.24–1.75, $p<0.001$) for SEC and 1.59 (CI95% 1.27–2.01, $p<0.001$) for INS. In INS group, future exposure to basal insulin analogues during follow-up did not changed the cancer mortality for both glargine (HR 0.59 CI95% 0.29–1.21, $p=0.15$) and detemir (HR 0.21 CI95% 0.03–1.55, $p=0.13$). Compared with BIG, the INS group had a higher risk for liver (HR 3.59 CI95% 1.68–7.66, $p<0.001$) and breast (HR 2.28 CI95% 1.09–4.79, $p=0.03$), but not for pulmonary, colorectal, pancreatic or prostate cancer mortality.

Conclusion: Taking into account the differences in age distribution, type 2 diabetes patients treated with insulin or insulin secretagogues are at increased risk for all-cause and cancer mortality compared with those on biguanides monotherapy. Exposure to long acting analogues was not associated with increased cancer mortality in insulin treated subjects.

Identification of molecular pathways involved in diabetes-associated cancers

V. D'Esposito¹, F. Passaretti^{1,2}, S. Cabaro¹, A. Hammarstedt³, R. Valentino¹, G. Perruolo¹, U. Smith³, F. Beguinot¹, P. Formisano¹;

¹DBPCM and IEOS-CNR, Università degli studi di Napoli Federico II, Napoli, ²Dipartimento di Scienze Farmaceutiche, Università degli studi di Salerno, Salerno, Italy, ³Laboratory for Diabetes Research, Department of Molecular and Clinical Medicine/Diabetes, Institute of Medicine, Sahlgrenska Universitetssjukhuset, Göteborg, Sweden.

Background and aim: A growing body of evidence indicates that diabetes mellitus increases the risks of site-specific cancers of the bladder, endometrium, liver, colorectum, pancreas and breast. Adipocytes and their precursor cells, may provide key factors needed for tumor development, progression, or even enable tumor cell invasion. Nevertheless, whether metabolic alterations at the level of the adipose tissue may affect specific phenotypes of the cancer cells is still unclear. Thus, the aim of this study is to evaluate whether metabolic factors, such as glucose and free fatty acids, may affect the functions of adipocytes in promoting breast cancer cell growth.

Methods: 3T3-L1 cells, human adipocytes and their undifferentiated precursors were incubated in the presence or in the absence of different concentrations of glucose (5.5mM–25mM) or fatty acids (Oleate 0.5–10uM; Palmitate 10–100uM); upon treatment, the cells were washed and incubated with serum-free media for 8 h. Conditioned medium (CM) has been collected and added to serum-starved MCF7 and MDA-MB-231 breast cancer cells for different times. Next, we have analyzed cell proliferation by cellular count, cell cycle phases by cytometric determinations and intracellular pathways by Western Blot analysis. To identify the growth factors and cytokines released from the pre-adipocytes/adipocytes, we have used ELISA multiplex.

Results: We have obtained evidence that CM from 3T3-L1 and human adipocytes cultured in 25 mM glucose (high glucose) induced growth of MCF7 and MDA-MB-231 cells, in a time-dependent manner. In particular, CM from fully differentiated adipocytes was 2-fold more effective than CM from pre-adipocytes in inducing breast cancer cell growth. Cell cycle analysis by flow cytometry revealed that these changes were accompanied by reduced apoptosis. Moreover, adipocyte CM activated PI3K, MAPK and JAK/STAT pathways in breast cancer cells. Interestingly, the pre-incubation of adipocytes with 5.5 mM glucose, a concentration corresponding to normal fasting glucose levels in humans, significantly prevented their ability to induce breast cancer cell growth. At variance, the stimulation of adipocytes with palmitate or oleate in 5.5 mM glucose almost completely restored their growth promoting action (1,43 and 1,37 fold increase over basal, respectively) to levels similar to those observed for cells cultured in high glucose. Secretion of IGF-1, RANTES and IL-8 was higher in adipocytes than in pre-adipocytes and was enhanced by incubation with high glucose or fatty acids. We have also confirmed these results by RT-PCR analysis of IGF1, RANTES and IL-8 mRNA levels. Moreover, treatment of breast cancer cells with IGF-1R or cytokine inhibitors reduced the adipocyte CM effect on cell growth.

Conclusion: In conclusion, adipocyte-derived factors promote breast cancer cell growth by inhibiting apoptosis. This effect is more evident for factors released by adipocytes than by pre-adipocytes and is modified by glucose and fatty acids. IGF-1, RANTES and IL-8 could be good candidates in mediating growth-promoting actions of adipocytes on breast cancer cells.

Function of cardiac adipose differentiation-related protein (ADRP) in the pathogenesis of diabetic cardiomyopathy

J. Suzuki¹, T. Kimura¹, M. Ichikawa¹, M. Imagawa¹, S. Takahashi¹, S. Ikuyama², T. Koizumi³, M. Ueno⁴, F.B. Kraemer⁴, I. Miyamori¹;

¹Medical Science, University of Fukui, Eihei, ²The medical institute of bioregulation, University of Kyushu, Oita, ³Laboratory Animal Resources, University of Fukui, Eihei, Japan, ⁴Medicine, Stanford University School of Medicine, Palo Alto, USA.

Background and aims: Diabetic cardiomyopathy is characterized by intracellular lipid accumulation (steatosis) that generates lipotoxicity and eventually leads to cardiac dysfunction. The adipose differentiation-related protein (ADRP) is a lipid droplet-associated molecule expressed in many tissues including heart, although its pathophysiological function remains uncertain. We have found that cardiac ADRP expression is increased upon fasting in concert with lipid accumulation, whereas ADRP is decreased in diabetic hearts despite steatosis. In order to explore the pathophysiological function of cardiac ADRP, diabetes was induced in transgenic mice with heart-specific overexpression of ADRP and hearts were analyzed.

Materials and methods: Cardiac-specific ADRP-overexpressing (Tg) mice were generated using cDNA of mouse ADRP and enhanced green fluorescent protein under control of the myosin heavy-chain- α promoter. The founders were backcrossed with C56BL/6 for 7 generations and heterozygous transgenic (Tg) mice and their wildtype (Wt) littermates were studied. The mice were injected with streptozotocin to induce diabetes and hearts were analyzed 3 weeks afterward. Cardiac collagen was extracted for measurement, and fibrosis was evaluated by sirius-red staining. Cardiac gene expression profiles were analyzed using Affymetrix microarrays and the diabetic profile was compared between Wt and Tg hearts. Cardiac function was studied with ultrasonography.

Results: In the absence of diabetes, Tg mice accumulated numerous lipid droplets around clusters of mitochondria in cardiomyocytes, which contained 8 times more triglyceride compared to Wt hearts. With diabetes, interstitial fibrosis in Tg hearts was comparable to that in Wt hearts, despite greater steatosis in Tg than Wt hearts. However, diabetes-induced fresh collagen was diminished in Tg hearts. Cardiac contractile function was impaired 15–18% with diabetes in both Wt and Tg mice. Microarray expression analysis showed that diabetes altered (>2-fold) expression of 1094 genes in Wt hearts and 1404 genes in Tg hearts. In Wt hearts expression of a fatty acid-responsive gene HMG-CoA synthase 2 and collagen IX were increased, but matrix metalloproteinase (MMP)-15 was decreased with diabetes. In contrast, in Tg hearts expression of HMG-CoA synthase 2 was unaltered and collagen 1 was decreased, but MMP-3, -12 and -15 were increased with diabetes. In addition, expression of a potent antioxidant protein metallothionein I and glucose 6-phosphate dehydrogenase, which directs excess glucose into the pentose phosphate pathway, were increased with diabetes in Tg hearts.

Conclusion: ADRP appears to play a role in packaging lipotoxic fatty acids into lipid droplets, leading to induction of cardio-protective genes and inhibition of excess collagen production when overexpressed in diabetes. Thus, cardiac ADRP could be a target to ameliorate diabetic cardiomyopathy.

Burden of cardiovascular disease in „metabolically benign“ obese compared with „insulin-resistant“ normal-weight individuals

C. Voulgari¹, P. Dilaveris¹, C. Tsioufis¹, N. Katsilambros¹, C. Stefanadis¹, N. Tentolouris¹;

Athens University Medical School, Greece.

Background and aims: “Metabolically benign obese” people, despite their body-fat, display a favorable metabolic profile characterized by high levels of insulin-sensitivity, and a beneficial blood-pressure, metabolic and inflammation profile. However, it remains controversial whether this healthier metabolic profile is translated into a lower cardiovascular disease (CVD) risk compared with “insulin-resistant” normal-weight individuals.

Materials and methods: A total of 550 individuals without diabetes or baseline macrovascular complications were studied. Participants were clas-

sified by presence ($n=271$) or absence ($n=279$) of Metabolic Syndrome and by Body Mass Index (BMI; <25 Kg/m²=normal-weight, $n=177$; 25 – 29.9 Kg/m²=overweight, $n=234$; ≥ 30 Kg/m²=obese, $n=139$). Metabolic Syndrome was diagnosed with the NCEP-ATP-III criteria. Left ventricular functional capacity, myocardial structure and performance were assessed by ultrasound.

Results: Six-year CVD incidence (nonfatal myocardial infarction, stroke, congestive heart failure) was compared by obesity and metabolic status. Obesity or BMI were not associated with increased CVD risk (HR 0.88, 95%CI 0.41–1.32). Presence of Metabolic Syndrome conferred 2.5-fold higher CVD risk (HR 2.5, 95%CI 1.68–3.40). Overweight/obese “metabolically-benign” individuals had the lowest 6-year CVD risk (HR 1.12, 95%CI 0.35–1.33) compared with normal-weight “insulin-resistant” people (HR 2.33, 95%CI 1.25, 4.36, $P=0.007$). From the metabolic components studied, impaired fasting glucose (HR 1.5, 95% 1.23–1.92), hypertension (HR 1.1, 95% 1.03–1.47), dyslipidemia (HR 0.48, 95% 0.39–0.58) and central-obesity (HR 1.33, 95% 1.17–1.64) were all associated with increased CVD risk. Physical inactivity (<7.5 Metabolic Equivalent-hours/week, smoking, insulin-resistance (HOMA-IR <2.5), low-grade inflammation (high-sensitivity C-reactive protein ≥ 1.5 mg/dl, micro-albuminuria) were independently associated with CVD incidence.

Conclusion: In contrast to normal-weight insulin-resistant people, “metabolically benign” individuals show decreased CVD-risk in a 6-year follow-up study.

223

Plasma omentin levels in relation to cardiac function in patients with type 2 diabetes and healthy controls: effect of pioglitazone versus metformin

W.J.Y. Chen¹, S. Greulich², L.J. Rijzewijk¹, J.T. Jonker³, R.W. van der Meer⁴, H.J. Lamb⁴, D. Herzfeld de Wiza², A. de Roos⁴, J.A. Romijn³, J. Eckel², J.W.A. Smit¹, J.J. Bax⁵, D.M. Ouwens², M. Diamant¹;
¹Diabetes Centre, Dept. of Internal Medicine, VU University Medical Centre, Amsterdam, Netherlands, ²German Diabetes Centre, Institute of Clinical Biochemistry and Pathobiochemistry, Duesseldorf, Germany, ³Department of Endocrinology and Metabolic Diseases, ⁴Department of Radiology, ⁵Department of Cardiology, Leiden University Medical Centre, Netherlands.

Background and aims: The adipokine omentin is highly and selectively expressed in visceral adipose tissue and its circulating levels are decreased in obesity and type 2 diabetes mellitus (T2DM). In this study, we assessed the relationships between plasma omentin levels and cardiometabolic variables in T2DM men and age-matched overweight healthy controls. Next, only in the T2DM men, the effects of 24-wk treatment with pioglitazone or metformin on plasma omentin levels were investigated.

Materials and methods: We studied 78 asymptomatic T2DM men, treated with glimipiride monotherapy, in whom inducible ischaemia was excluded by dobutamine stress echocardiography, and 14 age-matched controls at baseline. Then, the T2DM patients were randomly assigned to pioglitazone or metformin therapy. Plasma omentin levels were measured at baseline and after the 24-wk treatment. Measurements included fasting cardiometabolic variables, clamp-measured insulin sensitivity, as well as magnetic resonance imaging to quantify body fat compartments and cardiac function.

Results: T2DM men had a higher body mass index, systolic blood pressure, HbA1c, visceral fat and subcutaneous fat volumes and a lower M-value compared to controls (all $P<0.02$). Plasma omentin levels were lower ($P=0.008$) in T2DM men vs. controls. Previously, we reported in this cohort that diastolic function differs between DM2 en controls. At baseline plasma omentin showed a significant correlation with visceral fat tissue volume ($r=-0.269$, $P=0.009$), while the association with subcutaneous and pericardial adipose tissue volumes were only marginally statistically significant (both $P=0.09$). Furthermore, plasma omentin levels correlated positively with early peak filing rate, early deceleration peak and early deceleration mean (all $P<0.05$). Plasma omentin levels were correlated with M-value as well ($r=0.379$, $P=0.001$). Twenty-four week of pioglitazone, vs. metformin, resulted in higher plasma omentin levels in T2DM men ($P=0.01$), in the presence of similar glycaemic improvements.

Conclusion: Plasma omentin levels were decreased in asymptomatic T2DM compared to age-matched healthy males, and were positively associated with cardiac diastolic function, while a negative relationship was observed with body fat compartments. Furthermore, pioglitazone versus metformin therapy increased circulating omentin levels. Based on these findings, we hypothesize that circulating omentin levels may be a marker of cardiac risk in T2DM.

Relation of changes in components of the metabolic syndrome to changes in fat depots in a cardiovascular prevention programme

S. Jenni^{1,2}, T. Tillin¹, L. Thomas³, K. March¹, C. Tuson¹, C.M. Park¹, M.D. Baker¹, J. Fitzpatrick³, J. Bell³, S.B. Connolly¹, D. Wood¹, A.D. Hughes¹, N. Chaturvedi¹;

¹National Heart and Lung Institute, Imperial College, London, UK,

²Endocrinology, Diabetes and Clinical Nutrition, University Hospital,

Inselspital, Bern, Switzerland, ³Metabolic and Molecular Imaging Group,

MRC Clinical Sciences Centre, London, UK.

Background and aims: Prevention programmes designed to reduce cardiovascular risk, using lifestyle, medication or a combination, are likely to generate some of their beneficial effects through reductions in adiposity; more specifically *via* effects on ectopic fat depots. Therefore, we wished to explore the association between alterations in total and ectopic fat and changes in components of the metabolic syndrome in response to a multi-factorial prevention programme.

Materials and methods: We assessed the components of the metabolic syndrome (IDF consensus 2006) together with fat depots before and at completion of a twelve week family based multi-factorial cardiovascular prevention programme (the MYACTION programme) including lifestyle and medication changes. Eighteen patients with cardiovascular risk $>20\%$ over 10 years were included. Fat depots were determined from whole body MR imaging; and ectopic fat in liver, pancreas and tibialis anterior muscle were determined using MR spectroscopy.

Results: Participants were aged 68.5 (SD 4.4) years. Their weight was 78.9 (13.1) kg and total fat volume 29.3 (6.4) L at baseline. Weight was reduced by -2.5% (95% CI -4.0% to -1.0% , $p=0.002$) and total fat by -10.8% (95% CI -15.7% to -5.8% , $p=0.0006$). Marked reductions in subcutaneous fat, and ectopic fat, were observed in response to MYACTION (table). Robust regression analysis, showed change in triglycerides was most closely associated with change in hepatic fat ($r^2=0.57$, $p=0.002$). In contrast, change in fasting glucose was predicted by change in both subcutaneous and visceral fat (r^2 0.59, $p=0.006$). Blood pressure and HDL change were not associated with change in any fat depot.

Conclusion: A short cardiovascular prevention programme is associated with profound reductions in ectopic fat. Individual components of the metabolic syndrome were differently related to changes in specific ectopic fat depots. Our findings have implications understanding how ectopic fat deposition impacts on cardiovascular risk factors, and how interventions reduce risk. They may also have implications for how we best target lifestyle interventions.

Effects of the 12 week MYACTION cardiovascular prevention programme

Measure	Baseline	Percent change	p-value
Subcutaneous fat, L	20.5 (4.6)	-10.2 (-14.3, -6.0)	0.0002
Visceral fat, L	4.8 (1.8)	-13.3 (-22.0, -4.5)	0.0066
Hepatic fat, AU	2.3 (1.5, 7.4)	-41.3 (-59.0, -23.6)	0.0002
Pancreatic fat, AU	8.4 (2.1, 15.4)	-35.5 (-55.9, -15.1)	0.0031
IMCL tibialis anterior, AU	6.7 (3.8, 9.0)	13.4 (-7.2, 33.9)	0.18
Waist circumference, cm	99.3 (7.6)	-3.7 (-5.3, -2.3)	0.0001
Fasting glucose, mmol/l	6.0 (1.5)	-0.3 (-5.7, 5.0)	0.89
Systolic BP, mmHg	134 (15)	-2.6 (-8.3, 3.0)	0.33

Physical activity, abdominal and general obesity and the risk of developing type 2 diabetes: a case-cohort study (InterAct)

U. Ekelund, L. Palla, N.J. Wareham, InterAct Consortium;
MRC Epidemiology Unit, Cambridge, UK.

Background and aims: The independent and joint effects of physical activity, overall and central adiposity on incident diabetes risk in population based samples are largely unknown. We examined whether physical activity predicts incident diabetes independent of overall and abdominal adiposity and also the joint effect of physical activity, overall and abdominal adiposity on diabetes risk.

Materials and methods: Case-cohort study nested within the European Prospective Investigation into Cancer (EPIC) study including 12,403 verified incident diabetes cases and a randomly selected sub-cohort of 16,154 individuals prospectively followed for 12.3 years. Overall physical activity was assessed by self-report, categorised into 4 groups and validated against combined heart rate and movement sensing in an independent sample ($n=1,941$) across study locations. Adiposity was measured by BMI and waist circumference (waist circumference >94 cm and >80 cm in men and women, respectively). Hazard ratios per unit increase in PA were estimated separately within each centre/country using Prentice weighted Cox regression, with age as the underlying timescale and additionally adjusting for educational level, smoking status, alcohol consumption and energy intake. Hazard Ratios were combined across centres/countries using random effects meta-analysis, and the percentage of variation between centres/countries due to real heterogeneity was calculated (I^2).

Results: Over a median follow-up time of 12.28 years (192,876 total person years), 6.3% of men and 3.9% of women developed diabetes. Diabetes incident rates decreased by increasing levels of physical activity in men (5.78, 5.93, 5.36, 4.14 per 1000 person years) and in women (4.57, 3.03, 2.57, 2.54 per 1000 person years). A one level increase in overall physical activity was associated with a 12% (HR, 0.88, 95% CI 0.81;0.95) and 7% (HR 0.93, 95% CI 0.89;0.98) relative reduction in the risk of type 2 diabetes independent of BMI, study centre, education, smoking status, alcohol consumption and energy intake in men and women, respectively. Similar effect sizes were observed after further adjustments for waist circumference and when examining the associations between leisure time physical activity with incident diabetes in both men and women. In joint analyses, the risk of developing diabetes was significantly increased with lower levels of overall physical activity across BMI categories in men (p for trend <0.003) and women (p for trend <0.003), except for obese women (p for trend $=0.25$). The risk of developing diabetes increased by decreasing levels of overall physical activity in both abdominally lean (P for trend $=0.009$) and abdominally obese (P for trend $=2.5 \times 10^{-7}$) men and in abdominally lean (P for trend $=0.002$) and abdominally obese (P for trend $=10^{-4}$) women.

Conclusion: Overall physical activity is associated with reduced risk of developing type 2 diabetes independent of general and abdominal adiposity. Overall physical activity also reduces the risk across BMI categories and to a similar magnitude in both abdominally lean and obese men and women. Prevention of type 2 diabetes needs to consider both weight reduction and increasing levels of overall physical activity.

Combination of FINDRISC and fasting plasma glucose (FPG) in screening for type 2 diabetes in an Irish population: the type 2 diabetes mellitus and vascular health initiative (DMVHI)

M. Sinnott¹, B.M. Carr¹, C. Walsh², T. O'Grady³, P. Gaffney⁴, G. Boran⁴, J.J. Nolan⁵, B.T. Kinsley⁶;

¹Medical, Vhi Healthcare, Dublin, ²Statistics, Trinity College, Dublin, ³Medical Planning, Vhi Healthcare, Dublin, ⁴Clinical Chemistry, Adelaide and Meath Hospital Incorporating The National Childrens Hospital, Dublin, Ireland, ⁵Steno Diabetes Centre, Copenhagen, Denmark, ⁶Endocrinology, Mater Misericordiae University Hospital, Dublin, Ireland.

Background and aims: Lifestyle modification in high risk and pre-diabetic individuals will prevent or delay development of T2DM. However, screening for T2DM is complex and expensive. To identify those at risk, the largest

Irish health insurer has undertaken a study to assess prevalence of undiagnosed T2DM and pre-diabetes by screening a subset of its 1.3 million policy holders (representing 62% of the insured population in Ireland). Our aims were to identify the prevalence of undiagnosed T2DM, impaired fasting glucose (IFG), impaired glucose tolerance (IGT) in an Irish population and to develop criteria combining FINDRISC and FPG for use in population screening.

Materials and methods: All policy holders aged 45–75 years, without known diabetes, living within the catchment area of two Dublin University Teaching Hospitals were invited to participate. Participants completed a detailed medical questionnaire. FINDRISC, FPG, lipid profile, blood pressure, weight, height, BMI, waist and hip circumference were measured. Subjects with initial results in the IFG range ($FPG \geq 5.6 \leq 6.9$ mmol/L) had an OGTT. Multiple logistic regression was used to estimate the coefficients of FINDRISC and FPG in a model where T2DM was the outcome variable.

Results: Over 11,500 participants (56% women; 44% men) have been screened to date. The mean age was 60 ± 8.0 years. 21% required OGTT. The prevalence of T2DM, IFG, and IGT was 2.2%, 6.9%, and 3.4% respectively. A model was constructed combining the FINDRISC and FPG by adding 2 points per 0.1 mmol/L of FPG above 5.5 mmol/L to the FINDRISC score. The ROC AUC for the combined score was 0.818 (95% CI 0.780–0.854) versus AUC for FINDRISC alone of 0.675 (95% CI 0.632–0.718), $p < 0.001$. The new scoring system with a cutoff of 15 had 91% sensitivity for T2DM.

Conclusion: The combined FINDRISC and FPG score, as outlined above, would identify 91% of undiagnosed T2DM and 74% of pre-diabetic individuals for further investigation and reduce the number of OGTTs from 21% to 12% of the screened population. Our data suggests that this new scale could provide a practical and effective population screening tool.

Excess diabetes in ethnic minorities - incidence and predictors

T. Tillin¹, A.D. Hughes¹, P. Whincup², N.G. Forouhi³, I.F. Godsland⁴, N. Sattar⁵, P. McKeigue⁶, N. Chaturvedi¹;

¹National Heart and Lung Institute, Imperial College, London, ²Cardiovascular Epidemiology, St George's University of London, ³Institute of Metabolic Science, MRC Epidemiology Unit, Cambridge, ⁴Metabolic Medicine, Imperial College, London, ⁵Metabolic Medicine, University of Glasgow, ⁶Public Health Sciences, University of Edinburgh, UK.

Background and aims: Excess prevalence of diabetes in people of Indian Asian (IA) and African Caribbean (AfC) descent is well known. However, risks of incident diabetes, diabetes in older age and predictors thereof are poorly understood. We addressed these questions in a tri-ethnic cohort.

Materials and methods: Population based sample of 2945 men and women (1457 European (E), 1070 IA and 418 AfC) aged 40–70 years and living in north west London. Baseline (1988–91) and follow-up (2008–2011) measures included fasting and post OGTT bloods, anthropometrics, blood pressure and health/lifestyle questionnaire. Follow-up also included primary care medical record review.

Results: Diabetes prevalence at baseline (mean age 52.3 ± 6.9) was 6% (E), 20% (IA) and 19% (AfC). After 20 years of follow-up (mean age 70.3 ± 6.3), prevalence was 19% (E), 45% (IA) and 41% (AfC). An additional 26% E, 20% IA and 18% AfC had pre-diabetes (IFG, IGT or both). Age and sex adjusted hazard ratios for ethnicity as a predictor of incident diabetes (Europeans=reference): IA: 2.50 (2.11, 3.03), AfC: 2.38 (1.86, 3.05). Adjustment for baseline risk factors (fasting blood glucose, insulin and lipids, blood pressure, occupational status, physical activity and obesity) partially attenuated the IA excess, but did not alter the AfC excess (fully adjusted HRs respectively: 1.94 (1.54, 2.45), 2.33 (1.72, 3.16)). However, baseline glucose and insulin relationships from the OGTT in those who developed diabetes differed markedly by ethnicity. Post OGTT glucose was significantly higher in AfC than in either E or IA. Post OGTT insulin was comparable in AfC and E, whilst in IA plasma post OGTT insulin was nearly doubled. (Figure).

Conclusion: Diabetes and pre-diabetes are astonishingly frequent in all older people, affecting around two thirds of British Indian Asians and African Caribbeans and nearly half of Europeans. Ethnic differences in incidence are unexplained by conventional risk factors measured 20 years earlier. Development of diabetes in African Caribbeans may be a consequence of a poor insulin secretory response to glucose. In contrast, Indian Asians who developed diabetes exhibited a markedly greater insulin secretory response to glucose, suggesting greater insulin resistance. Pathways to diabetes differ by ethnicity.

Baseline 2 hour post OGTT glucose and insulin in people who developed diabetes during follow-up

Metabolic markers of insulin sensitivity predict progression to IGT and type 2 diabetes

W.E. Gall¹, M.W. Mitchell¹, K.-P. Adam¹, J.E. Lucas², M.V. Milburn¹, A. Natali³, V. Lyssenko⁴, L. Groop⁴, E. Ferrannini³

¹Diagnostics Division, Metabolon, Inc., Durham, ²Institute for Genome Sciences and Policy, Duke University, Durham, USA, ³Internal Medicine, University of Pisa, Italy, ⁴Department of Clinical Sciences, Diabetes, and Endocrinology, Lund University, Malmö, Sweden.

Background and aims: Insulin resistance (IR) is a risk factor for type 2 diabetes. An unmet medical need exists for a practical measurement of insulin sensitivity to identify high-risk, IR patients for more effective lifestyle intervention and disease prevention. We previously identified biomarkers of insulin sensitivity in a cross-sectional metabolic profiling analysis of a nondiabetic, healthy population (n=399), RISC, an observational, prospective study, based on their highly significant correlations to the euglycemic clamp glucose disposal rate.

Materials and methods: Using UHPLC-mass spectrometry with absolute quantitative measurements of the top-ranking predictors of insulin sensitivity, we describe their incorporation into an algorithm developed from an expanded analysis of the entire RISC cohort (n=1277) and validate their predictiveness of dysglycemia on the independent Botnia Prospective cohort.

Results: One model (IR algorithm), incorporating insulin, alpha-hydroxybutyrate (AHB), linoleoylglycerophosphocholine (L-GPC), oleate, and BMI, resulted in AUCs of 0.86 and 0.85 for identifying the bottom quintile and bottom tertile of insulin sensitivity, respectively (p<0.001). Using 3-year follow-up data in RISC, we observed that our IR algorithm was statistically equivalent to the clamp's glucose disposal rate in predicting conversion from NGT to IGT (AUC=0.70, n=880). In a separate cohort, to assess the clinical utility of the top-ranking insulin sensitivity markers identified in the RISC study, we carried out a targeted analysis of subjects followed in the Botnia Prospective Study (n=2585). In this family history type 2 diabetes cohort, we measured said analytes and IR algorithm and compared T2D progressors to non-progressors. Based upon multiple logistic regression analysis, L-GPC and AHB was significantly associated with diabetes progression, independent of sex, age, family history diabetes, BMI, and basal FPG, with an odds ratio of 0.66 (C.I.: 0.523–0.832) and 1.28 (C.I.: 1.09–1.51, p=0.0029), respectively, for each SD of their targeted plasma measurements. In a 5-year timeline, using leave-one-out cross-validation, L-GPC and AHB had AUCs of 0.68 (p=6.93 e-6) and 0.65 (p=0.0002), respectively, for predicting T2D progression, whereas our multi-analyte IR algorithm had an AUC of 0.78 (p=1.049 e-11) when removing insulin, and an AUC of 0.82 (p=2.934 e-15) when adding age, sex, and FPG.

Conclusion: We demonstrate that measurement of a panel of insulin sensitivity markers in a fasting plasma sample can identify high-risk, IR subjects with high accuracy, and predict progression to IGT and T2D.

Achievement of good long-term glycaemic control after islet transplantation: single or multiple initial islet transplantations?

P.A. Gerber¹, E. Ajdler-Schaeffler², R.A. Zuellig¹, T. Pfammatter³, J. Brockmann⁴, R. Wüthrich⁵, G.A. Spinas¹, R. Lehmann¹

¹Endocrinology, Diabetes and Clinical Nutrition, ²Internal Medicine, ³Diagnostic and Interventional Radiology, ⁴Transplantation Surgery, ⁵Nephrology, University Hospital Zurich, Switzerland.

Background and aims: The main goal of islet transplantation in patients with type 1 diabetes mellitus has changed over the last years from insulin independence to good glycemic control and avoidance of severe hypoglycaemia. However, no data exists about the optimal initial islet mass. The aim of this study was to compare posttransplant outcome in patients with different initial islet mass.

Materials and methods: Patients who underwent combined islet-kidney or islet after kidney transplantation at our institution with multiple initial islet transplantations (11 patients with maximal 5 transplants, 1st group) as compared to single initial islet transplantation (22 patients who were retransplanted only if good metabolic control was no longer achieved, 2nd group) were included in this study. Patients were seen before and every three months after transplantation to assess posttransplant glycemic control and to adjust insulin therapy if necessary.

Results: The time between the first and second transplantation was 2.4±2 and 25.8±9 months, respectively. There was no significant difference in baseline characteristics in the two groups: Age was 50.8±8.5 and 53.6±7.4 y with 45.5% and 72.7% male patients, diabetes duration of 38.1±7.8 and 37.4±11.3 y. BMI was comparable at baseline (22.6±1.8 and 24.6±5.1 kg/m²). Total follow-up was 78 and 51 months. Islet retransplantation was performed 0.35 times per patient-year of follow-up in the 1st group and 0.11 times in the 2nd group. HbA1c decreased significantly in both groups after transplantation (p=0.017 and p=0.026) but did not differ between the groups during follow-up (Figure). Frequency of severe hypoglycaemia (need for assistance, loss of consciousness) was comparable in the two groups after transplantation (0.16 vs 0.13 hypoglycaemia/patient-year, p=0.88). Insulin dosage decreased significantly in the 1st group (from 0.62 IE/kg to 0.25 IE/kg, p=0.017) during the first year after transplantation, but not in the 2nd group (from 0.54 IE/kg to 0.4 IE/kg, p=0.38). Similarly, C-peptide was higher one year after transplantation in the 1st group (1454±554 pM) as compared to 655±443 pM (p=0.028) in the 2nd group (single transplants).

Conclusion: This study demonstrates that a single initial transplantation with retransplantation only if glycemic control deteriorates, uses less pancreas donors as compared to multiple initial transplantations, but results in equal glycemic control and rate of severe hypoglycemic episodes despite a higher demand of exogenous insulin.

230

Sustained improvement of cardiovascular risk factors (CVRF) and cardiac function in type 1 diabetic (TD1) patients with successful pancreas transplant alone (PTA)

M. Occhipinti, E.A. Mangione, U. Boggi, F. Vistoli, G. Amorese, M. Barsotti, R. Giannarelli, A. Coppelli, L. Rondinini, R. Mariotti, P. Marchetti; Dept. Endocrinology and Metabolism, University of Pisa, Italy.

Background and aims: The role of PTA in the treatment of T1D patients (pts) is still debated. Aim of this study was to investigate the course of several CVRF and cardiac function in T1D after PTA, comparing pts with functioning or failed pancreas graft.

Materials and methods: We studied 47 T1D pts (age: 36 ± 8 yrs, BMI 23.3 ± 2.8 kg/m², diabetes duration 23 ± 10 yrs) who underwent PTA (72% portal-enteric drainage, tacrolimus- and MMF-based immunosuppression) and were followed for 6.4 ± 1.9 yrs. Clinical and laboratory assessments were performed by standard procedures and doppler echocardiographic examinations were accomplished with the Sonos 5500 Agilent echograph.

Results: During the follow-up (FU), 35 pts (74.4%, group A) maintained PTA function (normoglycemia without exogenous insulin therapy), whereas in 12 pts (25.6%, group B), the graft failed. The two groups did not differ for any major clinical pretransplant (preTx) feature. Compared to preTx, the functioning PTA (FU: 6.3 ± 1.8 yrs) established sustained insulin and C-peptide secretion (3.6 ± 2.2 vs 0.08 ± 0.12 ng/ml, $p < 0.01$), normalized HbA1c (5.6 ± 0.4 vs $8.5 \pm 1.7\%$, $p < 0.01$) and improved total cholesterol (170 ± 33 vs 200 ± 45 mg/dl), LDL-cholesterol (93 ± 29 vs 125 ± 43 mg/dl), fibrinogen (330 ± 65 vs 370 ± 83 mg/dl) and diastolic blood pressure (76 ± 10 vs 81 ± 10 mmHg) (all $p < 0.01$), without significant changes in statin or antihypertensive therapy. In addition, ultrasound measured ejection fraction (EF) of heart left ventricle increased from 55.2 ± 2.9 to $58.1 \pm 2.0\%$ ($p < 0.01$). Successful PTA did not affect triglycerides, HDL-cholesterol and systolic blood pressure. In group B, PTA functioned for 0.35 ± 0.16 yrs, and parameters were analysed 6.7 ± 2.0 yrs after graft loss, with withdrawn of immunosuppressive therapy. In these pts, all the above parameters were similar preTx and at the last FU control. In both groups creatinine levels increased similarly (A: 1.18 ± 0.32 vs 0.92 ± 0.23 mg/dl, +28%, $p < 0.01$; B: 1.06 ± 0.31 vs 0.83 ± 0.17 mg/dl, +27%, $p < 0.01$).

Conclusion: Successful PTA restores long-term endogenous insulin secretion and, hence, normoglycemia, also leading to improvements of several CVRF and left ventricle ejection fraction; in our series, the decline of kidney function was similar in patients with and without functioning PTA, suggesting that the nephrotoxicity of long-term immunosuppression was balanced by the overall beneficial effects of normoglycemia.

Successful clinical translation of intramuscular islet autotransplantation

T. Hubert¹, A. Sterkers¹, E. Torres¹, V. Gmyr¹, D. Wild², J. Kerr-Conte¹, F. Pattou¹;

¹Inserm U859, University Hospital of Lille, France, ²University Hospital of Freiburg, Germany.

Background and aims: Intra muscular transplantation (IMT) offers attractive prospects for islet transplantation. The clinical relevance of this non invasive alternative to the intraportal route is not clearly established. We developed in the minipig a simple and reproducible technique for islet IMT and tested its clinical relevance for islet autotransplantation.

Materials and methods: Islets were isolated from adult minipigs (n=25) with standard automated technique following distal pancreatectomy. Standardized autologous islet grafts were implanted in the thigh gracilis muscle. Transplant sites were explanted and analyzed by immunochemistry for cell composition (insulin, glucagon) and vascularization (vWF). A similar technique was applied in two patients who underwent islet autotransplantation in the left forearm after an extended pancreatectomy for benign tumors.

Results: In the minipig, immunochemistry confirmed the presence of alpha and beta cells up to 6 months after transplantation. Islets revascularization increased between day 15 and day 30 and was correlated with islet survival. Graft function was documented by acute insulin response (AIR) after completion of the pancreatectomy at one month in 2 animals. Clinical islet IMT was uneventful in both cases. Ectopic insulin secretion could be documented by AIR with or without forearm vascular exclusion, and represented 53% and 22% of the overall systemic insulin secretion, respectively. Islet survival was confirmed by scintigraphy with radiolabeled GLP1 analogs after one year in our first patient.

Conclusion: These results provided unequivocal proof of prolonged survival, revascularization and function of pancreatic islets after IMT and confirmed the clinical relevance of this strategy for islet autotransplantation.

Culture and injection of desferrioxamine (DFO) improves islet transplant outcomes

R.A. Stokes¹, K. Cheng¹, L. Mariana², A. Patel³, L. Williams³, S.T. Grey⁴, W.J. Hawthorne³, P. O'Connell³, T. Kay², T. Loudovaris², H. MacLean², J.E. Gunton¹;

¹Immunology-Diabetes and transcription factors, The Garvan Institute of Medical Research, Darlinghurst, ²Immunology & Diabetes, St Vincent's Institute, Melbourne, ³National Pancreas and Islet Laboratory, Westmead Millenium Institute, Westmead, ⁴Immunology-Gene therapy and autoimmunity, The Garvan Institute of Medical Research, Darlinghurst, Australia.

Background and aims: Hypoxia-inducible factor-1α (HIF-1α) is a transcription factor which co-ordinates a program of cellular response to stressors including hypoxia. Islet transplantation subjects islets to hypoxic environments and it is thought that up to 70% of islets die within 1 week of transplantation. We hypothesised that increasing HIF-1α would improve outcomes in adequate mass islet transplants and that treating recipient mice would further improve outcomes.

Aim: To investigate the effects of increasing HIF-1α protein in human islets upon islet-transplant outcomes.

Materials and methods: Isolated human islets were cultured overnight in control media, or media supplemented with desferrioxamine (DFO), a small-molecular stimulator of the HIF-1α protein. For each donor, at least 1 transplant was performed for each group, thus avoiding inter-donor variability. Islets were transplanted into diabetic SCID mice. Adequate mass model: Isolated human pancreatic islets from 12 separate donors were treated in the following groups:

- 1) Supra-physiological-mass transplant of 2000-control IEQ (islet equivalent)
- 2) 2000-DFO- islets were cultured overnight with DFO prior to transplantation and
- 3) 2000-DFO+injection- where islets were cultured with DFO and recipient mice additionally received DFO on days 1, 2, 4 and 7 post-transplantation. Mice were followed for 28 days post-transplantation and then underwent nephrectomy to confirm diabetes recurrence. In a subset of mice (4 donors), the graft was removed at 24 hours to assess apoptosis.

Results: Recipients of 2000 control IEQ achieved normoglycaemia in 74% of cases. 2000-DFO transplants were successful in 73% of mice and 2000-DFO+Injections in 92% of cases. Considering only successful transplants, recipients of DFO treated islets had significantly better random-fed glucose levels ($p = 0.03$ by ANOVA for repeated measures). Similarly, DFO+Injection mice had significantly better random-fed glucose levels than controls ($p = 0.02$). On glucose tolerance testing 25 days post-transplantation, a significantly higher proportion of mice receiving islets cultured with DFO had normal glucose tolerance ($p < 0.05$). Apoptosis 24 hours post-transplantation was decreased in both DFO groups by 30–50%. Beta cell mass was 40–50% greater at 28 days post transplantation in both DFO groups.

Conclusion: Glucose control post transplantation was improved by DFO. The mechanism is decreased short-term apoptosis leading to increased β-cell mass at 28 days. This data demonstrates that increasing HIF-1α in human islets in the pre- and peri-transplant period improves outcomes. HIF-1α and DFO may have a therapeutic role in human islet transplantation.

Diabetes or high glucose-induced apoptosis involves mitochondrial fragmentation in retinal pericytes

K. Trudeau¹, B. Dulmovits², I.M. Herman², S. Roy¹;

¹Boston University, ²Department of Molecular Physiology and Pharmacology, Tufts University School of Medicine, Boston, USA.

Background and aims: Previously we have reported that high glucose (HG) induces mitochondrial fragmentation and promotes apoptosis in retinal endothelial cells, a critical step in the pathogenesis of diabetic retinopathy. In this study, we examined if HG induces mitochondrial fragmentation by altering expression of Fis1, a mitochondrial fission protein, in bovine retinal pericytes (BRPs). Additionally, the proapoptotic event was verified in diabetic human retinal pericytes.

Materials and methods: To assess if HG induced changes in mitochondrial morphology and Fis1 expression, BRPs were grown for 7 days in normal (5 mM) or HG (30 mM) conditions, stained with MitoTracker Green, a mitochondria-specific dye, and digitally-captured images analyzed for Aspect Ratio (AR) and Form Factor (FF); Fis1 expression was determined by Western blot analysis and cells undergoing apoptosis was assessed by TUNEL assay. To determine temporal effects of HG on mitochondrial morphology, a time course study was performed at 0.5, 1, 2, 6, 24, 48 hours and 7 days and mitochondrial morphology assessed through AR and FF analyses. In addition, human retinal pericytes isolated from age-matched normal, non-diabetic (NHuRP) and diabetic (DHuRP) septuagenarian donor eyes were analyzed for mitochondrial morphology.

Results: Significant increase in cells with fragmented mitochondria was observed in BRPs grown in HG (FF=3.00 compared to 4.71 in normal, $p<0.001$; AR = 2.54 compared to 2.92 in normal, $p=0.006$; $52.8\pm13.6\%$ of cells with fragmented mitochondria vs $22.3\pm10.4\%$ in normal, $p=0.004$) and DHuRPs compared to respective controls (35% of cells with fragmented mitochondria vs 13% in normal). Increased mitochondrial fragmentation was concomitant with increased apoptosis in BRPs grown in HG (5.6 ± 2.6 TUNEL-positive cells/1000 cells compared to 13.6 ± 3.5 TUNEL-positive cells/1000 cells in HG, $p=0.007$). A bimodal pattern in mitochondrial fragmentation was evident after 30 minutes of HG exposure, followed by recovery of the elongated normal mitochondrial morphology after 6 hours, continuing up to 48 hours (30 minutes: FF=3.16 compared to 4.88 in normal, $p<0.001$; AR=2.47 compared to 2.92 in normal, $p=0.015$; 6 hours: FF=4.35, $p<0.001$; AR=2.95, $p=0.03$). After initial recovery, mitochondrial fragmentation recurred and remained permanent. Importantly, Fis1 was significantly upregulated in BRPs following 7 days of HG exposure ($162\pm29\%$ of normal, $p<0.05$).

Conclusion: The findings indicate that diabetes promotes mitochondrial fragmentation in retinal pericytes, at least in part, through overexpression of Fis1 and plays an important role in mitochondrial dysfunction associated with accelerated cell death. Thus, mitochondrial fragmentation could represent a novel therapeutic target for preventing retinal pericyte apoptosis in diabetic retinopathy.

Retinal adenosinergic system is affected by diabetes/hyperglycaemia

P.F. Santos^{1,2}, J. Vindeirinho¹, G. Costa¹, A.F. Ambrósio^{3,4}, C. Cavadas^{1,5};

¹Centre for Neurosciences and Cell Biology, ²Life Sciences Department,

³University of Coimbra, Centre of Ophthalmology and Vision Sciences,

⁴Faculty of Medicine, ⁵Faculty of Pharmacy, Coimbra, Portugal.

Background and aims: Diabetic retinopathy exhibits characteristics of chronic inflammation. It is known that in diabetes there is an activation of microglial cells and a concomitant release of inflammatory mediators that cause death of retinal neurons. Microglial cells express all four types of adenosine receptors (A1, A2A, A2B, A3) and it is known that activation of A2A and A3 receptors in these cells leads to inhibition of pro-inflammatory cytokines expression and release and therefore could exert some protective effects on diabetic retinopathy. However, it is still unknown if this adenosinergic system is affected by diabetes/hyperglycemia (D/H). In this work we have studied the effect of diabetes or hyperglycemia, considered the main cause of diabetes complications, on this system in the retina.

Materials and methods: In this study we have used two cellular models: 1-retina cells, isolated from newborn Wistar rats, and cultured in control

(5mM glucose) or in high glucose (30 mM glucose) conditions. Cell cultured in media containing 5 mM glucose and 25 mM mannitol were used as an osmotic control; 2-whole retinas, obtained from control or STZ-induced diabetic Wistar rats. The effect diabetes or hyperglycemia has on adenosine receptors and adenosine deaminase (ADA) protein levels were evaluated by western blotting. The activity of ADA was evaluated by a enzymatic assay based on the Bertholet reaction and the viability tests were performed by the MMT assay.

Results: We have found that in retina cells, cultured in high glucose conditions (30 mM), the protein levels of A1 and A2A adenosine receptors are increased, up to $119.1\pm6.4\%$ and $192.5\pm19.9\%$ of control (5 mM glucose) whereas A2B and A3 protein levels were not different from control or mannitol cultures. In retinas, isolated from STZ-induced diabetic rats, we have found that A2A and A3 receptors protein levels were increased after one week of diabetes induction ($218.4\pm11.1\%$ and $150.6\pm11.7\%$ of control, respectively). Beside the effect on adenosine receptors, we have also found in retina cells, cultured in high glucose conditions, that although the protein levels of ADA were not different from control or osmotic control ($p>0.05$) the enzyme activity was significantly reduced to $24.4\pm6.5\%$ of control ($p<0.001$). We have already observed that there is a decrease in cell viability in retinal cells subjected to hyperglycemic environment (30 mM glucose). We have now found that this decrease in cell viability (to $90.0\pm3.3\%$ of control, $p<0.05$) was prevented by application of CGS 21680 (30 nM), an A2A adenosine receptor agonist ($96.7\pm1.9\%$ of control, $p>0.05$).

Conclusion: In this work we have found that D/H affects the retinal adenosinergic system. We have found that in D/H there is an increase in the protein levels of A2A receptors in both cellular models used. Since activation of this receptor subtype protects cells from high glucose induced cell death, it is tempting to propose that the transient increase in the expression of A2A receptors could function as a protective mechanism against D/H effects of retinal cells. The extent and implications of such changes are yet unclear, but if proven relevant in the context of DR, it would mean that extracellular adenosine dynamics and receptors could be aimed as new targets for the therapy or prevention of DR.

The contribution of NADPH oxidase (Nox)1 and 4 to diabetic retinopathy: role of microglia

A.G. Miller¹, K.J. Binger¹, G. Tan¹, L. Sutton¹, H. Schmidt², K. Winkler², M.E. Cooper³, K.A. Jandeleit-Dahm³, R.M. Touyz⁴, J.L. Wilkinson-Berka¹;

¹Department of Immunology, Monash University, Melbourne, ²National Stroke Research Institute, Melbourne, ³Baker Heart and International Diabetes Institute (IDI), Melbourne, Australia, ⁴Department of Medicine, Ottawa Hospital Research Institute, Canada.

Background and aims: Reactive oxygen species (ROS) are elevated in diabetic retinopathy and are implicated in cellular damage. The nicotinamide adenine dinucleotide phosphate-oxidase (Nox) enzyme is a major source of ROS production; however, the contribution of Nox to diabetic retinopathy is not fully understood. We aimed to determine if deletion of Nox1 and Nox4 isoforms influence the expression of angiogenic and inflammatory mediators involved in the development of diabetic retinopathy. As Nox expression is influenced by angiotensin II, and blockade of angiotensin II has benefits for neurovascular injury in diabetic retinopathy, we evaluated whether type 1 angiotensin receptor blockade (ARB) reduces retinal Nox expression. Finally, we evaluated which retinal cell types express Nox1 and Nox4.

Methods: Nox1 and Nox4 knockout (KO) mice and their wildtype (WT) controls were non-diabetic or made streptozotocin (STZ) diabetic and studied for 20 weeks. Sprague Dawley rats were randomized to be non-diabetic, STZ diabetic or diabetic+ARB (valsartan, 40mg/kg/day, gavage) and evaluated for 4 weeks. Primary rat retinal microglia, rat retinal ganglion cells, rat retinal glia, bovine retinal pericytes and bovine retinal endothelial cells were studied.

Results: WT diabetic mice showed significant increases in retinal VEGF and ICAM-1 mRNA levels compared to non-diabetic controls (1.4 fold and 2.5 fold mRNA respectively, $P<0.05$). In comparison, diabetic Nox1 KO and Nox4 KO mice had reduced levels of retinal VEGF and ICAM-1 mRNA compared to diabetic WT ($P<0.05$). In diabetic rats, retinal Nox4 expression was increased 2.7 fold compared to non-diabetic control ($P<0.05$), and was reduced to control levels with ARB. In vitro, microglia, the resident immune cell of the retina, most abundantly expressed Nox1 (50 fold increase) and Nox4 (100 fold increase) compared to retinal neurons, endothelial cells, glia and pericytes ($P<0.05$). Cultured microglia expressed components of the renin-angiotensin system including the angiotensin type 1 receptor. In diabetic rats,

ARB reduced the expression of the microglial activation markers, CD11b and major histocompatibility complex class II to control levels ($P < 0.05$).

Conclusion: In diabetic retinopathy, abundance of Nox1 and Nox4 is increased in retina, a phenomenon associated with augmented expression of angiogenic and pro-inflammatory factors. The abundance of Nox1 and Nox4 in retinal microglia, and the finding that ARB protects against the activation of retinal microglia, demonstrates that microglia may play a key role in ARB-mediated protective effects in diabetic retinopathy.

Inhibition of endoplasmic reticulum stress delays diabetic cataract formation and prevents retinal oxidative stress and apoptosis

A.A. Obrosova¹, S. Lupachyk², R. Stavnichuk², V.R. Drel², A.B. El-Remessy³, I. Ross², N.N. Veliky¹

¹A.V. Palladin Institute of Biochemistry, Kiev, Ukraine, ²Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, ³University of Georgia, Augusta, USA.

Background and aims: Evidence for the important role for endoplasmic reticulum (ER) stress in diabetes is emerging, but its contribution to diabetic complications is poorly explored. The purpose of this study was to evaluate the role for this phenomenon in diabetic cataract formation and retinal oxidative stress and apoptosis using a pharmacological approach with two chemical chaperones counteracting ER stress *in toto*, trimethylamine-N-oxide (TMAO) and 4-phenylbutyric acid (PBA).

Materials and methods: Control and streptozotocin-diabetic rats were maintained with or without TMAO (110 mg kg⁻¹d⁻¹, in the drinking water) or PBA (100 mg kg⁻¹d⁻¹, i.p.), for 12 weeks starting from induction of diabetes (a prevention paradigm). Diabetic rats received suboptimal doses of insulin to prevent ketoacidosis and weight loss. Lens clarity was evaluated by indirect ophthalmoscopy and slit lamp examination on weekly basis. Cataracts were scored (0 - clear lenses, 1-vacuoles, 2-opacities, 3-mature cataract). At the end of the study, the rate of apoptosis was assessed by the number of TUNEL-positive nuclei in the flat-mounted retinae. The expression of retinal ER stress variables including total and phosphorylated PKR-like eukaryotic initiation factor 2A kinase (PERK), total and phosphorylated inositol-requiring enzyme-1 (IRE1), and CAAT/enhancer-binding protein homologous protein (CHOP), was measured by Western blot analysis. The indices of oxidative-nitrosative stress, 4-hydroxynonenal (HNE) adducts and nitrotyrosine (NT), were evaluated by ELISA.

Results: All the lenses were clear 2 wks after induction of diabetes. During the next 6 wks, TMAO slightly delayed diabetic cataract formation, with significant differences in cataract scores for the 5th wk only (0.667 ± 0.114 vs 0.944 ± 0.151 in untreated diabetic group, $p < 0.05$). The anticataract effect of PBA was more potent, and was observed till the end of the study, with significant differences in the cataract scores for the 10th, 11th, and 12th wks. Rats with 12-wk STZ-diabetes displayed ER stress, manifest by reduced phospho-PERK/PERK ratios, with unchanged phospho-IRE1/IRE1 ratio and CHOP expression. A chemical chaperone treatment increased retinal phospho-PERK/PERK and phospho-IRE1/IRE1 ratios and reduced CHOP expression, this potentiating unfolded protein response and counteracting ER stress. A 4.3-fold increase in retinal apoptosis in diabetes was completely prevented by TMAO, and essentially prevented by PBA. Both chemical chaperones counteracted diabetes-induced retinal HNE adduct and NT accumulation.

Conclusion: ER stress is implicated in diabetes-induced cataract formation, and retinal oxidative-nitrosative stress and apoptosis. The findings identify a new therapeutic target for diabetic ocular complications.

A prospective longitudinal observational study on the effect of dietary sugar intake in adolescence and early adulthood on measures of glucose metabolism in early adulthood

A.S. Lewis¹, H.J. McCourt², C.A. Boreham³, H. Courtney¹, M.C. McKinley², L.J. Murray⁴, J.V. Woodside², I.S. Young², S.J. Hunter¹

¹Regional Centre for Endocrinology and Diabetes, Royal Victoria Hospital, Belfast, ²Nutrition and Metabolism Group, Queens University Belfast, UK, ³School of Physiotherapy and Performance Science, University College Dublin, Ireland, ⁴School of Epidemiology and Public Health, Queens University Belfast, UK.

Background and aims: There is conflicting evidence concerning carbohydrate type, insulin resistance and the development of diabetes. The increased consumption of the westernised diet in society, which is high in refined sugar and fat, has led to increased rates of obesity, insulin resistance and type 2 diabetes mellitus. The effect of the high sugar intake in adolescence is less well demonstrated. We examined the effect of sugar intake in early teenage years on glucose tolerance and insulin resistance in early adulthood.

Materials and methods: A detailed dietary history was performed in subjects aged 12 - 15y between 1989-1990 and again in early adulthood aged between 20-25y between 1997-1999. A total of 489 subjects returned for assessment in early adulthood and had an oral glucose tolerance test, from which the homeostatic model assessment of insulin resistance (HOMA-IR) was calculated. Univariate analysis was performed to assess the relationship between dietary sugar intake and outcome measures with adjustment for sex, height, weight, BMI, social class, physical activity level, total calorie intake, total fat intake and skinfold thickness.

Results: In early teens mean dietary proportions of carbohydrate, fat and protein were $52 \pm 0.2\%$, $39 \pm 0.2\%$ and $11 \pm 0.1\%$ and mean total daily sugar intake (expressed as % of total energy) was $22 \pm 0.3\%$. Mean fasting plasma glucose in early adulthood was 4.4 ± 0.02 mmol/L, median fasting serum insulin level was 10.0 mU/L (Interquartile range 8.0, 14.0) and median HOMA-IR score was 2.0 (Interquartile range 1.5, 2.9). There was no association between dietary sugar intake in early adulthood and measures of glucose metabolism in early adulthood. There was a linear relationship between sugar intake in adolescence and fasting plasma glucose in adulthood with a 0.01 mmol/L increase for every % increase in dietary sugar $p = 0.04$. There was also a linear relationship between dietary sugar intake in adolescence and HOMA-IR score in early adulthood with a 2% increase in the HOMA-IR score for every % increase in dietary sugar ($p < 0.01$).

Conclusion: Higher dietary sugar intake in early teenage years independently affects longer term glucose metabolism and is associated higher fasting plasma glucose and relative insulin resistance. These findings indicate a potential legacy effect of the adolescent diet and a need to address dietary advice in this age group.

Postprandial glucose metabolism in carriers of TCF7L2 risk allele with abnormal glucose regulation (AGR)

G.A. Daniele¹, A. Gastaldelli², A. Mari³, C. Bianchi¹, M. Maggini², I. Crisci¹, G. Penno¹, R. Miccoli¹, S. Del Prato¹

¹Department of Endocrinology and Metabolism, Pisa University, ²Clinical Physiology, CNR Institute, Pisa, ³ISIB-CNR, Padova, Italy.

Background and aims: The mechanisms responsible for contribution of common variants in the gene TCF7L2 to the risk of developing Type 2 diabetes remains far from being completely understood. In order to gain better insights in the metabolic implications of this genotype, studies were undertaken to evaluate postprandial glucose metabolism in subjects with AGR (i.e., IGT and/or IFG) carrying the TCF7L2 risk allele.

Materials and methods: Fourteen subjects (age: 59 ± 10 years; BMI 28 ± 4 kg/m²) with risk-conferring TCF7L2 genotypes (TT or CT at rs7903146) and 8 subjects (age 54 ± 11 ; BMI 28 ± 4) with wild-type genotype (CC) underwent a 4-hr meal-tolerance test with [6,6-(3)H]glucose infusion and [U-13C] glucose ingestion to study endogenous glucose production (EGP) and gut glucose absorption. All subjects had AGR as determined by OGTT. Glucose metabolism was determined along with measurements of plasma concentra-

tions of insulin, C-peptide and glucagon. Insulin secretory profiles were determined by C-peptide deconvolution and mathematical modeling.

Results: There was no difference between individuals carrying the risk genotype and the control group with respect to basal levels of glucose (99 ± 3 vs. 93 ± 4 mg), insulin (12 ± 1 vs. 13 ± 2 mU/l), C-peptide (3.4 ± 0.1 vs. 3.5 ± 0.1 ng/ml), and endogenous glucose production (EGP: 13.6 ± 2.2 vs. 18.1 ± 3.1 $\mu\text{mol/Kg/min}$), whereas plasma glucagon was lower in the risk allele carriers (62 ± 4 vs. 93 ± 9 pg/ml; $p=0.002$). In response to meal ingestion there was no difference in glucose concentration although the risk allele carriers had reduced insulin secretion rates during the 1st and the 2nd hour ($p<0.05$). No difference, however, emerged with respect to dose-response, and potentiation. Average EPG during the meal test did not differ between the 2 groups (4.4 ± 1.1 vs. 7.1 ± 2.1 $\mu\text{mol/kg/min}$). In contrast, AUC for total rate of appearance (Ra) tended to be lower in TT/CT (4016 ± 1503 $\mu\text{mol/min}$ vs. 7304 ± 4180 $\mu\text{mol/min}$) mainly due to significantly reduced oral Ra (3225 ± 1396 $\mu\text{mol/min}$ vs. 5888 ± 2877 $\mu\text{mol/min}$, $p=0.04$). In the whole population oral glucose Ra correlated with mean PG following the meal ingestion ($r=0.44$; $p=0.07$). Plasma glucagon levels remained constantly lower in risk carrying subjects (97 ± 11 vs. 60 ± 4 pg/ml; $p=0.018$) accounting for slightly greater insulin:glucagon ratio (1.09 vs. 0.85).

Conclusion: Individuals with abnormal glucose regulation carrying the rs7903146 TCF7L2 risk genotype do not have significant alteration in glucose tolerance after the ingestion of a mixed meal in spite of impaired insulin secretion rate. This impairment may be compensated by lower glucagon levels and reduced rate of appearance of oral glucose.

Assessment of diurnal variations of insulin sensitivity, beta cell responsivity and hepatic insulin extraction in normal subjects

C. Dalla Man¹, D. Nandy², A. Saad², R. Basu², Y. Kudva², C. Cobelli¹, A. Basu²;

¹Department of Information Engineering, University of Padova, Italy,

²Department of Internal Medicine, Division of Endocrinology, Mayo Clinic, Rochester, USA.

Background and aims: Assessing whether postprandial glucose metabolism follows a diurnal pattern could be of great help in the development of an Artificial Pancreas. However, such variations in post prandial insulin action, secretion and hepatic extraction have never been studied with state of the art methods, in healthy or in type 1 diabetic subjects. The aim of present study was thus to determine the presence/absence of a diurnal pattern in insulin sensitivity (S_i), beta-cell responsivity to glucose (Φ) and hepatic insulin extraction (HE) in response to identical mixed meals in normal individuals.

Materials and methods: We studied 14 nondiabetic subjects (7 men, BMI 25.1 ± 1.0 kg/m², age 29.6 ± 2.0 yrs) with normal fasting glucose (4.8 ± 0.1 mM) and HbA_{1c} ($5.3 \pm 0.1\%$), who received, on three consecutive days, three identical mixed meals (10 cal/kg, 50 g carbs; 35% carbs, 30% protein, 35% fat) either for breakfast (B), lunch (L) or dinner (D) at 0700, 1300 and 1900 in randomized latin square order. Physical activity measured with accelerometers was equal on all three days. Plasma glucose, insulin and c-peptide concentrations were frequently sampled during each test. Oral glucose, c-peptide and insulin minimal models were applied to provide estimates of S_i , dynamic Φ (Φ_d), static Φ (Φ_s), overall Φ (Φ_{tot}), basal (HE_b) and total HE (HE_{tot}).

Results: S_i was higher at B than L and D, but not significantly ($S_i^B=10.41 \pm 2.11$, mean \pm SE, $S_i^L=7.82 \pm 0.90$, $S_i^D=7.45 \pm 0.82$ 10^{-4} dl/kg/min per $\mu\text{U/ml}$); Φ_d was significantly lower at L compared to B and D ($p=0.004$ and $p=0.042$, respectively; $\Phi_d^B=695.17 \pm 62.95$, $\Phi_d^L=527.32 \pm 75.59$, $\Phi_d^D=625.15 \pm 103.26$ 10^{-9}); Φ_s was significantly lower at L compared to B ($p=0.035$; $\Phi_s^B=42.67 \pm 4.19$, $\Phi_s^L=38.21 \pm 3.39$, $\Phi_s^D=38.43 \pm 3.95$ 10^{-9} min⁻¹); Φ_{tot} was significantly lower at L and D compared to B ($p=0.017$ and $p=0.042$, respectively; $\Phi_{tot}^B=54.24 \pm 4.89$, $\Phi_{tot}^L=45.74 \pm 4.54$, $\Phi_{tot}^D=47.39 \pm 5.70$ 10^{-9} min⁻¹); HE_b was significantly higher at D compared to B ($p=0.010$; $HE_b^B=0.69 \pm 0.02$, $HE_b^L=0.72 \pm 0.03$, $HE_b^D=0.74 \pm 0.03$) and total HE was significantly higher at L and D compared to B ($p=0.040$ and $p=0.004$, respectively; $HE_{tot}^B=0.48 \pm 0.03$, $HE_{tot}^L=0.62 \pm 0.03$, $HE_{tot}^D=0.54 \pm 0.03$).

Conclusion: Our results demonstrate the existence of diurnal pattern in insulin action, secretion and extraction in healthy humans. This is represented by a progressive decrease in insulin sensitivity and beta-cell function with a concomitant increase in hepatic insulin extraction from B to D. Similar studies in type 1 diabetes are currently underway.

Effect of age, sex, mitochondrial function and exercise training on insulin sensitivity, beta cell responsivity and fatty acid concentrations in response to a mixed-meal

I. Brian¹, I.R. Lanza¹, C. Dalla Man², G.C. Henderson³, R. Nelson¹, J. Miles¹, C. Cobelli², K. Nair¹;

¹Mayo Clinic, Rochester, USA, ²University of Padova, Italy, ³Rutgers, New Brunswick, USA.

Background and aims: It remains to be determined whether the effect of specific exercise programs on muscle mitochondrial function is related to improvement in insulin sensitivity. We determined the effects of different exercise programs in both young and elderly adults on skeletal muscle mitochondrial function and insulin sensitivity, beta cell responsivity, and free-fatty acid (FFA) concentrations.

Materials and methods: We studied the effects of 8 wk of endurance (ET), resistance (RT), and combined (CT) training on meal tolerance and muscle oxidative capacity in 34 young (25 ± 1 y, 46% female) and 31 elderly (70 ± 2 y, 50% female) adults. Participants ingested a mixed-meal (25 kcal/kgFFM: 50:30:20, CHO: FAT:PRO), followed by serial (20-min) blood draws for 2h to measure glucose, insulin, c-peptide, and FFA. Measures of insulin sensitivity (S_i) and beta-cell responsivity (dynamic Φ_d , static Φ_s and total Φ_{tot}) were calculated using the oral glucose and c-peptide minimal model. FFA concentrations were measured by HPLC. Mitochondria were isolated from muscle biopsies before and after training. State-3 O_2 flux was measured with substrates for complex I, I+II, and II by high-resolution respirometry.

Results: At baseline there were no significant differences in S_i between men and women, nor the young and the elderly (all $p>0.05$). However, men had higher baseline Φ_d and Φ_{tot} than women ($\sim 30\%$, $p=0.046$; $\sim 17\%$, $p=0.051$, respectively) and the young had higher baseline Φ_d and Φ_{tot} than the elderly ($\sim 40\%$, $p=0.010$; $\sim 30\%$, $p=0.051$, respectively). Although no significant increase in S_i or Φ occurred following exercise in general, the increase in S_i with RT was significantly different from the relative decline in S_i observed in controls ($p=0.027$). At baseline, premeal FFA concentrations were lower in men than women ($\sim 30\%$, $p=0.011$), and in the younger than the elderly ($\sim 16\%$, $p=0.024$). In contrast, FFA concentrations during the last hour following meal were higher in men than women ($\sim 20\%$, $p=0.042$), while they remained lower in the young than the elderly ($\sim 35\%$, $p=0.006$). Exercise training did not significantly affect premeal FFA concentrations nor suppression by meal-induced insulin secretion. There were no statistical differences in mitochondrial O_2 flux between men and women. However, the young had higher complex I and I+II O_2 flux rates than the elderly ($\sim 24\%$, $p=0.010$; $\sim 16\%$, $p=0.050$, respectively). Moreover, both ET and CT significantly increased complex I O_2 flux rates ($\sim 28\%$, $p=0.029$; $\sim 60\%$, $p<0.001$, respectively), complex I+II O_2 flux rates ($\sim 20\%$, $p=0.010$; $\sim 50\%$, $p<0.001$, respectively) and complex II O_2 flux rates ($\sim 20\%$, $p=0.021$; $\sim 30\%$, $p<0.001$, respectively) independent of age ($p>0.05$) and sex ($p>0.05$). No association between pre- to post training changes in S_i and changes in O_2 flux was observed.

Conclusion: In summary, beta cell responsivity in response to a mixed-meal was higher in men than women and higher in the young than the elderly. Resistance exercise positively affected insulin sensitivity in the absence of improvements in mitochondrial oxidative capacity. Both endurance and combined training increased mitochondrial oxidative capacity in the absence of improvements in insulin sensitivity. In conclusion, exercise related improvements in mitochondrial function were unrelated to changes in insulin sensitivity.

OP 43 DPP-4 inhibitors

241

Blocking GLP-1 action with exendin [9-39] to determine the contribution of GLP-1 to the insulinotropic effects of the DPP-4 inhibitor vildagliptin

M.A. Nauck¹, J. Kind², C.F. Deacon³, J.J. Holst³, Y. He⁴, M. Broschag², I. Vardarli¹, L. Kjems⁵, J. Foley⁵;

¹Diabeteszentrum Bad Lauterberg, ²Parexel, Berlin, Germany, ³Biomedical Institute, University of Copenhagen, Denmark, ⁴Novartis Institute for BioMedical Research, Cambridge, ⁵Novartis, East Hanover, USA.

Background and aims: DPP-4 inhibitors are thought to augment glucose-induced insulin secretion and suppress glucagon release by preserving higher plasma concentrations of endogenously secreted GLP-1. This view, however, has been challenged. The present study aimed at quantifying the contribution of GLP-1 to therapeutic effects of vildagliptin by using the GLP-1 receptor antagonist exendin [9-39] to specifically block GLP-1-mediated mechanisms, both in type 2 diabetic patients and in healthy subjects.

Materials and methods: 34 patients with type 2 diabetes (31m/3f; age 61 ± 9 years, BMI 28.6 ± 3.4 kg/m²; HbA_{1c} > 6.0 %; fasting plasma glucose 90–200 mg/dl; 32 completers analysed) and 34 age- and weight-matched healthy subjects (29m/5f; age 60 ± 9 years; BMI 27.0 ± 2.8 kg/m²; 30 completers analysed) participated. They were treated, in randomized order, with vildagliptin 50 mg b.i.d. or matching placebo for 10 days. Meal tests were performed on days 9 and 10, without and with the intravenous infusion of exendin [9-39] (500 pmol/kg⁻¹·min⁻¹ from -60 to 0 min followed by 350 pmol/kg⁻¹·min⁻¹ for 300 min). At -30 min, study medication was administered, and at 0 min, mixed meal ingestion was started. Glucose, insulin, C-peptide, insulin secretion rates (deconvolution), glucagon, total and intact GLP-1 and GIP were measured. The main study endpoint was the ratio of integrated incremental (AUCi) insulin secretion rates (ISR, 0–4 h) and AUCi glucose. Statistics: Friedman test (non-parametric analysis due to non-normally distributed data). Medians and inter-quartile ranges (IQR).

Results: In type 2-diabetic patients, vildagliptin treatment increased the median AUCi intact GLP-1 after meal stimulation from 2.4 (IQR 0.5;4.9) to 5.0 (1.8;9.3) pmol·h⁻¹ (p = 0.0003). Similar differences were observed for intact GIP. AUCi ISR/glucose ratios were significantly affected by treatment (p = 0.0002). Exendin [9-39] reduced the median of this ratio both when given in addition to placebo (1.5 [1.2;1.9] vs. 2.3 [1.4; 3.6] pmol/kg⁻¹·mmol⁻¹·min⁻¹; p = 0.0079) and to vildagliptin (2.0 [1.3; 2.5] vs. 2.8 [1.8; 3.8] pmol/kg⁻¹·mmol⁻¹·min⁻¹; p = 0.0039), in the latter case not, however, to the levels after placebo plus exendin [9-39] (p = 0.0028). C-peptide/glucose ratios followed a similar pattern. In healthy subjects, incretin hormones were changed similarly, but AUCi ISR/glucose or C-peptide/glucose ratios were not affected significantly. Glucagon concentrations could not meaningfully be analysed due to significant cross-reactivity of exendin [9-39] in the assay.

Conclusion: Therapeutic effects of the DPP-4 inhibitor vildagliptin on meal-stimulated insulin secretion could partially, but not completely be blocked by a GLP-1 receptor agonist administered at a dose that completely blocks insulinotropic effects of exogenous GLP-1. Therefore, some, but not all effects of DPP-4 inhibitors appear to be mediated through GLP-1. In healthy subjects, vildagliptin only affected incretin plasma concentrations, without a significant effect on insulin secretion.

Long-term safety and efficacy of the DPP-4 inhibitor linagliptin: data from a large 2-year study in subjects with type 2 diabetes mellitus

A. Schlosser¹, D. Owens², M.-R. Taskinen³, S. Del Prato⁴, R. Gomis⁵, S. Patel⁶, A. Pivovaro⁷, H.-J. Woerle⁸;

¹Boehringer Ingelheim, Alkmaar, Netherlands, ²Diabetes Research Unit, Llandough Hospital, Cardiff, UK, ³Helsinki University Central Hospital, Finland, ⁴University of Pisa, Italy, ⁵Hospital Clínic Villarreal, Barcelona, Spain, ⁶Boehringer Ingelheim, Bracknell, UK, ⁷Boehringer Ingelheim, Biberach, ⁸Boehringer Ingelheim, Ingelheim, Germany.

Background and aims: Linagliptin is a novel, once daily, oral DPP-4 inhibitor currently in late-stage clinical development for the treatment of type 2 diabetes mellitus (T2DM). This trial investigated the safety, tolerability, and efficacy of linagliptin in a large study population during long-term treatment.

Materials and methods: T2DM subjects who completed one of four 24-wk double-blind, placebo-controlled Phase III studies exploring linagliptin efficacy and safety as mono-, dual-, or triple therapy, could enrol in a 78-wk open-label extension study (a combined total of 2 yrs' follow up). Subjects who received placebo in 24-wk trials switched to linagliptin in the extension study. Thus, during the extension all subjects received once-daily linagliptin 5 mg as monotherapy, as combination with metformin or pioglitazone or with metformin plus sulphonylurea. Efficacy analyses were based on completers of the full analysis set (FAS) after 102 wks.

Results: In total, 2121 subjects (mean age, 58 yrs; 48.2% female; mean BMI, 29.0 kg/m²) who completed the double-blind studies after 24 wks entered the extension trial and 1826 completed 102 wks. Baseline characteristics at the beginning of treatment for the FAS completers set were balanced between those randomized to linagliptin (n = 1310; HbA_{1c}, 8.1%) or placebo (n = 516; HbA_{1c}, 8.2%). Significant reductions in HbA_{1c} achieved with linagliptin after 24 wks' blinded treatment (-0.8%) were sustained over the further 78-wks extension (2-yr change vs. baseline of -0.8%; Figure). For those initially randomized to placebo, switching to linagliptin at wk 24 resulted in an additional decrease in HbA_{1c} of -0.5% after the extension period. Treatment with linagliptin continued to be well tolerated with no major trends of clinical relevance during the extension study (up to 2 yrs). The overall incidence of hypoglycaemic events during the extension period was similar for subjects continuing with linagliptin (14.6%) and those switching from placebo (13.6%). Approximately one-third of subjects in each group were receiving background metformin plus sulphonylurea therapy, hypoglycaemic events were most frequent in these subjects. Body weight was not substantially altered after switching to linagliptin or continuing linagliptin during long-term treatment.

Conclusion: Linagliptin provides sustained long-term glycaemic control when used as monotherapy or add-on to other oral glucose-lowering agents. Linagliptin treatment was well tolerated without clinically relevant increases in the risk of hypoglycaemia or causing weight gain.

HbA_{1c} (%) mean change over time for patients who received linagliptin at the start of the 2-year treatment period

Saxagliptin add-on therapy to insulin with or without metformin for type 2 diabetes mellitus: 52-week safety and efficacy

A.H. Barnett¹, B. Charbonnel², J. Li³, M. Donovan³, D. Fleming³;

¹University of Birmingham and BioMedical Research Unit Heart of England, UK, ²Centre Hospitalier Universitaire de Nantes, France, ³Bristol-Myers Squibb, Princeton, USA.

Background and aims: The safety and efficacy of the dipeptidyl peptidase-4 inhibitor saxagliptin (SAXA) were evaluated as add-on therapy in patients with type 2 diabetes mellitus (T2DM) inadequately controlled with insulin (INS) alone or INS combined with metformin (MET).

Materials and methods: In a phase IIIB, double-blind, parallel-group trial, adults with HbA_{1c} 7.5–11% on stable INS (30–150 U/d ± MET) for ≥8 weeks

at screening were stratified by MET use and randomly assigned 2:1 to oral SAXA 5 mg/d (n=304) or placebo (PBO; n=151) for a 24-week short-term (ST) period followed by a 28-week long-term (LT) period (52 weeks total). MET doses were kept stable. INS doses were kept stable during the ST period before rescue, but could be adjusted without rescue during the LT period to optimize glycemic control.

Results: Mean age was 57 y, mean T2DM duration was 12 y, and mean baseline (BL) HbA_{1c} was 8.7%. LT completion rates were similar in the SAXA (81%) and PBO groups (83%). Most patients used MET along with INS (69% in the SAXA arm [mean BL dose, 1805 mg/d]; 70% in the PBO arm [mean BL dose, 1861 mg/d]). The most common INS regimens were premixed (57% of patients), intermediate acting (19%), and long acting (18%). In repeated measures analysis, adjusted mean HbA_{1c} decreased more from BL to week 52 with SAXA (−0.8%) vs PBO (−0.4%; difference, −0.4% [95% CI: −0.6 to −0.2]), whether MET was used (difference, −0.4% [95% CI, −0.6 to −0.2]) or not (difference, −0.4% [95% CI, −0.7 to −0.03]). At week 52, 21.3% of SAXA-treated patients and 8.7% of patients receiving PBO achieved HbA_{1c} <7% (difference, 12.6% [95% CI, 6.1 to 19.1]). More SAXA-treated patients vs patients in the PBO group achieved HbA_{1c} <7%, whether MET was used (23.8% vs 8.7%) or not (16.0% vs 8.7%). Mean total daily INS dose increased from BL in both treatment groups through week 52, with a numerically smaller increase in the SAXA group (repeated measures, 5.7 vs 6.6 U; 95% CI for difference, −3.2 to 1.3). SAXA + INS was well tolerated vs PBO + INS: 66.4% and 71.5% of patients had ≥1 adverse event (AE) and few patients discontinued owing to AEs in the SAXA and PBO groups (3.0% and 2.0%, respectively). Overall AE incidences were similar regardless of MET use. Most AEs were mild or moderate. Serious AEs were infrequent and balanced across groups. Two deaths in SAXA-treated patients (myocardial infarction, intestinal necrosis) were judged unrelated to study drug. The most common AE classes were infections and infestations (35.5% vs 41.1%, SAXA vs PBO), gastrointestinal disorders (18.8% vs 16.6%), and musculoskeletal and connective tissue disorders (16.4% vs 19.9%). Patients in the SAXA and PBO groups both experienced small, similar weight gains (adjusted mean change from BL [repeated measures], 0.8 vs 0.5 kg; 95% CI for difference, −0.3 to 0.8). Hypoglycemia was reported in 22.7% of SAXA-treated patients and 26.5% of patients receiving PBO. Hypoglycemia was confirmed (fingerstick glucose ≤50 mg/dL [2.8 mmol/L] with associated symptoms) in 7.6% of SAXA-treated patients and 6.6% of patients in the PBO group.

Conclusion: SAXA 5 mg add-on therapy improved glycemic control in patients with T2DM on INS alone or INS + MET, an effect sustained through 52 weeks. Despite the flexible INS regimen, SAXA did not increase risk of hypoglycemia and was well tolerated.

Dipeptidyl peptidase-4 inhibitors and cardiovascular events: a protective effect?

C. Lamanna¹, M. Monami², N. Bartoli², S. Zannoni², E. Mannucci¹;

¹Careggi Teaching Hospital, Diabetes Agency, Florence, ²Cardiovascular Medicine - University of Florence, Section of Geriatric Cardiology and Medicine, Italy.

Background and aims: Data from randomized clinical trials with metabolic outcomes can be used to address concerns about potential issues of cardiovascular safety for newer drugs for type 2 diabetes. This meta-analysis was designed to assess cardiovascular safety of Dipeptidyl Peptidase-4 inhibitors (DPP-4i).

Materials and methods: Medline, Embase, Cochrane databases, and www.clinicaltrials.gov website were searched for randomized trials of DPP-4 inhibitors (versus placebo or other comparators) with duration ≥ 24 weeks, performed in type 2 diabetic patients. Mantel-Haenszel odds ratio with 95% Confidence Interval (MH-OR) was calculated for major cardiovascular events (MACE), on an intention-to-treat basis, excluding trials with zero events.

Results: Fifty-three trials enrolling 20,312 and 13,569 patients for DPP4i and comparators, respectively, were included, reporting 257 MACE. DPP4i, compared with placebo or other treatment, were associated with a reduced risk of MACE (MH-OR 0.689 [0.528;0.899], p=0.006).

Conclusion: The present meta-analysis suggests a possible protection from cardiovascular events with the use of DPP-4i.

Glucagon-like peptide-1 receptor (GLP-1R) agonism ameliorates non-alcoholic steatohepatitis (NASH) in rodent models

J.D. Roth¹, J.L. Trevaskis¹, P.S. Griffin¹, C. Wittmer¹, B.A. Neuschwander-Tetri², E.M. Brunt², C.S. Dolman¹, M.R. Erickson¹, D.G. Parkes¹;

¹Amylin Pharmaceuticals, Inc., San Diego, ²Saint Louis University, St Louis, USA.

Background and aims: Pharmacotherapies for non-alcoholic steatohepatitis (NASH) are lacking. The present studies aimed to expand on the potential beneficial effect of GLP-1 receptor agonism in rodent models of NASH.

Materials and methods: We examined the effects of the exenatide analog AC3174 (30 µg/kg/d for 28 days) in Lep^{ob}/Lep^{ob} and C57BL6J (B6) mice that were maintained on a high trans-fat/high fructose/high cholesterol (HTF) diet. In a separate study, the effects of AC3174 were compared to (drug-naïve) calorie-restricted weight matched controls. AC3174 was also administered to GLP-1 receptor-deficient (Glp1rKO) mice.

Results: The HTF diet increased micro- and macro-steatosis in both strains of mice. In Lep^{ob}/Lep^{ob}, but not B6 mice, induction of fibrosis coupled with a ~6-fold increase in collagen-1 mRNA and protein was also evident. AC3174 treatment reduced: body weight (by 7.3% in Lep^{ob}/Lep^{ob} and 15.5% in B6 mice vs vehicle), liver mass (by 20% and 30%), liver lipid (by 11% and 38%), and attenuated fibrosis. In the next study, AC3174-treated mice exhibited significantly reduced body weight (8.3%), liver mass (14.2%), liver lipid (12.9%), plasma alanine aminotransferase, and triglycerides, whereas a calorie-restricted weight-matched group demonstrated only modest non-significant reductions in liver mass (9%) and liver lipid (5.1%) relative to controls. Treatment of Glp1rKO mice with AC3174 had no effect on body weight, adiposity, hepatic, or plasma indices, suggesting that the observed beneficial effects of AC3174 are mediated via the known GLP-1 receptor.

Conclusion: Together, these data support the clinical evaluation of the utility of GLP-1 receptor agonists for treatment of NASH.

Non alcoholic fatty liver disease (NAFLD) is a major risk factor for cardiovascular disease in patients with type 2 diabetes mellitus

E. Gova¹, A. Sianni¹, C. Feretou¹, E. Tzamparlis¹, A. Ganotopoulou², H. Agelis¹, Z. Tagkalaki¹, C. Kosma³, L. Skorda¹, C. Masgala¹, I. Liouris¹;

¹Department of Internal Medicine, Konstantopoulou General Hospital of Nea Ionia Athens, ²Tzaneio General Hospital of Piraeus, ³Dromokaiteio General Hospital of Athens, Greece.

Introduction: Non-alcoholic fatty liver disease is a spectrum of metabolic liver disease that extends from: bland steatosis (fatty liver), where the histology and the function of the liver are not affected, and non alcoholic steatohepatitis, where steatosis, pericellular and hepatocellular inflammation, Mallory bodies, fibrosis and elevation of liver biochemical parameters (AST, ALT) are present to cirrhosis and hepatocellular cancer as a result of NAFLD. Aim: To determine if NAFLD is a major risk factor for cardiovascular disease in patients with type 2 diabetes mellitus.

Materials and methods: The study included 468 patients with type 2 DM, out of them 290 were men (62%) and 178 (38%) were women, with mean age of 62±13 years old. All the patients underwent liver ultrasound scan and biochemical exams (fasting glucose, HbA_{1c}, AST, ALT, γ-GT, total bilirubin) during 3 years.

Results: The patients were divided in 2 groups: group A consisted of 184 (39%) patients with NAFLD and DM and group B consisted of 284 (61%) patients with type 2 DM without NAFLD. During the 3 years mean follow up a major cardiovascular event (non fatal myocardial infarction, revascularisation or cardiovascular death) occurred in 102 (55%) patients of group A and only in 42 (15%) of group B.

Conclusion: NAFLD is a major risk factor for cardiovascular events in Patients with type 2 diabetes mellitus. These patients should be treated and often examined both by an internist and a cardiologist. Early start of treatment for diabetes mellitus and strict control of blood sugar prevent cardiovascular events and the progress of liver disease.

247

Non-alcoholic fatty liver disease severity is related to increased cardiovascular risk independently of hyperglycaemia and obesity

S. Hudson¹, L.S. Bhatia¹, K.G. McCormick¹, A. Bateman², K. Nash², N.P. Curzen², G.F. Clough¹, P.C. Calder¹, C.D. Byrne¹, WELCOME study investigators;

¹University of Southampton, ²Southampton University Hospitals NHS Trust, UK.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a common chronic condition which is strongly linked to obesity and diabetes, being prevalent in up to 90% of obese subjects and up to 70% of people with type 2 diabetes. The risk of cardiovascular (CV) disease is significantly increased in NAFLD and represents the main cause of death in these patients. NAFLD forms a spectrum of fat-related liver conditions extending from simple and relatively harmless steatosis, to end-stage progressive liver disease requiring transplantation because of decompensated cirrhosis or hepatocellular carcinoma. Non-invasive techniques are available to quantify the severity of fat infiltration and to assess fibrosis. However, histopathological assessment of liver tissue remains the gold standard to assess NAFLD severity. Although NAFLD is associated with obesity and diabetes, the precise nature of the relationship between NAFLD severity, hyperglycaemia, obesity and CV risk is uncertain. Our aim was to establish the relationships between a histopathological marker of NAFLD disease severity, levels of glycaemic control, obesity and a 10-year CV risk estimate.

Materials and methods: Retrospective data on patients with biopsy-proven NAFLD were obtained using patient hospital notes and the electronic patient management system 'e-Quest'. These data were utilized to calculate CV risk using online QRISK2 and Framingham heart study 10-year risk calculators (three patients were omitted due to documented CV disease). NAFLD severity was assessed by histopathological evaluation of liver biopsy specimens using the 12-point Kleiner scoring system. Total and truncal fat were measured using dual energy x-ray absorptiometry (DEXA) scans.

Results: NAFLD severity by Kleiner score was available on $n=104$ people (67 men). Kleiner score was 5.3 ± 2.3 (mean \pm SD), (range 1–11). 32 subjects had a prior diagnosis of diabetes. Kleiner score in people with diabetes, compared to without, was 6.4 ± 2.0 and 4.8 ± 2.1 respectively ($p < 0.001$). The age of the whole cohort was 47.9 ± 12.6 years (mean \pm SD). Kleiner score was associated with fasting glucose ($r=0.21$, $p=0.038$), HbA_{1c} ($r=0.26$, $p=0.034$) and 10-year CV risk calculated by both QRISK2 ($r=0.458$, $p < 0.001$) and Framingham risk score (FRS) ($r=0.374$, $p < 0.001$). There was no relationship between BMI and Kleiner score ($r=0.06$, $p=0.58$), although in a sub-group ($n=45$), there was a trend toward an association between Kleiner score and truncal fat percentage ($r=-0.29$, $p=0.077$). In multivariable linear regression analyses that included measures of glycaemic control (glucose and HbA_{1c}) and BMI, both QRISK2 (β -coefficient 0.42, $p=0.001$) and FRS (β -coefficient 0.38, $p=0.003$) were strongly and independently associated with Kleiner score.

Conclusion: These data show for the first time a strong association between a histological measure of NAFLD severity and calculated estimates of CV risk, which was independent of markers of glucose control and obesity.

Prevalence and markers of advanced liver disease in people with type 2 diabetes: the Edinburgh type 2 diabetes study

R.M. Williamson¹, J.F. Price², P.C. Hayes³, S. Glancy⁴, B.M. Frier⁵, G.I. Johnston⁶, R.M. Reynolds⁷, M.W.J. Strachan¹;

¹Metabolic Unit, Western General Hospital, Edinburgh, ²Centre for Population Health Sciences, University of Edinburgh, ³Department of Hepatology, Royal Infirmary of Edinburgh, ⁴Department of Radiology, Western General Hospital, Edinburgh, ⁵Department of Diabetes, Royal Infirmary of Edinburgh, ⁶Pfizer Global R&D, Kent, ⁷Endocrinology Unit, University/BHF Centre for Cardiovascular Science, Edinburgh, UK.

Background and aims: Type 2 diabetes is a risk factor for the progression of hepatic steatosis and non-alcoholic fatty liver disease (NAFLD) to fibrosis and cirrhosis. We examined the prevalence of hepatic fibrosis and portal hypertension, in addition to hepatocellular carcinoma (HCC), in people with type 2 diabetes, using the non-invasive markers hyaluronic acid (HA) and platelet count/spleen diameter ratio (PSR), and analysed the effectiveness of liver function tests (LFTs) in screening for liver disease in this population.

Materials and methods: Subjects recorded as having type 2 diabetes, aged 61–76 years, were invited at random from the Lothian Diabetes Register to participate in the Edinburgh Type 2 Diabetes Study. Ultrasonography was performed in 939 participants to record cirrhosis, spleen size (mm) and focal liver abnormalities. Serum HA (ng/ml), platelets (/mm³), alpha fetoprotein (AFP, kU/l), bilirubin (Bi, umol/l), alanine transferase (ALT, units/l) and gamma glutamyltransferase (GGT, units/l) were measured. Participants with no secondary cause for liver disease (possible NAFLD) were split into 5 groups according to increasing levels of fibrosis (Group 1, normal; Group 2, hepatic steatosis alone; Group 3, HA 50–100 ng/ml, no arthritis; Group 4, HA 100–300 ng/ml, no arthritis; Group 5, cirrhosis, PSR < 909 or HA > 300 ng/ml, no arthritis).

Results: Cirrhosis was identified by ultrasound in 4 participants (0.4%). 10 (1.1%) had evidence of portal hypertension (PSR < 909). 222 (23.6%) had evidence of hepatic fibrosis (HA > 50 ng/ml, no arthritis), and 53 of these had HA > 100 ng/ml. Of 663 participants with no secondary cause for liver disease, 1 (0.2%) had cirrhosis, 4 (0.6%) had PSR < 909 and 166 (25.0%) had HA > 50 ng/ml of whom 40 had HA > 100 ng/ml. Two participants had HCC, a prevalence in the study population of 0.2%. Tests of liver function were compared across the Fibrosis Groups (Table 1). Bi, ALT and GGT were highest in Groups 4 and 5, with statistically significant differences between groups ($p < 0.05$). Mean levels remained within normal limits in all groups. The positive predictive values of ALT and GGT levels above normal in predicting fibrosis (i.e. Groups 3–5) were 26.1% and 28.6%. The negative predictive values of normal values were 75.2% and 75.3% respectively.

Conclusion: The prevalence of hepatic fibrosis was high, but that of cirrhosis or likely portal hypertension was lower than anticipated. The use of conventional LFTs to screen for liver disease missed a significant proportion of cases of fibrosis predicted by raised HA levels.

OP 45 Hypoglycaemia

249

High levels of stimulated glucagon 12 months after diagnosis of type 1 diabetes decrease the risk of severe hypoglycaemia in the following years

S. Fredheim¹, M.M.C. Andersen¹, S. Porsken¹, J. Johannesen¹, A. Johansen¹, B. Carstensen², H.B. Mortensen¹, J. Svensson¹

¹Pediatric Ward, Herlev University Hospital, ²Steno Diabetes Center, Gentofte, Denmark.

Background and aims: The risk of severe hypoglycaemia (SH) is the major factor for preventing good glycemic regulation as assessed by HbA_{1c}. The aim of the study is identification of individuals at high risk for acute diabetic complications within one year after onset of disease.

Materials and methods: A sample of 129 children and adolescents < 17 years from four centres in Denmark with newly diagnosed Type 1 Diabetes (T1D) diagnosed from April 2004 to April 2005 were followed for 6 years, prospectively. HbA_{1c}, liquid mixed-meal stimulated C-peptide and glucagon were analyzed centrally 1, 3, 6 and 12 months after diagnosis. Data such as gender, age and events of SH, including annual recordings of HbA_{1c} were recorded. SH was defined as unconsciousness and/or seizures and a blood glucose level < 3.5 mmol/L. Logistic regression was used to analyse the influence of glucagon and C-peptide levels after 12 months on the subsequent risk of severe hypoglycaemic events in the following 6 years.

Results: 129 children were included, 66 boys (51 %) and 63 girls (49 %). 94 children did not experience SH (mean age 10.3 (range 1.5 - 16.7) years), and 30 children had a severe hypoglycaemic event (mean age 9.0 (range 0.6 - 15.7) years), (missing data for age on 5 children). There were 7 children who experienced a severe hypoglycaemic event within the first year after diagnosis and 30 children experienced SH over the following 6 years. Age at onset and gender was not associated with an increased risk of SH. Individuals with severe hypoglycaemic events within the first year had a 15 times risk of future severe hypoglycaemic events ($p < 0.01$). Median glucagon levels at 12 months among 30 children who experienced SH over the six years follow-up was 7.0 (range 3.0 - 15.0) pmol/L. Median stimulated C-peptide levels at 12 months in the same group was 236.0 (range 10.0 - 1096.0) pmol/L. There is a 19.3% decreased risk of long-term SH (95% CI 4.5-31.6%) per [pmol/L] increase of glucagon at 12 months, after adjusting for C-peptide levels and first-year severe hypoglycaemic events in the statistical analyses.

Conclusion: Early severe hypoglycaemic events and decreased stimulated glucagon levels at 12 months seem to identify individuals at higher risk of future severe hypoglycaemic events indicating a role for glucagon in preventing SH in some individuals. How glucagon should be incorporated in future treatment of diabetes needs further investigations.

Quantitative EEG in type 1 diabetic adults with childhood exposure to severe hypoglycaemia: a 16-year follow-up study

M.R. Bjorgaas¹, B.O. Åsvold¹, K. Hestad², T. Sand³

¹Department of Endocrinology, Trondheim University Hospital,

²Department of Psychology, Norwegian University of Science and

Technology (NTNU), Trondheim, ³Department of Neuroscience, NTNU, Trondheim, Norway.

Background and aims: In diabetic children, a history of severe hypoglycaemia (SH) has been associated with increased slow EEG activity. Our aim was to assess whether EEG abnormalities associated with childhood SH persist into adulthood.

Materials and methods: In 1992, we studied quantitative EEG in 28 diabetic children and 28 matched controls. Sixteen years later, we repeated the investigations in 96% of this cohort. Diabetic subjects were classified as with ($n = 9$) or without ($n = 18$) early SH, defined as episodes with convulsions or loss of consciousness by ten years of age. For each EEG band (delta, theta, alpha, and beta) and cerebral region (frontocentral, temporal, and parietoccipital), we calculated relative amplitudes and amplitude asymmetry. We used a mixed linear model to calculate occipital alpha mean frequency, alpha peak frequency at maximum amplitude and alpha peak width. We examined whether these EEG measures, relative to age- and sex-matched controls, differed between diabetic subjects with and without early exposure to SH. In separate analyses, we adjusted for blood glucose at the EEG recording.

Results: Participants were 27 diabetic (13 female) and 27 control subjects (13 female), age (mean(SD) 28.1(2.2)/ 28.8(2.0) / 28.7(2.1) years (diabetic subjects with /without early SH/ controls). In diabetic subjects with and without early SH, age at diabetes onset was 5.4 (2.6) and 9.8 (2.9) years, diabetes duration 22.7 (2.8) and 19.1 (1.8) years, lifetime number of SH episodes (median (range)) 7 (3-27) and 3 (0-14), mean HbA_{1c} since diabetes onset (weighted for frequency of measurements) 9.3 (1.1) and 8.5 (0.7) %, number of HbA_{1c} measurements 72 (12) and 53(13), and blood glucose at EEG recording (median (range)) 11.6 (5.5-23.3) and 10.1 (4.8-21.0) mmol/l, respectively. We found no association between early exposure to SH and quantitative EEG variables neither in the frontocentral region (Table) nor in any other cerebral region. The total number of SHs and mean HbA_{1c} levels were not significantly associated with regional mean relative amplitudes or EEG frequencies, and adjustment for blood glucose at the recordings did not substantially influence the results (data not shown).

Conclusion: Early exposure to SH was not associated with EEG abnormalities in young adults with type 1 diabetes. Our results suggest that EEG abnormalities associated with childhood exposure to SH do not persist into adulthood. Table: Mean relative EEG amplitudes in the frontocentral region in diabetic subjects and controls, by early^a exposure to SH, and the association of early SH with mean relative amplitudes.

Mean relative EEG amplitudes (%)							
	Diabetes with early SH		Diabetes without early SH		Association with early SH		
	Diabetic subjects	Controls	Diabetic subjects	Controls	Difference ^b	(95% CI)	P ^c
Delta	17.1	18.1	18.9	20.6	0.7	(-3.4 - 4.8)	0.73
Theta	16.9	16.6	17.7	18.5	1.1	(-2.9 - 5.2)	0.57
Alpha	26.8	28.3	25.6	24.1	-3.0	(-10.0 - 4.0)	0.39
Beta	39.2	37.0	37.7	36.8	1.2	(-6.4 - 8.8)	0.76

The relationship between plasma and brain glucose levels under hypoglycaemic conditions in humans

K.C.C. van de Ven¹, B.E. de Galan², M. van der Graaf³, A. Heerschap¹, C.J.J. Tack²

¹Radiology, ²General Internal Medicine, ³Radiology & Clinical Physics

Laboratory, Radboud University Nijmegen Medical Centre, Netherlands.

Background and aims: Since glucose is the main source of energy for the brain, understanding the kinetics of brain glucose uptake under hypoglycaemic conditions is highly important. Under normo- and hyperglycaemic conditions the relationship between plasma and brain glucose levels is linear and behaves according to reversible Michaelis-Menten (MM) kinetics. The present study was conducted to test whether these kinetics also describe the relationship between plasma and brain glucose during hypoglycaemia, by measuring human cerebral glucose content during hypoglycaemia using ¹³C magnetic resonance spectroscopy (MRS).

Materials and methods: Eight healthy volunteers underwent ¹³C MRS at a magnetic field strength of 3T in a 125 ml voxel in occipital brain tissue during 2-hour hyperinsulinemic (60 mU/min/m²) euglycaemic and hypoglycaemic glucose clamps, performed in random order on separate days. [1-¹³C]glucose was infused during the clamps to increase plasma ¹³C isotopic enrichment. Plasma glucose and plasma ¹³C enrichment were measured every 5 minutes. MR spectra acquired during steady-state ($t = 50$ -100 min) were averaged. The peaks of α - and β -glucose were fitted with the AMARES algorithm in jMRUI. To quantify metabolite levels the natural abundance ¹³C myo-inositol signals were assumed to represent 1.1% of 6 mM. In addition, glucose signals were corrected for the ¹³C enrichment of plasma glucose and for 5% contamination by blood vessels. The values of reversible MM kinetic parameters (T_{max}/CMR_{glc} and K_1) for glucose transport were calculated from plasma and brain glucose values during steady-state.

Results: Plasma glucose levels ranged from 4.38-5.26 (normoglycaemic) to 2.54-3.26 mM (hypoglycaemic) during steady-state. The quality of the ¹³C-

MR spectra was good under both conditions. Steady-state brain glucose levels averaged $0.5 \pm 0.2 \mu\text{mol/g}$ during hypoglycaemia (plasma glucose, $3.0 \pm 0.3 \text{ mM}$) and $1.3 \pm 0.5 \mu\text{mol/g}$ during euglycaemia (plasma glucose, $5.1 \pm 0.3 \text{ mM}$). Individual steady-state brain glucose levels as a function of plasma glucose concentrations are presented in figure 1. The best fit of the data to the reversible MM kinetic model resulted in the following values for the glucose transport parameters: $T_{\text{max}}/\text{CMR}_{\text{glc}} = 2.93 (-)$ and $K_t = 3.27 \text{ mM}$.

Conclusion: This study demonstrates that the relationship between steady-state plasma and brain glucose under hypoglycaemic conditions in humans is linear and follows reversible MM kinetics. These data extend those previously obtained under normo- and hyperglycaemic conditions, and provide further refinement of the reversible MM kinetic parameters in humans *in vivo*.

Figure 1: Plasma versus brain glucose relationship as measured by ^{13}C MRS (diamonds) together with linear regression fit (solid line) and 95% confidence intervals (dashed lines).

Relationship of hypoglycaemia with QTc prolongation in patients with type 2 diabetes

S. Kalopita¹, C. Stathi¹, P. Thomakos¹, I. Vlahodimitris², S. Liatis¹, K. Makrilakis¹;

¹First Department of Propaedeutic Medicine, Athens University Medical School, ²Department of Cardiology, Laiko General Hospital, Athens, Greece.

Background and aims: Recent clinical studies show that hypoglycemia is associated with increased risk of death, mainly attributed to lethal arrhythmias and QTc prolongation. This is mostly studied in type 1 diabetes patients. The aim of the present study was to study the relationship of hypoglycemic episodes (examined during continuous glucose monitoring subcutaneously [CGMS]) with QTc prolongation (measured by continuous ECG monitoring) in patients with type 2 diabetes (T2D).

Materials and methods: A total of 26 (14 males) patients with T2D (mean age \pm SD): 60.3 ± 10.9 years, HbA_{1c} : $6.73 \pm 0.73\%$, diabetes duration 6.9 ± 5.0 years, 7 treated with insulin, 19 treated with insulin secretagogues) were studied with simultaneous CGMS and 24-hour ECG monitoring. Hypoglycemia was defined as episodes of blood glucose (BG) $<70 \text{ mg/dl}$ (3.9 mmol/L), lasting for >5 minutes, while hyperglycemia as episodes of BG $>200 \text{ mg/dl}$ (11.1 mmol/L), lasting for >5 minutes. The mean QTc of these episodes was compared with the mean QTc of normoglycemic intervals (BG between 70 – 120 mg/dl [3.9 – 6.7 mmol/L] of similar duration).

Results: A total of 26 non-severe hypoglycemic episodes in 5 insulin-treated and 8 insulin secretagogue-treated patients were identified. Mean BG during hypoglycemia was 59.2 [95% CI 56.4 – 62.0] mg/dl , while BG during normoglycemia was 98.7 [90.4–107.0] mg/dl . Mean QTc during hypoglycemic episodes was significantly higher than during normoglycaemia (431.4 [416.6–446.2] vs. 416.6 [397.6–435.5] msec, $p=0.015$).

Conclusion: Mild/moderate hypoglycemia in patients with T2D is associated with prolongation of the QTc interval and may contribute to the increased adverse outcomes seen with intensive treatment of the disease.

The Cav1.2 calcium channel spatial expression in pancreatic beta cells is regulated by eIF3e - eukaryotic translation initiation factor subunit 'e'

P. Buda, E. Zhang, T. Mahdi, T. Reinbothe, E. Renström;
Islets Pathophysiology, Lund University, Malmö, Sweden.

Background and aims: Cav1.2 channels regulate insulin secretion in rodent beta-cells. The magnitude of cytosolic calcium may be controlled via changing calcium channel density in the plasma membrane by altering the balance between channels trafficking to and from the cell surface. This process is poorly elucidated, but it is known that beta and alpha2delta auxiliary subunits of L-type calcium channels are implicated in Cav1.2 surface expression whilst little is known about other regulators. In this study we investigated whether the eukaryotic translation initiation factor subunit 'e' (eIF3e) acts as a regulator of Cav1.2 surface expression in beta-cells.

Materials and methods: The interaction between Cav1.2 and eIF3e was investigated by immunoprecipitation and confocal microscopy in INS-1 cells. Cav1.2 distribution was assessed by immunostaining and quantitative comparison of the average signal intensity of Cav1.2 in the plasma membrane and the cytoplasm. The role of eIF3e in Cav1.2 surface expression was evaluated by using RNAi silencing in Cav1.2-GFP transfected INS-1 cells and subsequent real-time imaging. Apoptosis was measured as % of annexin-V positive cells in siRNA treated compared to untreated INS-1 cells at low (5 mM) and high (20 mM) glucose concentrations.

Results: INS-1 cells stimulated with high glucose revealed a substantial shift of Cav1.2 localization from the plasma membrane (PM) to the cytoplasm (CP). Glucose decreased the PM/CP expression ratio in immunostained cells from 1.40 ± 0.09 before, to 0.83 ± 0.05 after 30-min glucose stimulation. Similarly, in real-time imaging experiments the PM/CP ratio of Cav1.2-GFP fluorescence decreased from 1.22 ± 0.04 to 0.49 ± 0.06 after glucose stimulation. The eIF3e PM/CP expression ratio was also determined by immunostaining and amounted 1.11 ± 0.03 and 0.74 ± 0.10 in low and high glucose, respectively. The eIF3e interaction with Cav1.2 was revealed by immunoprecipitation. This interaction was glucose dependent as shown by confocal immunocytochemistry. After incubation at low glucose (30 min), Cav1.2 and eIF3e co-localization was $95 \pm 5\%$, whereas after 30 min in high glucose, it was reduced to $41 \pm 4\%$. Quantitative real-time imaging revealed that in eIF3e silenced INS-1 cells, the PM/CP expression ratio of Cav1.2-GFP decreased from 0.98 ± 0.07 to 0.91 ± 0.09 in INS-1 by glucose stimulation. The eIF3e protein exhibited glucose dependent effects on viability in both INS-1 cells and human pancreatic islets. In INS-1 cells cultured in low glucose apoptotic events were seen in $3.1 \pm 0.1\%$ of the cells, which increased slightly to $3.4 \pm 0.1\%$ in cells cultured for 6 h in high glucose. Knock-down of eIF3e increased apoptosis to $5.2 \pm 0.1\%$ in low glucose, and this effect was massively stimulated in high glucose ($28.6 \pm 0.3\%$ apoptotic cells). Finally, glucose-induced apoptosis was investigated in human islets, and amounted $3.3 \pm 0.8\%$ and $22.3 \pm 1.2\%$ after 72 h culture at 5 and 20 mM glucose, respectively. Silencing of eIF3e did not change apoptosis ($3.2 \pm 0.5\%$) at low glucose, but in 20 mM glucose it was doubled to ($45 \pm 5\%$).

Conclusion: Our study shows that stimulation-dependent Cav1.2 internalization requires eIF3e, which directly interacts with Cav1.2. eIF3e knockdown makes both rodent and human beta-cells more vulnerable to glucose-induced apoptosis.

Two pools of insulin granules with different dependence on Ca^{2+} entry are involved in rapid exocytosis

M.G. Pedersen, L. Eliasson;

Lund University Diabetes Centre, Malmö, Sweden.

Background and aims: Biphasic insulin secretion has been suggested to be caused by release of distinct pools of secretory granules. Such pools can be studied using membrane capacitance measurements and the patch-clamp technique. This study investigated how different phases of capacitance traces are shaped by pool depletion, calcium-current inactivation, and spatial organization using different depolarization protocols and mixed-effects statistical modeling.

Materials and methods: The whole-cell patch-clamp technique was used to measure depolarization-evoked capacitance increases reflecting exocytosis in

INS-1 832/13 cells. Exocytosis was analyzed as a function of Ca^{2+} entry using mixed-effects statistical models to account for cell heterogeneity.

Results: In response to depolarization of different lengths (10–640 ms), capacitance increases (ΔCm) reflecting exocytosis showed a typical biphasic pattern, where the rate of exocytosis was higher for shorter than for longer pulses. This pattern was unchanged by 7 mM free intracellular EGTA when free intracellular $[\text{Ca}^{2+}]$ was ~ 60 nM. The mixed-effects model included a fixed-effect of Ca^{2+} charge Q on ΔCm , which reports the overall Ca^{2+} sensitivity, a fixed-effect offset, and a random effect to allow for cell-to-cell variability. Ca^{2+} sensitivity was estimated to 0.82 ± 0.20 fF/pC, the offset was 5.9 ± 2.0 fF (significantly different from zero, $p=0.0034$, t -test), and cell heterogeneity was significant ($p<0.0001$, F -test). Again, high EGTA levels had no significant effect. Next, we applied a 50 ms pre-pulse 100 ms before another 50 ms pulse. The second pulse evoked significantly smaller exocytosis than the first one (5.0 ± 1.3 vs. 12.1 ± 3.6 fF, $p=0.02$, $n=11$, Wilcoxon paired signed-rank test). A linear model estimated that the Ca^{2+} sensitivity of the second pulse was significantly reduced ($p<0.002$, t -test) by $50 \pm 11\%$. Thus, a small immediately releasable pool (IRP) of granules is depleted within 100 ms. We combined the above protocols, so that each depolarization in a pulse-length protocol (50–800 ms) was preceded by a 50 ms pre-pulse. The capacitance increase of this second depolarization (ΔCm_2) as a function of duration was parallel to the response triggered by depolarizations without pre-pulses, with a downward shift comparable to the capacitance increase of the pre-pulse. In agreement, a mixed-effect analysis of ΔCm_2 as a function of Ca^{2+} entry showed a similar Ca^{2+} sensitivity of 0.83 ± 0.20 fF/pC, and cell heterogeneity was significant ($p<0.0001$, F -test), but in contrast to the results with no pre-pulse, the estimated offset-value was not significantly different from zero and amounted to -1.5 ± 3.3 fF.

Conclusion: We suggest that first-phase release reflects depletion of a small IRP and later exocytosis is due to recruitment of other granules. The latter phase is not due to refilling of the IRP, but rather because of release of another pool, such as a highly Ca^{2+} sensitive pool (HCSP) of granules. The lack of effect of high concentrations of EGTA suggests that both pools are situated within a few hundred nanometers from Ca^{2+} channels.

Bi-directional granule turnover in the submembrane space during K^+ depolarisation-induced secretion

K. Hatlapatka¹, M. Matz², K. Baummann¹, I. Rustenbeck¹

¹Institute of Pharmacology, Toxicology and Clinical Pharmacy, ²Institute of Medicinal Chemistry, University of Braunschweig, Germany.

Background and aims: The monophasic secretion elicited by a KCl depolarization is believed to correspond to the first phase of glucose-induced insulin secretion, in that both represent the release of a pool of membrane-adjacent secretory granules which await one final trigger, a depolarization-induced influx of Ca^{2+} . A number of recent observations have put this hypothesis into question.

Materials and methods: Insulin secretion was measured by perfusion of mouse islets and MIN6 pseudo-islets and ELISA of the fractionated effluat. The free cytosolic Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) of islets and MIN6 cells was measured with the Fura technique. Granules in the submembrane space were visualized by transient transfection of MIN6 cells with an insulin-EGFP fusion protein and imaging by TIRF microscopy (decay constant 80 nm) at 37°C . The images were evaluated by an in-house written program to achieve an observer-independent quantitation of the entire granule population.

Results: Like primary mouse islets, MIN6 pseudo-islets responded to the depolarization by 40 mM KCl and the resulting increase of the $[\text{Ca}^{2+}]_i$ with a massive increase in insulin secretion, whereas 15 mM KCl had little effect in spite of a clear increase of $[\text{Ca}^{2+}]_i$. Analysis of insulin-EGFP-labelled granules in MIN6 cells by TIRF microscopy showed that 40 mM KCl increased the number of short term-resident granules (less than 1 s presence in the submembrane space) while the total granule number and the number of long-term resident granules decreased. The rates of granule arrival at and departure from the submembrane space changed in parallel and were two orders of magnitude higher than the release rates, suggesting a back-and-forth movement of the granules as primary determinant of the submembrane granule number. The parameters of mobility parallel to the membrane were unchanged by the depolarization when corrected for the increased share of short term residents. The effect of 15 mM KCl resembled that of 40 mM but did not achieve significance. Both 15 and 40 mM KCl evoked a $[\text{Ca}^{2+}]_i$ increase, which was antagonized by 10 μM nifedipine. Nifedipine not only

antagonized the effect on secretion and exocytosis but also on submembrane granule number and mobility. The mobility parameters of the comparatively few granules that underwent exocytosis were remarkable in that they combined very long total itineraries with short net itineraries, suggesting intensified mobility within a cage. None of the short term resident granules was found to fuse.

Conclusion: During KCl-depolarization L-type Ca^{2+} channels seem to regulate two separate processes, granule turnover in the submembrane space and the insulin granule release. In contrast to current models of granule transport, which are strictly sequential, the majority of insulin granules present in submembrane space may return to a more distant pool without undergoing exocytosis.

256

The influence of beta cell microfilaments on insulin secretion depends on the source of triggering calcium

N.I. Mourad, M. Nenquin, J.-C. Henquin;

Unit of Endocrinology and Metabolism, University of Louvain, Brussels, Belgium.

Background and aims: Glucose- or sulphonylurea-induced insulin secretion depends on depolarization-mediated influx of Ca^{2+} through voltage-dependent calcium channels (VDCC) in beta cells. The ensuing rise in the cytosolic concentration of ionized Ca^{2+} ($[\text{Ca}^{2+}]_i$) triggers exocytosis of insulin granules thought to be localized near the inner mouth of VDCC. Disruption of the sub-membrane web of actin microfilaments facilitates access of granules to these release sites. It is not known whether microfilaments also influence the size of granule pools that are released when triggering Ca^{2+} originates from intracellular stores or enters beta cells via routes other than VDCC. We addressed the question by using acetylcholine (ACh) to mobilize intracellular Ca^{2+} and promote capacitative Ca^{2+} influx via voltage-independent, store-operated channels that are activated by depletion of intracellular calcium stores.

Materials and methods: After 1–2 days of culture, normal mouse islets were treated with 1 μM /l latrunculin B to depolymerize or 1 μM /l jasplakinolide to polymerize beta cell microfilaments. They were then perfused to measure insulin secretion and $[\text{Ca}^{2+}]_i$ (fura-2 method). The proportion of globular/filamentous actin was measured biochemically.

Results: Filamentous actin (25% in control islets) was decreased to $\sim 5\%$ after latrunculin and increased to $\sim 95\%$ after jasplakinolide. In most experiments, islets were perfused with 10 mM/l glucose and 250 μM /l diazoxide (to hold beta cells hyperpolarized). ACh (100 μM /l) induced sharp and large peaks of $[\text{Ca}^{2+}]_i$ and insulin, followed by lower but sustained and reversible plateaus. Latrunculin did not affect $[\text{Ca}^{2+}]_i$ changes but doubled both phases of secretion. Jasplakinolide had little effect on first peak but suppressed second phase of ACh-induced secretion without attenuating the $[\text{Ca}^{2+}]_i$ signal. In Ca^{2+} -free medium, ACh induced rapid increases in $[\text{Ca}^{2+}]_i$ (mobilization from intracellular stores) and insulin secretion, but no sustained second phases. The $[\text{Ca}^{2+}]_i$ peak was slightly reduced by latrunculin and jasplakinolide, but only jasplakinolide decreased the insulin peak. After 30 min in absence of Ca^{2+} , reintroduction of CaCl_2 , in the presence of methoxyverapamil (a blocker of VDCC), was followed by an increase in islet $[\text{Ca}^{2+}]_i$ that was larger after pretreatment with ACh (indicative of capacitative Ca^{2+} entry) and unaffected by latrunculin or jasplakinolide. Insulin secretion also occurred, and was augmented 2x by latrunculin and diminished 2x by jasplakinolide as compared with controls. In other experiments Ca^{2+} entry through VDCC was induced by depolarization with KCl or tolbutamide. The ensuing increase in $[\text{Ca}^{2+}]_i$ was unaffected by latrunculin B or jasplakinolide treatment, but the resulting secretion of insulin was augmented by both agents.

Conclusion: The influence of beta cell actin microfilaments on insulin secretion differs with the source of triggering Ca^{2+} . Both disruption and stabilization increase the secretory response to Ca^{2+} entering via VDCC, whereas the response to intracellular Ca^{2+} mobilization is augmented only by microfilament disruption. Insulin secretion induced by capacitative Ca^{2+} entry is augmented by microfilament disruption and inhibited by microfilament stabilization. The results therefore suggest that distinct pools of insulin granules are implicated in response to Ca^{2+} from different sources.

Implementation of integrated diabetes care in a diabetes care system for type 2 diabetes patients in primary care: an evaluation of resource use and costs

J.M. Dekker¹, A.A.W. van der Heijden¹, M.C. de Bruijne¹, T.L. Feenstra², C.A. Baan², S.D.M. Bot¹, G.A. Donker², I. Rootjes⁴, P. Kaiser⁴, G. Nijpels¹;

¹The EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, ²National Institute for Public Health and the Environment (RIVM), Bilthoven, ³Netherlands Institute for Health Services (NIVEL), Utrecht, ⁴Univé insurance, Alkmaar, Netherlands.

Background and aims: Diabetes is associated with a high impact on health care use and costs. A strategy to improve the quality of care, manage the increasing demand for care and control the costs of care is the implementation of integrated diabetes care. Studies evaluating the effects and costs of integrated diabetes care have shown inconsistent results. In most studies a control group or information on costs on the societal perspective is missing. We evaluated care and costs on the societal perspective of integrated diabetes care compared with usual diabetes care for type 2 diabetes patients.

Materials and methods: Patients treated by the Diabetes Care System (DCS) receive integrated diabetes care. The DCS coordinates the care between involved health care professionals. Patients have a central role in the care and were stimulated to make their own choices regarding treatment and lifestyle behaviour. Diabetes nurses visit participating general practitioners to give feedback on patient and population level. A random sample of 253 diabetes patients, who were treated by the DCS were compared with 414 diabetes patients who received usual care according to current diabetes guidelines, generally organized in a single general practice. Patients reported received screenings and assessments and which health care professionals they had visited during the last year. Regression analysis was performed, estimating differences in costs between the DCS and usual care. Because of the skewed distribution of costs, we used bootstrapping methods (5000 replications) to estimate 95% confidence intervals (CI's) around the differences in costs. To take into account the (nonlinear) effect of diabetes duration on costs, we stratified for diabetes duration (1–2, 3–5 and ≥ 6 years).

Results: A higher proportion of DCS patients received medical examinations according to current diabetes guidelines (e.g. foot screening: 98.4% vs. 81.5%, $p < 0.001$). Compared to usual care patients treated by the DCS had fewer consultations with specialists in secondary care. Direct costs were lower in the DCS compared to usual care, in patients with diabetes duration of 3 to 5 years (Euro: -261 (95% Confidence Interval (CI): -617 to 96)), and with diabetes duration of more than 5 years (Euro: -671 (95% CI: -1187 to -154)), but equal in patients with duration < 3 years. (Euro: 7 (95% CI: -125 to 121)) (Table).

Conclusion: The Diabetes Care System is associated with better diabetes care as well as lower health care costs.

Mean (SD) costs during three months according to diabetes care group		
	Integrated care	Usual care
Diabetes duration 1–2 years	n=60	n=67
Direct costs	250 (323)	249 (303)
Total costs	926 (3092)	372 (584)
Diabetes duration 3–5 years	n=65	n=113
Direct costs	257 (249)	538 (2072)
Total costs	510 (856)	888 (2561)
Diabetes duration > 5 years	n=128	n=234
Direct costs	363 (814)*	1037 (3867)
Total costs	529 (1087)*	1351 (4275)

Direct costs: costs of visits to health care professionals, laboratory tests, use of home care, hospitalizations and costs of integrated care

Total costs: direct costs and costs related to productivity loss

* Indicates a significant difference (< 0.05) between integrated care and usual care after adjustment for age, sex, educational level and work status.

Clinical Trial Registration Number: ISRCTN 66124817

Impact of the secondary diagnosis of diabetes in inpatient outcomes: areas of strategic intervention

J. Quevedo Juanals¹, F.J. Morado Xumet², J. Olivares Alcolea¹, J. Nicolau Ramis¹, I. Rodríguez Rodríguez¹, A. Gómez Gómez¹, A. Gil Palmer¹, R. Rivera Irigoin¹, C. Francés Artigas¹, V. Juan Verger³, L. Alegre Latorre³, L. Masmiel Comas¹;

¹Endocrinology and Nutrition, Hospital Son Llàtzer, ²Documentation and coding, Hospital Son Llàtzer, ³Management, Hospital Son Llàtzer, Palma, Spain.

Background and aims: Hyperglycemia in hospitalized patients is an indicator of poor outcome, increased length of stay (LOS) and cost. On this regard, more knowledge is necessary in order to identify strategic areas of intervention.

Materials and methods: 62,055 admissions of a tertiary care center were studied with discharge summaries analysis software (Clínical*). Patients with the secondary diagnosis of diabetes (SDD) identified by Diagnostic Related Groups (DRG) in the Minimum Basic Set of Data (MBSDD) were compared with those without it. Variables considered were age, LOS, complexity (DRG weight), number of diagnostics and procedures per admission, major diagnostic category (MDC), unit of admission, rate of complications, readmission rate, patient safety indicators (PSI), and mortality. Obstetrics, Pediatrics and Diabetes departments were excluded.

Results: Diabetes was identified in 21% of episodes (12,751). Higher age (71 vs 59 years) and LOS (8.7 vs 7.3 days) were observed in patients with SDD. More difference in LOS was detected in the range between 26 and 65 years old. No differences in LOS were shown in older than 65yo. SDD was related to a greater DRG weight (1.95 vs 1.81), number of diagnostics (8.29 vs 5.78) and procedures (5.18 vs 4.77). 7 MDC accounted for 84% of the diabetic cases (44% were gathered in circulatory and respiratory system, 40% were distributed into gastrointestinal, kidney-urinary tract, hepatobiliary-pancreatic system, nervous system and musculoskeletal system). Only differences in surgical complications were observed (3.34% vs 2.83%). Readmissions were higher among diabetics (11.67% vs 8.24%). Regarding PSI; pressure ulcers (5.97_{0/00} vs 3.56_{0/00}), death in low mortality DRG (Dlm-DRG) (9.46_{0/00} vs 2.13_{0/00}), post-operative bleeding and hematomas (2.39_{0/00} vs 1.09_{0/00}) and postoperative pulmonary embolism or deep vein thrombosis (DVT) (4.43_{0/00} vs 2.69_{0/00}) were more frequent in diabetics. No differences in global mortality were observed. Major differences in LOS were observed in the following GRDs: hip joint replacement, bronchitis and asthma, urethral and transurethral procedures, other respiratory diagnoses with complications, acute myocardial infarction, hip and femur procedures excluding joint replacement, pulmonary edema and respiratory failure, and kidney-urinary tract infections. Surgical complications were more prevalent in Hematology, Oncology, Otolaryngology, Orthopedics, Urology and Ophthalmology units.

Conclusion: Diabetic patients have higher LOS, complexity of acute hospitalization episodes, number of procedures, surgical complications and readmissions. Furthermore, diabetes is associated to a higher percentage of PSI. According to our results, areas of strategic intervention would be Cardiology, Orthopedics, Urology and Respiratory units. Furthermore, surgical diabetic patients with hematologic and oncologic conditions should also deserve special attention. Also, a special consideration to Dlm-DRGs is warranted. Finally, pressure ulcers, DTV and bleeding prevention programs should consider diabetes as a risk factor.

259

Duration of time off paid employment for conditions commonly associated with diabetes-related complications

A. Beaudet¹, K.-J. Myren², D. Grant³, A. Lloyd³;

¹IMS Health, Basel, Switzerland, ²IMS Health, Stockholm, Sweden, ³IMS Health, London, UK.

Background and aims: Diabetes mellitus (DM) is associated with a high and growing burden on health care systems and society. Days of paid work missed due to complications are part of the economic burden of DM. A study was undertaken to elicit time off work associated with DM-related complications in the working population in Sweden.

Materials and methods: The study utilised the STORE database which is maintained by the Swedish Social Insurance Agency and records all claims for sick pay in Sweden. Sick pay may be claimed for sick periods lasting 14 days or longer including prevention, extended and continued sickness ben-

efit, rehabilitation and sickness due to work injury. We extracted episodes of sickness completed over a 12-month period between 1 October 2009 and 30 September 2010 for 16 conditions which are commonly associated with DM-related complications. Conditions were identified by 3 digit ICD-10 code. We extracted sick time (calendar days between the start and end of sick period) for all cases meeting our criteria and calculated mean, median and standard deviation of the number of sick days per episode for each condition.

Results: The most common conditions were related to coronary heart disease (AMI, angina heart failure) and to cerebrovascular accident (stroke events and post-stroke).

Estimated sick leave duration per DM-related condition

Condition (ICD-10)	Number of episodes (*, <10)	Duration of sick leave in calendar days		
		Mean	SD	Median
Post stroke	454	618	477	556
Renal dialysis	14	564	528	514
Renal transplant	330	461	510	252
Stroke event	2,514	403	419	233
Peripheral vascular disease	110	364	434	160
Heart failure	670	296	358	149
Severe vision loss	68	281	337	124
Cataract	*	266	349	266
Neuropathy / Amputation	14	231	441	59
Foot ulcer	136	183	271	67
Gangrene	*	182	241	75
Angina	1,120	159	290	62
Myocardial infarction	2,463	93	189	45
Metabolic acidosis event	22	75	136	28
Major hypoglycemia event	*	37	18	40

Conclusion: Data from Swedish Social Insurance Agency show that work loss due to major events associated with DM is frequent and extended. These estimates may underestimate burden in people with DM as the database does not collect absences of less than 14 days, also data are not limited to people with DM, and need to be adjusted for workforce participation. These new data will permit healthcare payers and decision makers to estimate with greater precision the impact of diabetes interventions on productivity loss.

260

Comparative US claims data in type 2 diabetes mellitus patients who have undergone bariatric procedures

M.G. Oefelein¹, J. Lebowitz^{2,3}, S. Burgess³, T. Okerson^{1,4};

¹Medical Affairs, Allergan, Inc, Irvine, ²School of Pharmacy, University of Southern California, Los Angeles, ³Global Health Outcomes Strategy and Research, Allergan, Inc, Irvine, ⁴Internal Medicine, University of California Irvine, Orange, USA.

Background and aims: Earlier this year, the use of bariatric surgery as a weight loss and treatment option for obese patients with type 2 diabetes (T2D) was the subject of a position paper by the International Diabetes Federation. To help inform patients and providers of potential costs in patients with T2D, we conducted a longitudinal study in the United States to measure the intermediate-term health care consumption and costs associated with a restrictive out-patient procedure, laparoscopic adjustable gastric banding (LAGB), and malabsorptive surgery, Roux-en-Y bypass (RYGB). For these patients, medical and prescription claims may serve as proxy measures to disease state severity.

Materials and methods: Utilizing Source® Lx integrated claims repository data from 2002-09, physician practice, pharmacy, and hospital claims identified RYGB and LAGB patients by CPT or ICD-9 code. Patients were screened for T2D using ICD-9 code and evaluated up to 4 years(yr) before and after their surgical procedure. Care consumption was analyzed across prescription claims, physician office visits, and hospital visits. Costs of care were measured through out-of-pocket prescription expenses and total cost, submitted physician office and hospital charges, and total healthcare charges.

Results: All subjects experienced a similar increase in metrics of care consumption from 4 years pre-procedure up to date of the procedure. However,

in the years following surgery, differences were observed in health care consumption and costs between RYGB and LAGB:

Avg. Per Patient Utilization or Cost	1 yr pre-op (baseline (BL))		1 yr post-op		4 yr post-op			
	RYGB	LAGB	RYGB	LAGB	RYGB		LAGB	
					Value	Δ from BL	Value	Δ from BL
# T2D	2.23	2.14	1.67	1.53	1.64	-26%	1.58	-26%
Medications						p=.0001		P=.017
T2D Rx	10.7	9.5	5.2	4.3	6.5	-39%	4.0	-58%
Claims						p=.0001		p=.0001
Rx Claims	28	21	19	16	20	-30%	13	-46%
(total cost USD)	(2200)	(2280)	(1530)	(1730)	(1540)	p=.0001	(1230)	p=.0038
Office Visits	10	8.5	8	8	6	-4%	4	-54%
(charges USD)	(2590)	(2110)	(1790)	(1770)	(2480)	p=.72	(970)	p=.0001
Hospital Visits	5.1	4.8	6.3	5.1	5.8	+81%	3.6	+3%
(total charges USD)	(7963)	(8165)	(9934)	(8862)	(14435)	p=.0001	(8448)	p=.91
Total Healthcare charges (USD)	7743	7630	7245	4833	9254	+20%	4288	-44%
						p=.31		p=.001

Conclusion: These data demonstrate that both surgical procedures are similarly effective at reducing both care consumption and cost in T2D patients in the short-term. Of note, longer-term costs then increased in patients undergoing RYGB, driven by increased hospital cost. In contrast, patients with LAGB had a continued reduction in health care cost and utilization. It is hypothesized that the increased 4 year costs of RYGB are related to surgical complications and to morbidity caused by malabsorption of various micro-nutrients. These differences suggest the need for additional study.

Efficacy and safety of continuous glucose monitoring systems vs self-monitoring blood glucose in patients with type 1 diabetes mellitus: a systematic review and meta-analysis

P. Rys¹, A. Mucha¹, M. Koprowski¹, M. Nowicki², M.T. Malecki³;

¹HTA Consulting, Krakow, ²Medtronic, Warsaw, ³Department of Metabolic Diseases, Jagiellonian University, Krakow, Poland.

Background and aims: There is an ongoing debate concerning the role of continuous glucose monitoring (CGM) systems in diabetes care. Several studies regarding the efficacy and safety of CGM have recently been published, so there is a great need to summarize their results in a comprehensive way. We performed a systematic review and meta-analysis to evaluate the effect of CGM on glycaemic outcomes as compared with self-monitoring of blood glucose (SMBG) with conventional glucometer readings in type 1 diabetes mellitus (T1DM).

Materials and methods: The assessment was based on randomized controlled trials (RCTs) identified by means of a systematic literature search in medical databases (Medline, EMBASE, Cochrane Library and others) up to January 2010. Studies met the inclusion criteria if they compared CGM vs. SMBG in T1DM patients on an intensive insulin regimen (continuous subcutaneous insulin infusion or multiple daily injections). It was required that the same regimen be used in both arms. Weighted mean difference (WMD), standardized mean difference (SMD) or odds ratio (OR) were calculated with a 95% confidence interval. Subgroup analysis was also performed regarding patient age (children, adolescent, adults), glycaemic control (measured by mean HbA_{1c} at baseline), type of CGM system.

Results: We identified 13 trials including together 1125 patients followed for at least 3 months. A meta-analysis of 9 RCTs demonstrated lower glycated hemoglobin (HbA_{1c}) level at the end of follow up in the CGM group compared with the SMBG one (WMD = -0.31 [-0.50; -0.12]). Pooled data of 13 RCTs showed greater HbA_{1c} change from baseline in favor of CGM (WMD = -0.26 [-0.34; -0.18]) and these results were consistent across most analyzed subgroups. Moreover, in the CGM group, a higher percentage of patients achieved predefined target HbA_{1c} (29% vs. 16%; OR = 2.13 [1.39; 3.26]) as well as HbA_{1c} reduction by at least 10% (22% vs. 9%; OR = 2.95 [1.53; 5.71]). It was also shown that incidence of any hypoglycaemic episodes was lower in the CGM group than in the SMBG one (SMD = -0.33 [-0.56; -0.10]). No differences between CGM and SMBG were revealed with respect to the percentage of patients with severe hypoglycemia or duration of hyperglycemic episodes (>180 mg/dL) or hypoglycaemic incidents. The safety analysis showed that CGM was well tolerated. Reported adverse events (AEs) included adverse reactions at the sensor implantation site (tenderness, redness). No severe AEs were observed.

Conclusion: The use of CGM may contribute to the improvement of glycaemic control and reduction of incidence of hypoglycaemic episodes in T1DM. Supported by: Medtronic Poland

Efficacy of a bi-hormonal closed loop system to control postprandial and post exercise glucose excursions

A.C. van Bon¹, L.D. Jonker¹, R. Koops², J.B.L. Hoekstra¹, J.H. DeVries¹;

¹Academic Medical Center Amsterdam, ²Inreda, Goor, Netherlands.

Background and aim: Continuous Subcutaneous Insulin Infusion (CSII) and Continuous Glucose Monitoring (CGM) sensors combined with an insulin and optionally a glucagon delivery algorithm constitute a closed loop system or artificial pancreas. The aim of this pilot study was to test the efficacy of a bihormonal closed loop system compared to CSII, challenging the system with two meals and an exercise bout. To our knowledge, this is the first report on exercise as a challenge for a closed loop system.

Materials and methods: Ten subjects with type 1 diabetes treated with CSII underwent a standardized day on three different occasions: a 40 grams carbohydrate breakfast was followed two hours later by 30 minutes of moderate exercise at 75–80% intensity of the heart rate reserve and one and a half hours later by a standardized 60 grams carbohydrate lunch. The first day served as control with open loop control, the second day as learning experiment for the algorithm to set individual patient parameters and the third day to compare the closed loop to the control day. Venous glucose was measured as refer-

ence every 30 minutes until 4 hours after lunch. In case of hypoglycaemia < 3.5 mmol/l the system recommended food intake. The closed-loop system consisted of two Medtronic CGM's (one primary and one back-up in case of failure of the first sensor) and two D-Tron+ pumps (Disetronic Medical Systems) for subcutaneous insulin and glucagon administration, all connected to a personal computer.

Results: Eight subjects were included, 6 were male. Mean (SD) age was 55.8 (10.0) years, mean HbA_{1c} 7.7 (0.9) %, mean duration of diabetes 33.8 (11.2) years and mean duration of pump use 9.5 (3.5) years. No significant differences in mean (minimum - maximum) venous glucose concentrations were seen; 8.5 mmol/l (5.4 - 11.7) in open loop compared to 8.2 mmol/l (6.3 - 9.4) in closed loop, $p = 0.76$. The median (minimum - maximum) AUC of the sensor glucose concentration in open loop was 3,973.8 mmol/l*minutes (2,669 - 5,253.2) compared to 4,300.3 mmol/l*minutes (356.2-4,867.8) in closed loop, $p = 0.78$. No differences in mean (minimum and maximum) insulin dosages were seen: open loop 23 (10.9 - 45) IU insulin, closed loop 30.6 (12 - 60.3) IU insulin, $p = 0.08$. On the control day the system advised food intake on two occasions, compared to four times on the intervention day, three of which in the post-exercise period.

Conclusion: Closed-loop glucose control was comparable to open loop glucose control with CSII. Hypoglycaemia was infrequent, but it was numerically more often in closed loop, despite glucagon use. Exercise is an important challenge for closed loop control.

263

Microcirculation and its relation with continuous subcutaneous glucose sensor accuracy in cardiac surgery patients in the intensive care unit

S.E. Siegelar¹, T. Barwari¹, J. Hermanides¹, P.H.J. van der Voort²,

J.B.L. Hoekstra¹, J.H. DeVries¹;

¹Internal Medicine, Academic Medical Centre, ²Intensive Care, Onze Lieve Vrouwe Gasthuis, Amsterdam, Netherlands.

Background and aims: Glucose regulation is important in critically ill patients following cardiac surgery. Continuous subcutaneous glucose monitoring (CGM) could help achieving glucose targets and preventing hypoglycemia. However, the accuracy of the systems is uncertain in these patients. We hypothesized that CGM accuracy is influenced by microcirculatory variables. Therefore, we investigated the microcirculation and its relation with accuracy of two CGM devices in patients after cardiac surgery.

Materials and methods: We performed a prospective, observational study in a 20-bed intensive care unit (ICU). We included 60 patients who were about to undergo cardiac surgery. Two CGM devices (Guardian Real-Time, Medtronic Minimed; FreeStyle Navigator, Abbott Diabetes Care) were placed subcutaneously in the abdominal wall before surgery. Relative absolute deviation (RAD) between sensor and arterial reference glucose was calculated to assess CGM accuracy every two hours. Microcirculation was measured by microvascular flow index (MFI), perfused vessel density (PVD) and proportion of perfused vessels (PPV) using sublingual sidestream dark-field (SDF) imaging, and tissue oxygenation (StO₂) obtained with near-infrared spectroscopy. Associations were assessed by a linear mixed-effects model for repeated measures.

Results: Thirty-two patients underwent only a CABG procedure. Median (IQR) APACHE IV PM was 0.01 (0.003-0.02). Median (IQR) RAD was 11% (8-16) for the Navigator and 14% (11-18) for the Guardian ($p = 0.05$). StO₂ significantly increased during ICU admission (maximum 91.2% [3.9] after 6 hours) and decreased thereafter, stabilizing after 20 hours. The increase in StO₂ was accompanied by a decrease in PVD. MFI and PPV did not show a time effect (median [IQR] MFI 2.8 [2.7-2.9], PPV 0.97 [0.96-0.99]). Microcirculatory parameters were not associated with sensor accuracy. For the Navigator lower peripheral temperature ($b = -0.008$, $SE = 0.003$, $p = 0.003$), higher APACHE IV PM ($b = 0.017$, $SE = 0.004$, $p < 0.001$) and higher age ($b = 0.002$, $SE = 0.001$, $p = 0.037$) and for the Guardian lower peripheral temperature ($b = -0.006$, $SE = 0.003$, $p = 0.048$) were significantly associated with decreased sensor accuracy.

Conclusion: This study showed that microcirculation was impaired in patients after cardiac surgery during the first hours of ICU admission, determined by a decrease in PVD and an increase in StO₂, but to a limited extent only compared with septic patients and healthy controls. None of the microcirculatory parameters showed a relationship with continuous glucose sensor accuracy. Parameters that were associated with worse sensor accuracy were lower peripheral temperature (both sensors) and higher APACHE IV PM or higher age (Navigator). These results support CGM use in cardiac surgery patients characterized by low severity of illness. Further studies need to as-

sess the influence of microcirculatory changes on sensor accuracy in more severely ill, e.g. septic, patients.

A wireless, fully implantable continuous glucose sensor

A.D. DeHennis, A. Modzelewska, B. Pearsall, C. Lorenz, C. Mdingi, H. Jiang, J. Lawrence, M. Mortellaro, O. Tymchyshyn, P. Huffstetler, S. Tankiewicz, T. Maiorana, X. Wang, S. Walters, A. Colvin;
Sensors for Medicine and Science, Inc., Germantown, MD, USA.

Background and aims: This sensor system implements a proprietary fluorescent transducer, optical sensor readout, and a wireless telemetry interface to enable a continuous glucose monitoring platform. The sensor part of this system is implanted into the subcutaneous space in the wrist and remotely powered through a wristwatch-based reader system. The glucose sensitive fluorescent indicator is excited with the embedded LED and then transduced through the filtered on-board photodiodes, which segments the various wavelengths of the fluorescence into signal and reference channel spectra. The sensor merges the optical signals with temperature transduction upon query from reader system, which externally provides power to the sensor during interrogation. A fully customized ASIC has been developed to merge this functionality into a multichip module that is the size of a swollen grain of rice and uses an on-site antenna that is loosely coupled to the reader of the external reader system. Overall, this sensor platform aims to provide high resolution, analytical glucose data that is transmitted wirelessly through the skin.

Materials and methods: The in-vitro testing of this sensor platform characterized the transducers baseline fluorescence, temperature sensitivity, dissociation constant, and transient response time to step changes in glucose. Part of the clinical investigations done with this platform includes long term implantation of the sensor system in primates with bi-weekly glucose clamp sessions and YSI blood samples drawn every 5 minutes.

Results: The overall function of the sensor system has proven to show continuous and automated tracking of ISF glucose through the wireless, passive telemetry interface. Watch-to-sensor communication and the implemented optical interface electronics designed into the ASIC have demonstrated a stable platform for wireless interrogation through the dermis. The transduction performance of this sensor platform shows an in-vitro sensor response time (t_{90}) of less than five minutes with a glucose dissociation constant of ~ 400 mg/dL, which provides an optimized accuracy range for detecting hypoglycaemia and hyperglycaemia events. The data acquired in monkey testing shows a high level of glucose accuracy, with a MARD of less than 7% for more than 2500 data points. A Clark Error Grid analysis of glucose excursions ranging between 40–340 mg/dL shows 94.4% and 5.6% of the data in the A and B regions, respectively. The pre-clinical sensor performance also supports the goals for this system in achieving implant times greater than six months.

Conclusion: This platform has been developed to provide transcutaneous communication and power delivery to an implanted fluorescent glucose sensor. The implanted performance has shown a high degree of glucose accuracy throughout primate pre-clinical studies and is currently moving into initial human clinical trials.

Factors associated with early versus late conversion to diabetes in community dwelling Danes

S.B. Haugaard^{1,2}, T.W. Hansen³, S. Madsbad¹, A. Linneberg⁴, M.H. Olsen⁵, T. Jørgensen⁴, K. Borch-Johnsen⁶, J. Jeppesen⁵;

¹Dept. of Endocrinology and Clinical Research Centre, Copenhagen University Hospital, Hvidovre, ²Dept. Internal Medicine, Copenhagen University Hospital, Amager, ³Dept. of Clinical Physiology, Copenhagen University Hospital, Rigshospitalet, ⁴Research Centre for Prevention and Health, Copenhagen University Hospital, Glostrup, ⁵Dept. of Medicine, Copenhagen University Hospital, Glostrup, ⁶Research Centre for Quality in Health Care, Institute of Public Health, University of Southern Denmark, Odense, Denmark.

Background and aims: The Danish National Diabetes Register (DNDR) enables sensitive and specific identification of new-onset diabetes by combining national registers. The aim was to evaluate factors associated with late versus early conversion to diabetes in community dwelling subjects.

Materials and methods: It has been shown that DNDR detects three times as many new-onset diabetes cases as do the ICD (International Classification of Diseases) system during a follow-up of median 13.8 years in the MONICA10 cohort (MONitoring trends and determinants of Cardiovascular disease) of 41 to 71 years old non-diabetic Danes. Out of a total of 2493 non-diabetic subjects in the MONICA10 cohort 186 were identified as new-onset diabetes during the follow-up period. Arbitrarily, early converters to diabetes were defined as those subjects converting within 8 years from baseline measurements.

Results: Early ($n=79$) versus late ($n=107$) converters displayed similar distribution of age, sex, body mass, waist circumference, physical activity, alcohol consumption, markers of low-grade inflammation (CRP and soluble UPAR), triglyceride, fasting insulin and markers of early organ damage as carotid plaques, aortic pulse wave velocity and urine albumin creatinine ratio. But early conversion to diabetes associated with a small increase in fasting plasma glucose (5.5 mmol/L vs. 5.2, $P<0.05$) and a diagnosis of hypertension (68% vs. 51, $P<0.05$) and inversely to smoking habits (current smoking, 34% vs. 50, $P<0.05$).

Conclusion: Minor increase in plasma glucose and hypertension but not measures of dyslipidemia, current smoking, early cardiovascular organ damage, low-grade inflammation or physical inactivity differentiated those prediabetic subjects who converted early versus late to diabetes. Intervention studies should evaluate the effect of addressing fasting glucose and blood pressure to postpone or prevent development of diabetes.

The Leicester Practice Computer Risk Score - an automated tool for identifying those with impaired glucose regulation or type 2 diabetes mellitus using the new diagnostic criteria

L.J. Gray¹, M. Davies², D.R. Webb², N.A. Taub¹, K. Khunti¹;

¹Department of Health Sciences, University of Leicester, UK, ²Department of Cardiovascular Sciences, University of Leicester, UK.

Background and aims: Modelling studies have suggested that early detection of impaired glucose regulation (IGR) and appropriate intervention can decrease morbidity and early mortality from cardiovascular disease. Risk scores utilising routinely collected data can identify those at high risk for further diagnostic testing. To date no automated risk scores have been developed and validated for using the new World Health Organization (WHO) 2011 diagnostic criteria for type 2 diabetes mellitus (T2DM).

Materials and methods: We used data on 6,390 subjects aged 40–75 from the ADDITION-Leicester (UK) screening study from a multi ethnic setting. All participants were given a 75g Oral Glucose Tolerance Test (OGTT). We developed logistic regression models for predicting IGR (impaired fasting glucose/impaired glucose tolerance/T2DM diagnosed according to the OGTT or HbA1c ≥ 6.5) from covariates which are routinely stored electronically in primary care. Using the best fitting model we developed the Leicester Practice Computer Risk Score by summing the beta coefficients. We externally validated the tool using data from 3,225 subjects aged 40–75 screened as part of a

second screening study. For both datasets the sensitivity, specificity, and positive and negative predictive values were calculated for cut points on the score for identifying the top deciles of risk. The discrimination was assessed using the area under the receiver operating characteristic (ROC) curve. Calibration was assessed using the Hosmer and Lemeshow (HL) statistic.

Results: The final model has an area under the ROC curve of 70.2% (95% CI 68.5–71.9%) and includes age, ethnicity (White European versus other - predominantly South Asian), sex, family history of T2DM, prescribed antihypertensive therapy and body mass index. There were no statistically significant two-way interactions. Polynomial terms were considered for age and BMI but this did not improve the fit of the model. This model gave good agreement between the observed and predicted estimates (HL 3.62, $p=0.89$). In the test data set using a cut-point which identifies the top 25% at risk identified 421 out of 774 who had IGR/T2DM and gave a sensitivity of 54.4% (95% CI 50.8–57.9%), specificity 72.8% (95% CI 71.0–74.5%), positive predictive value 38.7% (95% CI 35.8–41.7%), and negative predictive value 83.5% (95% CI 81.8–85.0%). This cut point can also be used to rule out T2DM alone, negative predictive value 92.4% (95% CI 91.2–93.5%), sensitivity 55.9% (95% CI 50.6–61.0%), specificity 69.1% (95% CI 67.4–70.8%), and positive predictive value 18.8% (95% CI 16.6–21.3%).

Conclusion: The Leicester Practice Computer Risk Score can be used to reliably identify those at high risk of IGR in multi ethnic populations. This is the first automated risk score based on the 2011 updated WHO diagnostic criteria for T2DM.

Leicester Practice Computer Risk Score =

0.040557 * age in years
+ 0.183559 if male, 0 otherwise
+ 0.081417 * BMI (kg/m²)
+ 0.753563 if South Asian, 0 otherwise
+ 0.536155 if prescribed antihypertensives, 0 otherwise
+ 0.468519 if family history of diabetes, 0 otherwise

Protein peak information improves the prediction of type 2 diabetes: the Whitehall II study

D. Vistisen¹, T. Mygind Jensen¹, D. Pieragostino^{2,3}, J.N. McGuire⁴, E.D. Schjerving⁴, C. Nardi³, A. Urbani^{3,5}, M. Kivimäki⁶, E.J. Brunner⁶, A.G. Tabák^{6,7}, D.R. Witte¹;

¹Steno Diabetes Center A/S, Gentofte, Denmark, ²Centre of Investigation on Ageing (Ce.S.I.), Chieti-Pescara, Italy, ³IRCCS-Santa Lucia Foundation, Rome, Italy, ⁴Hagedorn Research Institute, Gentofte, Denmark, ⁵Department of Internal Medicine, University Tor Vergata, Rome, Italy, ⁶Department of Epidemiology, University College London, UK, ⁷Semmelweis University Faculty of Medicine, Budapest, Hungary.

Background and aims: Improving prediction of type 2 diabetes (T2DM) is essential for refining diabetes prevention strategies. A number of protein biomarkers have recently been suggested to predict T2DM and advances in mass spectrometric methods now allow for the quantitative study across the entire human proteome. We examined whether information on protein peak signals improved prediction of incident T2DM beyond established lifestyle and biochemical risk factors for T2DM.

Materials and methods: The analysis is based on serum samples from 329 of the 560 participants in a nested case-control study within the Whitehall II cohort. Participants were free of diabetes at baseline (1991–1994). The 111 cases developed T2DM during the 16 year follow-up period. The 218 controls were frequency-matched for age, sex, and BMI. Diabetes was defined by the OGTT. Data on 364 protein peaks were acquired by linear matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) in the 1–20 kDa range. The 70 peaks present in at least 5% of the participants were analyzed together with 33 known risk factors for T2DM including age, sex, obesity measures, employment grade, smoking status, physical activity, alcohol intake, family history of diabetes, use of anti-hypertensive or lipid-lowering medication, blood pressure, lipid profile, apolipoproteins and inflammatory markers. Two prediction models for incident T2DM were derived. Model 1: the 33 known risk factors for T2DM were ranked using random forest analysis and the 10 most informative factors were selected for further analysis. A classification tree for incident T2DM was derived based on these 10 factors. Model 2: the 70 peaks were ranked according to their

added discriminatory value to the first model using random forest analysis. A second classification tree was derived based on the first model and the 10 most informative peaks from the random forest analysis. Model performance with and without peaks was evaluated and compared using receiver operating characteristics (ROC) analysis and integrated discrimination improvement (IDI).

Results: The first model included systolic blood pressure, triglycerides and family history of diabetes. The model with protein peak data additionally included two of the 10 protein peaks and this increased the area under the ROC curve (AUC) by 8% ($p<0.01$) and IDI by 63%.

Conclusion: Information on protein peak signals improves prediction of incident T2DM beyond established lifestyle and biochemical risk factors.

AUC with 95% confidence interval (CI) and IDI

	AUC (95%-CI)	P-value for increase in AUC	Relative IDI
Model 1	0.67 (0.61;0.73)	reference	reference
Model 2	0.73 (0.67;0.78)	0.003	63%

IDI: integrated discrimination improvement

Model 1: systolic blood pressure, triglycerides and family history of diabetes

Model 2: model 1 and two protein peaks

Long-term risk of type 2 diabetes and measures of overall and regional obesity: the European InterAct study

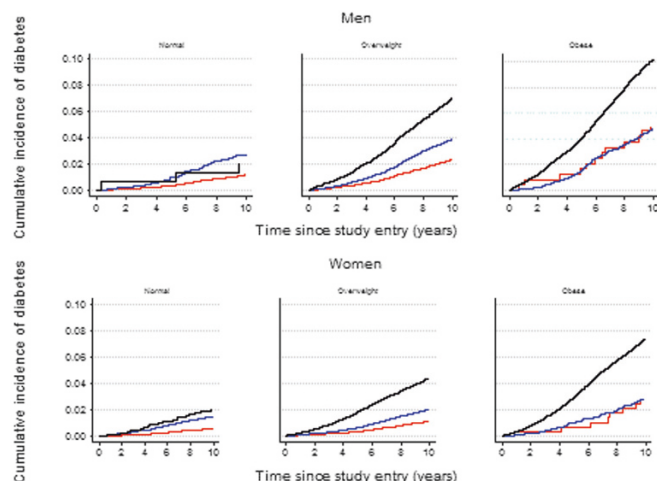

C. Langenberg, S.J. Sharp, N.J. Wareham, InterAct Consortium; MRC Epidemiology Unit, Cambridge, UK.

Background and aims: Individual lifestyle interventions can reduce diabetes risk, but need to target those at highest risk. Current clinical practice relies on measurement of body-mass index (BMI), but waist circumference (WC) provides a simple and reliable measure of fat distribution that may add to diabetes risk prediction. Previous studies have not been powered to precisely estimate the absolute risk of diabetes to identify population subgroups in whom measurement of waist circumference would be most informative. We assess the clinical usefulness of measuring WC in normal weight, overweight and obese individuals.

Materials and methods: The InterAct case-cohort study was conducted in 26 centres in 8 European countries and consists of 12,403 incident T2D cases and a stratified subcohort of 16,154 individuals identified amongst 340,234 EPIC participants followed-up for 3.99 million person-years. Hazard ratios for T2D were estimated using Prentice-weighted Cox-regression and random effects meta-analyses. Cumulative incidences were estimated using Kaplan-Meier methods.

Results: BMI and WC were independently associated with T2D. The cumulative 10-year T2D incidence (figure 1) in normal weight men and women was $\leq 2.7\%$ and 2.0% , irrespective of their WC. In overweight individuals, WC distinguished those with incidence rates comparable to normal weight from those with rates equivalent to obese individuals. The cumulative 10-year incidence for men with normal, moderately increased, or large WC was 2.3% , 3.9% and 7.0% in overweight and 5.0% , 4.8% and 10.2% in obese men, respectively. Corresponding figures were 1.1% , 2.0% and 4.4% in overweight and 2.8% , 2.7% and 7.4% in obese women.

Conclusion: A substantial proportion of overweight individuals with a large WC will develop T2D over a 10-year period. Current recommendations should target this group, whose risk is comparable to obese individuals and who may benefit from early lifestyle intervention. Measurement of WC can guide clinical decision making in overweight individuals. Figure 1. Cumulative incidence of T2D over 10 years by sex, BMI and waist groups.

Risk of diabetes and cardiovascular events in persons with early glucose metabolism impairments

I.V. Misnikova, A.V. Dreval, I.A. Barsukov, T.G. Dzebisashvili; Endocrinology, Moscow Regional Research Clinical Institute, Russian Federation.

Background and aims: Russia ranks fourth with regards to number of patients with diabetes (by IDF data) and prevalence reaches 9%. Aim is to assess relative risk (RR) of type 2 diabetes (T2DM), overall and acute cardiovascular mortality and cardiovascular events in persons with impaired fasting glucose (IFG) and impaired glucose tolerance (IGT).

Materials and methods: According to population based study among 2508 adults, the 3-year risk of T2DM, overall and acute cardiovascular mortality and cardiovascular events (fatal and nonfatal myocardial infarction and stroke, coronary heart disease) was estimated in people with glucose metabolism abnormalities (GMA): IFG, IGT, IFG+IGT diagnosed in 2006 in comparison with normal glucose tolerance. RR and regression coefficient (B) was calculated using Cox-regression analysis. RR of T2DM, cardiovascular events was adjusted for age, sex, BMI, systolic blood pressure (SBP), smoking.

Results: Prevalence of GMA was 24.9%, including IFG (8.8%), IGT (5.1%), IFG+IGT (3.8%) and first time diagnosed T2DM (7.2%). In 3 years highest percent of transformation to T2DM and adjusted RR of T2DM were in people with IFG+IGT (33.3% and 11.2[3.93–31.65], $p < 0.01$, correspondingly). The lowest percent of transformation to T2D and RR of T2DM were in people with isolated IGT (10.3% and 3.92 [1.11–13.90], $p = 0.034$). Adjusted RR of cardiovascular mortality was significantly 3.2-fold higher among people with IFG. People with IGT and newly diagnosed T2D had significantly 3.6-fold and 2.3-fold greater risk of overall mortality. RR of cardiovascular events was significantly increased 2.2-fold among people with IFG and 2.7-fold in persons with newly diagnosed T2D, people with IFG+IGT also showed 2.6-fold increase of cardiovascular events risk, but it was not significant.

Conclusion: 3 year risk of developing T2DM is not equal in persons with different early GMA: it is highest among persons with IFG+IGT and lowest among persons with isolated IGT. IFG increased 3-year risk of acute cardiovascular mortality.

Risk-stratified screening for type 2 diabetes in adult subjects: results from Hungary

G. Winkler^{1,2}, T. Hidvégi³, G. Vándorfi⁴, S. Balogh⁵, G. Jermendy⁶; ¹Dept. Int.Med. 2nd - Diabetology, St. John's Hospital Budapest, ²University of Miskolc Faculty of Health Care, Hungary, ³Dept. Int.Med. 4, Petz Aladár County Teaching Hospital, Győr, Hungary, ⁴Diabetes Center, Veszprém County Hospital, Veszprém, ⁵National Institute for Family Practice, Budapest, ⁶Dept. Int.Med. 3rd, Bajcsy-Zsilinszky Hospital, Budapest, Hungary.

Background and aims: The prevalence rate of Type 2 diabetes mellitus has been increasing worldwide. The early diagnosis of diabetes is of great im-

portance in order to improve the late prognosis of the disease. Due to cost-effectiveness, screening should primarily be implemented in subjects at high risk to glucose intolerance.

Materials and methods: A risk-stratified nationwide screening procedure was performed by the Hungarian Diabetes Association in collaboration with general practitioners (GPs) in adult subjects without known diabetes. The screening was performed in a two steps manner. At first step, the Hungarian version of the validated FINDRISC questionnaire (maximum score 26) was filled out by subjects while waiting for GP. At second step, a standard oral glucose tolerance test (OGTT) with 75 g glucose was performed in subjects with a score of ≥ 12 . Blood glucose values were measured in venous blood samples. The classification of glucose intolerance was based on the report from the WHO, 2006.

Results: As a total, 56,684 subjects (60.5% women, 40.5% men) were screened between 01, Sept 2010 and 01, March 2011. Out of 22,581 subjects with a score of ≥ 12 , 2,403 subjects refused to perform OGTT. In the remaining 20,178 subjects 10,429 (51.7%) had normal glucose tolerance, while 9,749 (48.3%) had abnormal glucose tolerance as follows: impaired fasting glycaemia (IFG) 2,797 (13.9%), isolated impaired glucose tolerance (IGT) 1,731 (8.6%), IFG+IGT 1,851 (9.2%) and previously unknown diabetes mellitus 3,370 (16.7%) subjects. Glucose intolerance of any degree proved to be more prevalent in men than in women (53.2% versus 45.3%, $p < 0.001$). If the score value requiring OGTT was set at higher level (≥ 15 or ≥ 21), the proportion of subjects with any degree of glucose intolerance significantly increased (58.7% and 75.1%, respectively).

Conclusion: The risk-stratified screening procedure proved to be simple and effective for detecting early impairment of the carbohydrate metabolism, therefore, its nationwide implementation should be considered in Hungary. Association between protein signals and type 2 diabetes incidence: the Whitehall-II study

T.M. Jensen¹, D. Vistisen¹, D. Pieragostino^{2,3}, J.N. McGuires⁴, E.D. Schjörning⁴, C. Nardi³, A. Urbani^{2,3}, M. Kivimäki⁵, E.J. Brunner⁵, A.G. Tabák^{5,6}, D.R. Witte¹; ¹Epidemiology, Steno Diabetes Center, Gentofte, Denmark, ²G. d'Annunzio University Foundation, Chieti-Pescara, Italy, ³IRCCS-Santa Lucia Foundation, Rome, Italy, ⁴Hagedorn Research Institute, Gentofte, Denmark, ⁵Epidemiology & Public Health, University College London, UK, ⁶Faculty of Medicine, Semmelweis University, Budapest, Hungary.

Background and aims: Predicting type 2 diabetes (T2DM) in early and progressive stages of disease development is essential for refining diabetes prevention strategies. Proteomic technologies allow for identification of novel proteins which reflect the pathophysiological changes in the lead up to diabetes. Our aim is to assess the association between protein signals and diabetes incidence.

Materials and methods: We analysed serum samples from 305 participants in a nested case-control selection within the Whitehall-II study. All participants were free of diabetes at baseline (1991–1994). Cases (N=100) developed T2DM during the follow-up period of 16.0 years; controls (N=205) were frequency-matched for age, sex, and BMI. Data on 36 4 peaks were acquired by linear matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) in the 1–20 kDa range. The 70 peaks present in at least 5% of the participants were ranked using random forest analysis. The 10 highest ranking peaks were selected for further analysis. Classification trees were used to assess the best binary split in peak intensity value for diabetes incidence. Odds ratios for diabetes in the group with peak intensities above the split were calculated using logistic regression for different levels of confounder adjustment.

Results: Table 1 presents the odds ratios for diabetes for the 10 highest ranking peaks. Most odds ratios were robust to adjustment for age, sex, BMI, smoking and systolic blood pressure.

Conclusion: We detected several peaks whose associated proteins may reflect mechanisms involved in diabetes pathogenesis. Further research is needed to determine the identity and functions of these proteins. Our study exemplifies the utility of an approach which combines proteomic and epidemiological data.

Table 1. Odds ratios for incident diabetes for different levels of confounder adjustment

	fraction (%) above intensity split value	Model 1	Model 2	Model 3
Peak 1	5	6.21 (1.93;20.04)	6.85 (2.07;22.71)	7.07 (2.08;24.03)
Peak 2	51	2.53 (1.54;4.16)	2.51 (1.53;4.14)	2.37 (1.42;3.96)

Validation of the FINDRISC score for prediction of type 2 diabetes in the Spanish population: the VIVA (variability of insulin with visceral adiposity) cohort study

R. Madero, C. Brotons, J. Fernández-Carreira, C. Gisbert, J. Parra, G. Rojo, A. Segura, S. Vega, J. Tuomilehto, R. Gabriel;
Clinical Epidemiology, Hospital Universitario La Paz, Madrid, Spain.

Background and aims: To describe the utility of the FINDRISC questionnaire as a risk predictor for Type 2 Diabetes (T2D) in the Spanish population. **Materials and methods:** Population-based cohort study (1,766 individuals 34–64 years; 58% women), randomly selected in 1997 and free of diabetes at baseline (FPG < 7.0 mmol/L and 2-h PG < 11.1 mmol/L and no treatment with any anti-diabetic medicine). Mean follow-up 11.5 years. New cases (incident) of T2D were defined by WHO criteria: FPG > 7.0 mmol/L or 2-h PG > 11.1 mmol/L or initiation of any anti-diabetic treatment during the follow-up. Two FINDRISC scores (FR) versions: the 8-item FR and the 7-item FR (without information on family history of diabetes) were analyzed. The probability of T2D was estimated using logistic regression analysis. The discriminatory power of the FR scale was calculated by the AUC analysis, for different cutoffs. Calibration analyses for the 8-item FR and 7-item FR models were performed grouping the FR score in 5 groups to calculate the observed: predicted probability ratio.

Results: The follow-up (OGTT, and clinical information on anti-diabetic treatment) was completed in 1,401 subjects (80%). During the follow-up 161 (10.3%) new T2D cases were identified. Discriminatory power of the 7-item FR test by ROC analysis was: 0.662 (95%CI: 0.621, 0.703), and 0.693 (95%CI: 0.649, 0.736) for the 8-item FR using the WHO definition for T2D. If only the information on “new anti-diabetic treatment” (n=58) is used as the outcome variable, the corresponding ROC values are: 0.731 (95%CI: 0.660, 0.801). The table shows the 10-year observed: predicted probability ratio of T2D grouped in 5 Ntiles.

Conclusion: The usefulness of the FR, both 7-item and 8-item, to predict T2D is discrete and overestimates the risk T2D in our population. The application of FR in a logistic model to our data, without using the FR cutoffs, might improve the predictive probability. Adjusting the weights of the variables in our data probably would improve its predictive ability.

Ntiles of FR	PObs 8-item FR	PPred 8-item FR	PObs 7-item FR	PPred 7-item FR

Influence of non-response in a population-based diabetes screening study evaluated by the Swedish Prescribed Drug Register

A.-K. Eriksson¹, A. Ekblom¹, A. Hilding², C.-G. Östenson²;

¹Dep. of Medicine, Clinical Epidemiology Unit, ²Dep. of Molecular Medicine and Surgery, Endocrine and Diabetes Unit, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Bias due to non-response may lead to over- or underestimation of disease risks. The aim was to evaluate potential selective non-participation in Stockholm Diabetes Prevention Program (SDPP), and whether this may have introduced bias and thereby influenced results in our previous studies.

Materials and methods: A population-based cohort in Stockholm comprising 12952 men and 19416 women aged 35–56 years, was screened for self-reported diabetes and family history of diabetes (FHD) by a postal questionnaire. Of these, two groups of similar size, one comprising all individuals with FHD and the other individuals without FHD, all without diagnosed diabetes, were selected to a baseline health examination with oral glucose tolerance test in 1992–94 for men (n=3128) and 1996–98 for women (n=4821). Follow-ups of 2383 men and 3329 women were performed in 2002–04 and 2004–06, respectively. In the present study, record linkage to the Swedish Prescribed Drug Register was used, and the absolute risk for diabetes was estimated as filled prescriptions of insulin or anti-diabetic drugs (in 2005–2008) for the total cohort of responders and non-responders at the SDPP screening step, and for participants and non-participants at baseline and follow-up steps. Odds ratios (OR) with 95% confidence intervals (CI) were calculated for the risk of drug-treated diabetes.

Results: At the screening step, absolute risks for diabetes did not differ in response and non-response groups, men 8.7/7.7% and women 4.0/3.8%. ORs in non-responders compared to responders were 0.9 (0.7–1.1) in men and 1.0 (0.8–1.2) in women. At baseline, absolute risks were 8.5/7.2% in men and 3.8/3.2% in women among participants and non-participants, respectively; ORs 1.0 (0.8–1.3) and 1.0 (0.7–1.3). At follow-up, the absolute risk for diabetes was lower among participants than non-participants, men 4.4/6.2% and women 1.6/2.6%, adjusted ORs 1.4 (0.9–2.3) and 1.5 (0.9–2.4) for non-participants. However, analyses did not exhibit overestimation of follow-up risks associated with FHD, smoking, physical activity, socioeconomic position and psychological distress. For overweight, the ORs for diabetes in participants and non-participants in men were 3.2 and 4.1 respectively, and for obesity 10.7 and 12.0, as opposed to women where ORs for overweight were 3.1 and 1.5, and for obesity 13.7 and 2.8. This indicated differential follow-up non-participation for BMI related to diabetes.

Conclusion: There was no selective non-response at either screening or baseline steps suggesting that the results from SDPP are generalizable. At follow-up, non-participants had an overall higher risk of diabetes compared to participants. However, analysis of risks associated with specific exposures revealed in general no overestimations. For BMI, the results illustrated different patterns among men and women, indicating that a higher share of overweight or obese men with diabetes seemed to avoid a follow-up health exam. This could lead to an underestimation of the risk estimate in men for high BMI, and also underlines the importance of targeting this risk group. Conversely, in women the impact of high BMI could be overestimated.

Low water intake and risk for new-onset hyperglycaemia

R. Roussel¹, L. Fezeu², N. Bouby³, B. Balkau⁴, O. Lantieri⁵, F. Alhenc-Gelas⁶, M. Marre¹, L. Bankir³, The D.E.S.I.R. Study Group;

¹Université Paris–Diderot, AP-HP, Hôpital Bichat, diabetology, ²INSERM, U872, Centre de Recherche des Cordeliers, ³INSERM U872, Centre de Recherche des Cordeliers, ⁴INSERM CESP centre for Research in Epidemiology and Population Health, U 1018, Epidemiology of Diabetes, Obesity and Chronic Kidney Disease Over the Life course, Villejuif, ⁵Institut Inter-Régional pour la Santé, La Riche, ⁶INSERM U872, Centre de Recherche des Cordeliers, and APHP, Hôpital Européen Georges Pompidou, Paris, France.

Background and aims: Recent data indicate an independent association between plasma copeptin, a surrogate for vasopressin, and risk of diabetes mellitus. Despite the known influence of water intake on vasopressin secretion, no

study has investigated a possible association between usual daily water intake and incidence of hyperglycemia. Our objective was to determine the relationship between water intake and the risk for hyperglycemia in a French cohort. **Materials and methods:** Participants were 3615 French men and women, aged 30–65 years, with normal baseline fasting glycemia (FG), recruited in the 9-year follow-up D.E.S.I.R study (Data from an Epidemiological Study on Insulin Resistance Syndrome). They were offered health examinations every three years, including a self-administered questionnaire with reports of mean daily intake of water, wine, beer-cider and sweet beverages. Main Outcome Measures were Odds Ratios (ORs) and 95% Confidence Intervals (95% CIs) for the incidence of hyperglycemia (impaired FG or diabetes, i.e., FG ≥ 6.1 mmol/l or treatment for diabetes) according to water intake classes.

Results: During follow-up, there were 565 incident cases of hyperglycemia. After adjustment for confounding factors (sex, baseline age, body mass index, FG, physical activity, smoking status, triglycerides, HOMA-IR, total cholesterol, gamma-GT and familial history of diabetes) ORs (95% CI) for hyperglycemia associated with the volume of daily water intake (<0.5 L, 0.5 to <1.0 L, more than 1.0 L) were 1.00, 0.64 (0.49–0.83), and 0.73 (0.55–0.97), $P=0.003$ (Figure). The ORs were similar when stratified by various characteristics, including gender and alcohol consumption.

Conclusion: Self-reported water intake was inversely associated with the risk of developing hyperglycemia. Further studies are needed to establish whether vasopressin levels mediated this association and whether interventions to increase water intake may protect against hyperglycemia.

Figure: OR (95% CI) for the association between daily water intake at baseline and the risk of incident hyperglycemia.

Model 1: Adjusted for age, sex, BMI, baseline fasting glycemia, physical activity, smoking status, triglycerides, HOMA-IR, and total cholesterol.

Model 2: Further adjusted on self-reported mean daily volumes of beer-cider, sweet drinks, and wine consumed per day.

Evaluation of the genetic effects of IGF2BP2 in the development of diabetic nephropathy

T. Gu¹, H.F. Gu¹, E. Horova², A. Möllsten³, H. Falhammar¹, M. Prazny², K. Brismar¹

¹Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden,

²Third Department of Internal Medicine, Charles University, Prague, Czech Republic, ³Department of Clinical Sciences, Pediatrics, Umeå University, Sweden.

Background and aims: Evidence has indicated that insulin-like growth factor 2 mRNA binding protein 2 (IGF2BP2) genetic polymorphism (rs4402960) is associated with type 2 diabetes (T2D) but not with type 1 diabetes (T1D). The IGF2BP2 gene is located on chromosome 3q27.2 and in a region linked to T1D, T2D and diabetic nephropathy (DN). In order to evaluate the genetic effects of IGF2BP2 in the development of DN, we have performed a genetic and biological study.

Materials and methods: Three cohorts, including T1D with and without DN (n=1139) in American Caucasians from the Genetics of Kidneys in Diabetes (GoKinD) study, T1D with and without DN (n=303) in Swedish Caucasians, non-diabetic control subjects, T1D, T2D with and without DN (n=1232) in Czech Caucasians were enrolled in the present study. Genotyping experiments for SNP rs4402960 in the IGF2BP2 gene was performed with TaqMan allele discrimination. IGF2BP2 mRNA expression levels in kidney tissues of db/db and control mice at the ages of 5, 14 and 26 weeks were determined by using real time RT-PCR.

Results: A strong association with T2D was found in the Czech population ($P=0.007$, OR=0.491 95% CI 0.290–0.831). There was also a borderline association with DN in Czech T2D patients ($P=0.040$, OR=0.571 95% CI 0.333–0.979). In the GoKinD population, a moderate association with DN was found in male T1D patients ($P=0.037$, OR=0.692 95% CI 0.490–0.978). No significant association with DN in Swedish T1D patients was detected due to limited sample size. IGF2BP2 mRNA expression in kidneys of db/db mice at the age of 5 weeks was increased compared to controls ($P=0.008$). The expression of IGF2BP2 in kidneys of control mice were dynamically increased from the ages of 5 weeks to 14 and 26 weeks. But, there was no significant difference among db/db mice at any age.

Conclusion: The present study provides the first evidence that IGF2BP2 expresses in kidneys of db/db mice and impaired in the progress of DN. IGF2BP2 has genetic impacts in the development of T2D. It may also be a susceptibility gene for DN in both T1D and T2D.

KCNQ1 and genetic susceptibility to diabetic nephropathy in type 2 diabetes: replication in the Singaporean Chinese population

D.P.K. Ng¹, S. Nurbaya¹, E.S. Tai², S. Maeda³, Y. Nakamura⁴

¹Epidemiology and Public Health, National University of Singapore,

²Medicine, National University of Singapore, Singapore, ³RIKEN, Yokohama,

Japan, ⁴University of Tokyo, Japan.

Background and aims: KCNQ1 has recently been suggested to confer susceptibility to diabetic nephropathy in Japanese patients with type 2 diabetes. To replicate this finding, we analysed SNPs rs2237895, rs2237897 and rs2283228 within the KCNQ1 locus for association with diabetic nephropathy among type 2 diabetic Chinese patients residing in Singapore.

Materials and methods: A total of 940 Chinese type 2 diabetic patients were included in the study. Controls were normoalbuminuric while cases were divided into those with micro- and macroalbuminuria. Genotyping was performed using realtime PCR and invader assays as appropriate. Logistic regression was used in analyzing the associations between SNPs and diabetic nephropathy.

Results: SNPs rs2237897 and rs2283228 were significantly associated with macroalbuminuria but not microalbuminuria. Particularly, CC homozygotes for rs2283228 were more likely to have macroalbuminuria even after adjustment for significant patient covariates including glycaemic control, blood

pressure, BMI, triacylglycerols, and diabetes duration (adjusted odds ratio 4.27 [95% CI 2.11–8.66], $P < 0.001$). TT homozygotes for rs2237897 were also at a higher risk of macroalbuminuria although the statistical evidence was more moderate (adjusted odds ratio = 2.76 [95% CI = 1.22–6.25], $P < 0.02$).

Conclusion: Together with the previous Japanese study, our findings support the hypothesis that in addition to being an established type 2 diabetes gene, KCNQ1 may also confer genetic susceptibility to diabetic nephropathy as evidenced by macroalbuminuria among Asians.

Allelic variations of superoxide dismutase 1 (SOD1) gene and diabetic nephropathy in type 2 diabetic patients

A.L. Neves^{1,2}, K. Mohammedi¹, N. Emery¹, R. Roussel¹, F. Fumeron¹, M. Marre¹, G. Velho¹

¹Research Unit 695, INSERM, Paris, France, ²Faculdade de Medicina, Universidade do Porto, Oporto, Portugal.

Background and aims: Oxidative stress is involved in the pathophysiology of diabetic nephropathy (DN), and the enzyme superoxide dismutase 1 (SOD1) is essential for reactive oxygen species detoxification. Associations of SOD1 gene variants with DN have been reported in patients with type 1 diabetes. In this study, we assessed the impact of SOD1 allelic variation in the development and progression of DN in individuals with type 2 diabetes (T2DM) followed prospectively for renal events.

Material and methods: We studied unrelated French type 2 diabetic patients from the DIABHYCAR (n=3137) and the DIABHYCAR_GENE (n=607) cohorts. DIABHYCAR was a 6-year clinical trial conducted in men and women with T2DM selected on the basis of persistent microalbuminuria (urinary albumin excretion, UAE=20–200 mg/l) or macroalbuminuria (UAE>200 mg/l) without renal failure at baseline. The trial tested whether a low dose of ramipril able to reduce UAE would also reduce cardiovascular and/or renal events. A renal event was defined as the doubling of the serum creatinine levels or the requirement of haemodialysis or renal transplantation during follow-up. It occurred in 77 cases (2.46%). Results were negative regarding the drug effect and were published previously. The DIABHYCAR_GENE cohort was recruited concomitantly to DIABHYCAR and included men and women with T2DM presenting with normal UAE (UAE<20 mg/l). Seven SNPs (rs2173962, rs9974610, rs10432782, rs2070424, rs1041740, rs17880135 and rs202449), giving information on ~90% of the allelic variation of the haplotypic block containing SOD1 gene were analyzed. Genotype associations with DN were assessed by logistic regression analyses and by Cox proportional hazards survival regression analyses. Adjustments for clinical and biological parameters were carried out by including these parameters as covariables in the regressive model. The power to detect associations of the SNPs with DN at baseline and with incidence of renal events during follow-up was 0.98 and 0.74, respectively, for odds ratio or hazard ratio equal or higher than 1.5 and alpha=0.05.

Results: In a first step, participants were divided into 3 groups according to UAE at baseline: normal UAE (DIABHYCAR_GENE cohort), microalbuminuria and macroalbuminuria (DIABHYCAR cohort, both groups). Allele and genotype frequencies of the seven SNPs were similar in the 3 groups. Next, we assessed the impact of allelic variations on the renal outcomes of the original DIABHYCAR study. We have not observed any association of the SNPs with the incidence of renal events during follow-up neither in univariate analyses nor in complex models adjusted for sex, age, BMI, duration of diabetes, HbA1c levels, presence of arterial hypertension, history of myocardial infarction, treatment with ACE inhibitors or treatment group in the original DIABHYCAR study. In these analyses, only HbA1c, BMI, arterial hypertension and history of myocardial infarction at baseline were significantly and independently associated with the incidence of renal events at follow-up.

Conclusions: Allelic variations in the SOD1 gene were not associated with micro or macroalbuminuria nor with the deterioration of renal function in patients with T2DM followed prospectively for 6 years. These results suggest that SOD1 does not play a major role in the genetic determinants of DN in type 2 diabetes.

Pilot application of multi-locus and time-to-event analysis to ascertain genetic risk factors for diabetic nephropathy and related adverse outcomes of diabetes mellitus

V. Tanhäuserová¹, V. Bartáková¹, K. Kuricová¹, L. Pácal¹, P. Linhartová¹, J. Svojanovský², D. Krusová², S. Štěpánková³, J. Olšovský², J. Bělobrádková³, J. Řehořová³, J. Ott⁴, K. Kaňková¹

¹Department of Pathological Physiology, Faculty of Medicine, Masaryk University, Brno, Czech Republic, ²Department of Internal Medicine, St. Anne's Faculty Hospital, Brno, Czech Republic, ³Department of Gastroenterology, Faculty Hospital Brno-Bohunice, Czech Republic, ⁴Institute of Psychology CAS, Beijing, China.

Background and aims: Diabetic complications and namely nephropathy (DN) contribute significantly to morbidity and mortality of diabetic patients. Their development and progression is influenced by several factors incl. treatment/compensation of diabetes, presence of co-morbidities, life style and genetic factors. The latter one is being intensively studied as potentially very powerful tool of personalised medicine. Using follow-up data from prospective study of diabetic population of South Moravia region of Czech Republic the aim of our study was to analyse contribution of genetic factors to progression of DN (primary end-point) and to major non-fatal cardiovascular event (MCVE), cardiovascular (CVM) and all-cause mortality (ACM) as secondary end-points using combination of analytical approaches.

Materials and methods: Study comprised a total of 459 diabetic subject with variable stage of DN (i.e. normoalbuminuria, persist. microalbuminuria, proteinuria and ESRD) prospectively followed for a median of 39 [IQR 21 - 59] months. Following end-points were considered: [1] progression of DN by stage, [2] MCVE (non-fatal myocardial infarction or stroke, limb amputation), [3] CVM (fatal myocardial infarction, stroke, heart failure or sudden death) and [4] ACM. Presently, 86 single nucleotide polymorphisms (SNPs) in 37 candidate genes were genotyped. After quality control, 82 SNPs remained. For each endpoint and SNP, two association statistics were computed, chi-square in 2x2 tables of alleles and chi-square in 2x3 tables of genotypes. Associated P-values were assessed in 10,000 permutation samples with the Sumstat program. For nominal P values <0.05 a corresponding experiment-wise significance levels were corrected for multiple testing. Selected best associated variants were subsequently used in time-to-event analysis of individual end-points.

Results: Kaplan-Meier curves were constructed for four best associated SNPs for given end-points: (1) progression of DN between genotype groups of cytochrome b-245 242C/T (CYBA, rs4673) log rank test $P=0.03738$, (2) MCVE and ACM vs. coagulation factor V R506Q genotypes (F5, rs6025) log rank test $P=0.02539$ and $P=0.00151$, respectively, and (3) ACM vs. dimethylarginine dimethylaminohydrolase 2 449C/G (DDAH2, rs805305) and DDAH2 1151A/C (rs805304) genotypes, log-rank test marginally significant ($P=0.06030$ and $P=0.06710$, respectively). In case of CYBA 242C/T heterozygotes and TT homozygotes were risk genotypes for DN progression, in case of F5 R506Q heterozygotes were associated with MCVE and ACM.

Conclusion: In the pilot analysis of our on-going prospective study we identified F5 506RQ and CYBA 242CT+TT (marginally also DDAH2) genotypes as risk factors for progression of DN, MCVE and ACM. Using combined approach of multi-locus and time-to-event analysis it is possible to analyse large amount of genetic and clinical data generated in follow-up studies.

Effect of vitamin D - therapy on insulin resistance and metabolic control in patients with type 2 diabetes mellitus and its pharmacogenetic analysis

K. Badenhop, F. Strobel, J. Reusch, E. Ramos-Lopez, M. Penna-Martinez, E. Klahold;
Endocrinology, Diabetes & Metabolism, University of Frankfurt am Main, Germany.

Background and aims: The effects of vitamin D (VD) on the metabolism have been mainly studied in non-diabetics. We investigated the influence of a six-month VD supplementation of 2000 U/d in patients with non-insulin-requiring type 2 diabetes mellitus (T2DM) and the pharmacogenetic impact of Vitamin D system polymorphisms (CYP27B1-rs10877012, VDR ApaI-rs7975323, VDR TaqI -rs731236 and CYP24A1-rs2248137).

Materials and methods: Patients with T2DM (n=86) were randomized in a double-blind, placebo-controlled study. During the first six months the pa-

tients received 20 drops Vigantol oil or placebo oil (medium chain triglycerides) once a week, followed by six months follow-up with measurements of 25D and 1,25D levels, PTH, calcium, phosphor, body weight, blood pressure, HbA1c and C-peptide. Vitamin D system gene polymorphisms were analysed by RFLP and RT-PCR. Wilcoxon-Mann-Whitney-U-Test was used for statistics.

Results: After 6 months of therapy the verum group ($n = 40$) 25D level had increased by a factor of 2.14 to a median of 28.4 ng/ml (71 nmol/l). The mean increase of 11.85 ng/ml ($p < 0.001$) in the verum group was significantly higher than in the placebo group. The PTH tended ($p = 0.08$) to decrease more in the verum group until the end of therapy. The verum group showed a non significant increase of calcium by 1.02 up to a median of 2.43 mmol/l but a significant increase of phosphor ($p = 0.04$) by 1.06 up to a median of 3.6 mg/dl. In the placebo group no change was seen, neither in calcium nor in phosphor. The changes in body weight and systolic blood pressure were not significant in any group. At baseline all patients with 25D levels > 20 ng/ml (52.5 nmol/l) ($n = 14$) had significantly lower HbA1c. The HbA1c was 0.35% ($p = 0.01$) lower than in patients with VD < 20 ng/ml ($n = 71$). After VD therapy all patients with 25D levels > 20 ng/ml showed higher C-peptide levels (by 0.95 ng/ml, $p = 0.01$). Pharmacogenetic differences were significant for the relative increase of 25D in carriers of CYP27B1 CC ($p < 0.001$) and AC ($p < 0.001$), VDR TaqI TT ($p < 0.001$) and Tt ($p < 0.001$) and VDR ApaI AA ($p = 0.005$) and Aa ($p < 0.001$) and CYP24A1 CC ($p = 0.005$), GG ($p = 0.004$) and CG ($p = 0.001$). Significant differences in relative increase of 1,25D were observed for CYP24A1 GG ($p = 0.05$). The difference in PTH suppression was significant for CYP27B1 AC ($p = 0.047$) and VDR ApaI Aa ($p = 0.042$) and for the increase of C-peptide with VDR ApaI AA ($p = 0.029$).

Conclusion: This study shows lower HbA1c at baseline as a function of the 25D status in patients with T2DM without insulin. Furthermore C-peptide increases significantly after six months of VD therapy. Some effects of this pilot vitamin D therapy appear to be under the influence of pharmacogenetic variation.

Association study of six type 2 diabetes genes and glucose-lowering effect of sulfonylurea drugs

Z. Schroner¹, M. Javorsky¹, L. Klimcakova², M. Dobrikova¹, V. Habalova², E. Babjakova¹, J. Zidzik², M. Fabianova¹, E. Slaba², M. Kozarova¹, R. Tkacova³, J. Salagovic², I. Tkac^{1,4}

¹4th Department of Medicine, ²Department of Medical Biology,

³Department of Respiratory Medicine and Tuberculosis, Medical School PJ Safarik University, ⁴L. Pasteur Teaching Hospital, Kosice, Slovakia.

Background and aims: Recently discovered gene polymorphisms associated with type 2 diabetes (T2D) unveiled the pathogenetic heterogeneity of T2D which may also influence the efficacy of antidiabetic treatment. Aim of our study was to determine the effect of gene polymorphisms associated with development of T2D on the parameters of glycemic control during treatment with sulfonylurea drugs.

Materials and methods: In 101 T2D patients (mean age 62 ± 10 years, 50% women, median T2D duration of 2.3 years) sulfonylurea drug was added to the antidiabetic treatment due to failure of metformin monotherapy (defined as HbA1c $> 7\%$). Fasting plasma glucose (FPG) and glycated hemoglobin (HbA1c, DCCT standard) was measured at the baseline and after 6 months of combination therapy (metformin and sulfonylurea). Six gene polymorphisms were determined by real-time PCR with melting curve analysis (ABCC8 rs757110 [Ser1369Ala], KCNJ11 rs5219 [Glu23Lys], TCF7L2 rs7903146, KCNQ1 rs163184, MTNR1B rs10830963, GIPR rs10423928).

Results: Mean baseline HbA1c was $8.07 \pm 0.97\%$ and mean HbA1c reduction after 6 months of sulfonylurea treatment was $1.07 \pm 0.77\%$. We observed smaller HbA1c decrease in carriers of the risk minor allele of TCF7L2 rs7903146 C \rightarrow T ($p = 0.007$) and larger HbA1c decrease in carriers of the risk minor alleles of polymorphisms located in the genes encoding subunits of the ATP-dependent potassium channel KCNJ11 rs5219 G \rightarrow A ($p = 0.030$) a ABCC8 rs757110 T \rightarrow G ($p = 0.042$). Reduction in on-treatment FPG was significantly lower in homozygous carriers of the risk allele G of the rs163184 T \rightarrow G polymorphism compared with alternative genotypes in the gene encoding voltage-gated potassium channel (KCNQ1) ($p = 0.037$). After Bonferroni's correction for multiple testing (6 polymorphisms) we confirmed significant association only for the polymorphism TCF7L2 rs7903146 and HbA1c decrease after 6 months of sulfonylurea treatment. Mean HbA1c decrease across the TCF7L2 rs7903146 genotypes was as follows (mean \pm SEM): CC

$1.22 \pm 0.11\%$, CT $0.90 \pm 0.10\%$ a TT $0.85 \pm 0.31\%$. In the additive genetic model adjusted for age, sex, baseline HbA1c, body mass index and sulfonylurea dose we found significant per T allele difference in the reduction of HbA1c (-0.22% , $p = 0.007$; $p = 0.042$ after Bonferroni's correction).

Conclusion: Our results indicate lower efficacy of the treatment with sulfonylurea drugs in carriers of the risk T allele of TCF7L2 rs7903146 polymorphism. Further studies are needed to confirm our findings, to elucidate the pathogenetic mechanism as well as to further study its clinical implications.

PPARGgamma Pro12Ala and ADAMTS9 rs4607103 are determinants of insulin sensitivity in both non-diabetic and type 2 diabetic Italian subjects

S. Bonetti¹, M. Trombetta¹, F. Turrini¹, M.L. Boselli¹, R. Miccoli², E. Trabetti³, G. Malerba³, P.F. Pignatti³, S. Del Prato², E. Bonora¹, R.C. Bonadonna¹;
¹Department of Medicine, University of Verona, ²Department of Endocrinology and Metabolism, University of Pisa, ³Department of Reproduction and Life Sciences, University of Verona, Italy.

Background and aims: The PPARGgamma Pro12Ala variant (rs1801282) is considered a determinant of type 2 diabetes risk at least in part through impaired insulin sensitivity and to play almost no role at all in Southern Mediterranean. The C allele of rs4607103 of a disintegrin-like and metalloprotease with thrombospondin type 1 motif, 9 gene (ADAMTS9) is associated to type 2 diabetes risk and to reduced insulin sensitivity. However, these latter data were obtained in cohorts of nondiabetic individuals of North European ancestry. We investigated whether PPARGgamma rs1801282 and/or ADAMTS9 rs4607103 affect type 2 diabetes and insulin sensitivity in Italian subjects with normal and impaired glucose regulation (NGR and IGR respectively) and with newly diagnosed type 2 diabetes belonging to the GENFIEV Study and to the Verona Newly Diagnosed Type 2 Diabetes Study (VNDS), respectively. **Materials and methods:** In 621 GAD-negative, drug treatment naive patients (mean±SD; age 58.6±10 years, BMI 29.9±5 kg/m², HbA1c 7±1.3 %) from VNDS and in 674 subjects (334 NGR and 340 IGR) from GENFIEV (age 48.8±11.4 years, BMI 29±6 kg/m², HbA1c 5.6±0.5 %) we: 1. genotyped rs1801282 of PPARGgamma and rs4607103 of ADAMTS9; 2. assessed beta cell function by state-of-art mathematical modelling of glucose/C-peptide curves during the OGTT; 3. assessed insulin sensitivity, as M value during the euglycemic hyperinsulinemic clamp in VNDS (units: µmol·min⁻¹·m⁻² BSA) and as the HOMA insulin resistance score (HOMA-IR) in the GENFIEV.

Results: Both rs1801282 of PPARGgamma and rs4607103 of ADAMTS9 showed weak, inconsistent associations with beta cell function. Both C risk alleles of rs1801282 (under a recessive model) and rs4607103 were associated to type 2 diabetes (O.R.= 1.6 p<0.04 and O.R.= 1.39 p=0.03, respectively, after correcting for age, gender and BMI). The C allele of rs1801282 was associated to more severe insulin resistance in the entire GENFIEV dataset under a recessive model (HOMA-IR: +0.32±0.05, p<0.03), while the C allele of rs4607103 was associated to reduced insulin sensitivity only in the NGR subjects (HOMA-IR: +0.18±0.08, p<0.04). Both alleles were associated to reduced insulin sensitivity in VNDS (rs1801282 C: -90.0± 6.5, p<0.04, under a recessive model; rs4607103 C allele: -63.45±2.3, p<0.02), with mutual additive effects of each variant (p<0.05 by multivariate ANOVA). We then computed a score ranging from a minimum of 0 (double genotype rs1801282GG/GC-rs4607103TT) to a maximum of 3 (double genotype rs1801282CC-rs4607103), in order to analyse the combined effect of rs1801282 and rs4607103. The higher was the score, the lower was the insulin sensitivity (-69.4±2.4, p<0.005).

Conclusion: Both PPARGgamma and ADAMTS9 variants are associated to the presence of type 2 diabetes and exert an additive detrimental effect on insulin sensitivity both in nondiabetic individuals and in diabetic patients. Thus, in Italians they may be considered two prominent “insulin resistance genes” of type 2 diabetes.

A genetic risk score for type 2 diabetes is also associated with a higher risk for impaired glucose tolerance among obese people

K. Dudziak, R. Wagner, F. Machicao, N. Stefan, H. Staiger, H.-U. Häring, A. Fritsche;
 Division of Endocrinology, Diabetology, Nephrology, Vascular Disease and Clinical Chemistry, University Hospital Tübingen, Germany.

Background and aims: Single nucleotide polymorphisms among approx. 40 genes have been associated with an increased risk for type 2 diabetes (T2D) in genome-wide association studies. It is not known whether a similar genetic impact on pre-diabetes (impaired glucose tolerance [IGT] or impaired fasting glycemia [IFG]) exists.

Materials and methods: In our cohort of 1442 non-diabetic subjects of European origin (normal glucose tolerance [NGT] n=1046, IFG n=142, IGT n=140, IFG+IGT n=114, reduced insulin secretion or reduced insulin sensitivity have been shown for 9 SNPs in previous studies. We analyzed these SNPs (within or in the vicinity of the genes TCF7L2, KCNJ11, HHEX, SLC30A8, WFS1, KCNQ1, MTNR1B, FTO, PPARG) for association with pre-diabetes.

Results: No association between the genetic risk load and the prevalence of IGT or IFG could be shown for the overall cohort. However, the risk score was significantly associated (p=0.005) with IGT or IGT+IFG for subjects with a body mass index over 30 kg/m². This association became significant for all subjects with pre-diabetes when only SNPs with a predominant effect on insulin secretion were taken into account.

Conclusion: We found an association of T2D genetic risk factors and IGT/IFG only in the obese. The absence of an influence of these genes on the transition from NGT to IGT in non-obese persons suggests that other (environmental) effects may be more important for this subgroup.

283

Variants in CACNA1E affect beta cell function and glucose homeostasis in newly diagnosed type 2 diabetes patients

M. Trombetta¹, F. Turrini¹, S. Bonetti¹, M.L. Boselli¹, G. Malerba², E. Trabetti², P.F. Pignatti², E. Bonora¹, R.C. Bonadonna¹;

¹Department of Medicine, Università degli Studi di Verona, ²Department of Reproduction and Life Sciences, Università degli Studi di Verona, Italy.

Background and aims: The voltage-dependent Ca²⁺ channel CaV2.3 gene (CACNA1E) has been associated to risk of type 2 diabetes and impaired insulin secretion. We tested whether CACNA1E variability, assessed by genotyping 10 tag SNPs (rs558994, rs679931, rs2184945, rs10797728, rs3905011, rs12071300, rs175338, rs3753737, rs225338 and rs4652679), covering ~95% of common variability of CACNA1E genomic region, affects type 2 diabetes related phenotypes in patients with newly diagnosed type 2 diabetes.

Materials and methods: We assessed the metabolic phenotype of 595 consecutive GAD-negative, drug treatment naive patients (mean±SD; age: 58.5±10.2 yrs; BMI: 29.9±5 kg/m², HbA1c: 7.0±1.3) with newly diagnosed type 2 diabetes by state-of-art methods (mathematical modelling of glucose/C-peptide curves during an OGTT and euglycemic insulin clamp, for β-cell function and insulin sensitivity, respectively). For β-cell function we analyzed the stimulus response curve relating glycemia (selected values of 5.5, 8.0, 11.0, 15.0 and 20.0 mmol/l) to insulin secretion rate (units: pmol·min⁻¹·m⁻² BSA). Insulin sensitivity was assessed as M value during the clamp (units: µmol·min⁻¹·m⁻² BSA).

Results: Both major alleles of rs2184945 and rs3905011 associated to reduced beta cell function (rs2184945 A allele p<0.01 under a recessive model; rs3905011 G allele p<0.005). We then computed a score ranging from a minimum of 0 (double genotype rs2184945AA-rs3905011GG) to a maximum of 4 (double genotype rs2184945TT-rs3905011AA), in order to analyse the combined effect of rs2184945 and rs3905011. The lower was the CACNA1E score, the lower was the insulin secretion rate in response to glucose (p<0.005). Additional associations were found between rs2184945 and 2-hours plasma glucose (p<0.01 under a recessive model) and between rs3905011 and fasting plasma glucose (p<0.02), 2-hours plasma glucose (p<0.05) and HbA1c (p<0.03). Finally the minor allele A of rs225338 was associated to higher insulin sensitivity (p<0.05).

Conclusion: Our data suggest that in patients with newly diagnosed type 2 diabetes genotyping CACNA1E might be useful to infer the metabolic phenotype and to select a personalized treatment.

Glucose-raising genetic variants in MADD and ADCY5 demonstrate effects on proinsulin-to-insulin conversion

R. Wagner, K. Dudziak, S.A. Herzberg-Schäfer, F. Machicao, N. Stefan, H. Staiger, H.-U. Häring, A. Fritsche;
 Division of Endocrinology, Diabetology, Nephrology, Vascular Disease and Clinical Chemistry, University Hospital of Tübingen, Germany.

Background and aims: Recent meta-analyses of genome-wide association studies revealed new genetic loci associated with fasting glycemia. For most of these loci, the mechanism of action in glucose homeostasis is unclear. Es-

tabulating metabolic phenotypes for these genetic variants can deliver clues to their pathomechanism.

Materials and methods: We genotyped our cohort of 1782 non-diabetic subjects for 12 single nucleotide polymorphisms in or near the genes GCK (rs4607517), DGKB (rs2191349), GCKR (rs780094), ADCY5 (rs11708067), MADD (rs7944584), ADRA2A (rs10885122), FADS1 (rs174550), CRY2 (rs11605924), SLC2A2 (rs11920090), PROX1 (rs340874), GLIS3 (rs7034200) and C2CD4B (rs11071657). Insulin, C-peptide and proinsulin were measured at 5 points during an oral glucose tolerance test (OGTT). Parameters of insulin secretion (AUC Insulin0-30/AUC Glucose0-30, AUC C-peptide0-120/AUC Glucose0-120), proinsulin-to-insulin conversion (fasting proinsulin, fasting proinsulin/insulin, AUC Proinsulin0-120/AUC Insulin0-120) and insulin resistance (HOMA-IR, Matsuda-Index) were calculated.

Results: After adjustment for confounding variables, the effect alleles of the ADCY5 and MADD SNPs were associated with proinsulin-to-insulin conversion ($p=0.002$ and $p=0.0001$, respectively). GLIS3 was nominally associated with proinsulin-to-insulin conversion and insulin secretion. DGKB and PROX1 were nominally associated with insulin secretion. Nominally significant effects on insulin sensitivity could be found for MADD and PROX1.

Conclusion: We confirmed previous findings on the role of a genetic variant in MADD on proinsulin-to-insulin conversion. By examining parameters of glucose-stimulated proinsulin-to-insulin conversion during an OGTT, we additionally established that the SNP in ADCY5 is also implicated in defective proinsulin-to-insulin conversion. These effects may also be related to neighboring regions of the genome.

The rs10195252 near the growth factor receptor-bound protein 14 (GRB14) gene is associated with diabetes risk and plasma triglycerides in a Mediterranean population

D. Godoy¹, J.V. Sorli², M. Guillen², O. Coltell³, O. Portoles², P. Carrasco², C. Ortega-Azorin², P. Guillem-Saiz², J.J. Verdú-Castillo², J.I. Gonzalez², C. Saiz², J.M. Ordovas⁴, D. Corella²

¹Internal Medicine. Hospital General of Valencia, Spain, ²Department of Preventive Medicine. University of Valencia and CIBER Fisiopatología de la Obesidad y Nutrición, Spain, ³Department of Computer Sciences. Jaume I University and Retic COMBIOMED, Castellon, Spain, ⁴Human Nutrition Research Center. Tufts University, Boston, USA.

Background and aims: The Grb proteins (growth factor receptor-bound proteins) constitute a family of structurally related multidomain adapters with diverse cellular functions. Grb14, in particular, has been implicated in the regulation of insulin receptor signalling. In animal models, ablation of Grb14 enhances insulin action in liver and skeletal muscle and improves whole-body tolerance. Elevated expression of Grb14 may contribute to states of insulin resistance. Taken together these results are consistent with a role of Grb14 in the regulation of insulin sensitivity and the development of insulin resistance in humans. However, there are not studies in humans investigating the association between GRB14 gene variation and diabetes. Our aim was to study the association between the rs10195252 polymorphism near the GRB14 gene and diabetes related variables in a high cardiovascular risk Mediterranean population.

Materials and methods: We studied 1050 high cardiovascular risk (average age: 67±6 years) subjects with either diabetes, or three or more cardiovascular risk factors participating in the PREDIMED (PREvención Dieta MEDiterránea) Study, recruited in the Valencia region, Spain. Anthropometric measures were directly measured by standard methods. Fasting glucose was determined. Type 2 diabetes was assessed by standard criteria and the rs10195252 was analyzed. Diet and other lifestyle variables were assessed by validated questionnaires.

Results: Genotype frequencies for rs10195252 polymorphism were 35% CC, 50% CT and 15% TT in the population as a whole. Prevalence of diabetes was 46%. We found a significant association between the rs10195252 polymorphism and diabetes. This inverse association was significant ($P=0.021$) when we considered an additive model. However, we obtained a higher significant association when a recessive model was considered. Thus, homozygous subjects for the variant allele (TT) have a reduced prevalence of diabetes as compared with the other genotypes (35% vs 65%; $P=0.003$). After adjustment for gender, age and body mass index (BMI) the lower risk associated with the variant allele did not change (OR: 0.56; 95% CI: 0.38–0.83). Moreover, although in the whole population we did not find a significant association of this polymorphism with plasma lipid, we detected a significant interaction between this polymorphism and diabetes in determining triglyceride con-

centrations. The variant allele was significantly associated with lower triglyceride concentrations in non-diabetics. In diabetic subjects an opposite trend was found.

Conclusion: We reported for the first time a significant inverse association between the rs10195252 polymorphism near the GRB14 gene and diabetes risk in an older Mediterranean population, supporting a relevant role of the GRB14 gene in insulin sensitivity in humans.

The melatonin receptor 1B gene (MTNR1B) in the self-contained population of Sorbs from Germany: association and evolutionary studies
K. Dietrich¹, S. Birkmeier², Y. Böttcher², D. Schleinitz¹, J. Breitfeld¹, I. Müller², B. Enigk¹, T. Lindner², M. Stumvoll^{2,3}, A. Tönjes^{2,3}, P. Kovacs¹

¹Interdisciplinary Centre for Clinical Research, Leipzig, Germany,

²Department of Medicine, Leipzig, Germany, ³IFB Adiposity Diseases, Leipzig, Germany.

Background and aims: Several single nucleotide polymorphisms (SNPs) of the melatonin receptor 1B gene (MTNR1B) have been shown to be associated with elevated fasting plasma glucose (FPG) and impaired early insulin release. We therefore initiated this study to assess effects of MTNR1B variants on traits related to type 2 diabetes mellitus (T2DM) in the self-contained population of Sorbs from Germany. Furthermore, since comprehensive studies concerning the conservation of MTNR1B are lacking, we investigated natural selection patterns in vertebrates and human populations at this locus.

Material and methods: Five SNPs (rs10830962, rs4753426, rs12804291, rs7951037 and rs10830963) representing all linkage disequilibrium groups in MTNR1B as well as 5 kb of the 5'- and 3.5 kb of the 3'-flanking region were genotyped in about 1000 subjects for subsequent association analyses on metabolic traits related to T2DM. All subjects are part of a cohort from an extensively phenotyped self-contained ethnic group in Eastern Germany, the Sorbs. Signatures of selection between species were investigated with phylogenetic analysis by maximum likelihood (PAML, $\omega = d_n/d_s$) and various tests of population genetic measures (e.g. the fixation index (Fst), Tajima's D) were performed.

Results: We were able to replicate previously known associations between MTNR1B SNPs and glucose parameters like FPG (rs10830963, adjusted $P < 0.001$) as well as insulin measurements (fasting plasma insulin: rs4753426 and rs10830963, adjusted $P < 0.05$, 30 min insulin: rs4753426 and rs10830963, adjusted $P < 0.05$). Also an impact on homeostasis model assessment of beta-cell function (rs4753426 and rs10830963, adjusted $P < 0.01$) could be shown. PAML-analyses revealed that MTNR1B was strongly conserved between species ($\omega = 0.2583$). Structures important for the receptor function are also conserved. On the lineage leading to human adaptive selection/few conservation was observed ($\omega = 1.1030$). Population genetic measures further indicated natural selection.

Conclusion: Our data support the physiologic relevance of MTNR1B in the context of glucose and insulin homeostasis and imply recent selection at this locus. The exact mechanisms linking this possible adaptation of circadian rhythm to alterations in glucose metabolism has to be further illuminated.

287

Common variation in lanosterol synthase gene predispose to type 2 diabetes

N. Iwasaki^{1,2}, K. Okamoto^{3,4}, E. Noiri⁴, M. Takizawa¹, M. Ogata¹, T. Hansen⁵, O. Pedersen⁵, K. Park⁶, Y. Iwamoto¹, K. Tokunaga³

¹Diabetes Center, Tokyo Women's Medical University, Japan, ²Institute of Integrated Medical Science, Tokyo Women's Medical University, Japan, ³Dept. of Human Genetics, Tokyo University, Japan, ⁴Dept. of Nephrology and Endocrinology, Tokyo University, Japan, ⁵Hagedorn Research Institute, Copenhagen, Denmark, ⁶Dept. of Internal Medicine, Seoul National University College of Medicine, Republic of Korea.

Background and aims: The aim of this study is to find causative genes/SNPs for T2DM in Japanese under the peak at 21q22.3 identified by genome-wide linkage analysis (affected sib-pair analysis), where the baseline LOD score of 1.92 increased to 2.42 and 2.59 when we used the leanest 116 families (BMI <24); and 146 families with age at diagnosis under 56 years, respectively.

Materials and methods: Capillary electrophoresis single-strand conformation polymorphism (CE-SSCP) analysis was performed for screening of

causative genes under the concerning region using 96 patients from original linkage study and 200 controls. The positive association was replicated using following sample sets (Japan: 779 cases / 1500 controls, Korea: 756 cases / 628 controls, Denmark: 3,531 cases / 4,885 controls, and U.K. 1,999 cases / 1,502 controls from WTCCC genotype data).

Results: We identified LSS (lanosterol synthase, 2,3-oxidosqualene cyclase) showed a significant association with T2DM in Japanese (rs2075906 at intron 17, $P = 3.2 \times 10^{-4}$, OR = 1.25). The association was further replicated in Korean and Europeans (overall $P = 2.0 \times 10^{-6}$, OR = 1.16). We found that rs2075906 variant matches to Yin Yang 1, the motif which binds to LSS promoter and represses the synthesis of LSS. The rs2075906 risk genotype (CT+TT) was associated with the expression level of LSS ($P = 0.029$) and cholesterol indicators in healthy subjects ($P < 0.05$). HOMA-IR of cases with risk genotype was significantly higher than those with non risk genotype ($P = 0.029$), while no association was observed in HOMA-beta in T2DM.

Conclusion: We found that LSS, a cholesterol biosynthesis enzyme, is a susceptible gene to T2DM in Asian and European populations through cholesterol metabolism and insulin sensitivity.

Association of rs2241766 and rs 1501299 ADIPOQ polymorphisms with coronary heart disease in Chinese Han population: a meta-analysis

J. Long, M. Gong, Y. Su, H. Deng;

Department of Endocrinology, the First Affiliated Hospital, Chongqing Medical University, China.

Background: Adiponectin is an important adipokine with insulin-enhance and anti-inflammatory action. The ADIPOQ rs2241766 and rs1501299 polymorphisms have been examined for association with coronary heart disease (CHD) over the past decade, but results remained inconsistent.

Aim: The meta-analysis of studies based on Chinese Han population to assess the association between the ADIPOQ rs2241766 and rs1501299 polymorphisms and the risk of CHD.

Data sources: A systematically search of the Chinese VIP, Chinese National Knowledge Infrastructure (CNKI) and Chinese Wang Fang database, and articles listed in reference lists of key article. No language restrictions.

Study selection: Studies were included if they had data on the ADIPOQ rs2241766 and rs1501299 polymorphisms genotype or alleles frequency and involved CHD as an outcome. Total 10 studies met these criteria.

Data extraction: Data were collected independently by two reviewers on ADIPOQ rs2241766 and rs1501299 genotype, alleles frequency and case-control status.

Results: For rs2241766, there was a trend toward increase CHD risk comparing variant genotype with wild-type genotype in Chinese Han population, the pooled OR was 1.07 (95% CI 0.81–1.42); however, in Chinese western region subgroup, individuals with variant genotype had 47% higher risk for CHD than those with wild-type genotype (OR, 1.47; 95% CI 1.08–2.00). For rs1501299, individuals with variant genotype had a significantly lower risk to CHD in comparison with individuals with wild-type genotype, the pooled OR was 0.86 (95% CI 0.68–1.08).

Conclusion: The rs1501299 polymorphism is found to be strongly associated with CHD risk, and wild-type genotype is susceptible to CHD in Chinese Han population. And the result of our meta-analysis supports a modest role for rs2241766 ADIPOQ polymorphisms in CHD risk, only in western region population, individuals with variant genotype are more susceptible to CHD.

Effect of the GRM8 Variant rs2237781 on eating behaviour in the self-contained population of Sorbs

Y. Böttcher^{1,2}, A. Tönjes^{1,2}, M. T. Gast¹, J. Breitfeld³, D. Schleinitz³, K. Dietrich³, B. Enigk³, I. Müller^{2,3}, P. Kovacs³, M. Stumvoll^{1,2};

¹III. Medical Department, ²IFB AdiposityDiseases, ³Interdisciplinary Center for Clinical Research, University of Leipzig, Germany.

Background and aims: The glutamate receptor, metabotropic 8 (GRM8) on chromosome 7q31 belongs to the group III of the G-protein-coupled glutamate receptors which are linked to the inhibition of the cyclic AMP cascade and regulate the pre-synaptic glutamate release. Data from animal studies in-

dicate that GRM8 may be involved in the regulation of the neuropeptide Y (NPY) and melanocortin pathway and thereby plays an integral role in food intake and metabolism via the hypothalamic pathway. Therefore, we studied effects of genetic variants in the GRM8 on eating behaviour assessed by the German version of the three factor eating behaviour questionnaire.

Materials and methods: All subjects are part of a self-contained population in Eastern Germany, the Sorbs. A total of 582 individuals (354 females, 228 males with mean age 47 ± 16 years and mean BMI 26.4 ± 4.7 kg/m²) extensively phenotyped for metabolic traits completed the revised version of the three-factor eating questionnaire. Genotyping of rs2237781 representing a linkage disequilibrium group within the GRM8 locus ($r^2 \geq 0.8$ and minor allele frequency ≥ 0.05) was performed using the TaqMan SNP Genotyping assay (Applied Biosystems, Inc., Foster City, CA). Genetic associations with restraint, disinhibition and hunger were assessed in an additive logistic regression model using age, gender and BMI as covariates. In addition, we performed further analyses stratified by gender. P-values < 0.05 were considered to provide nominal evidence for association.

Results: The minor A allele of variant rs2237781 (MAF 0.06) located in intron 2 of GRM8 is significantly associated with diminished restraint in eating behaviour (adjusted $P = 1.2 \times 10^{-4}$). Gender stratified analyses revealed stronger association in women (adjusted $P = 7.2 \times 10^{-4}$) compared to men (adjusted $P = 0.05$). Moreover, for disinhibition the association has been found in males only (adjusted $P = 7.0 \times 10^{-4}$). No association could be identified for intensity of hunger.

Conclusion: We propose GRM8 to be a candidate gene involved in eating behaviour. Further replication studies in independent cohorts and analyses of central effects of GRM8 in functional magnet resonance imaging (MRI)-studies are currently ongoing to elucidate the role of genetic variation in GRM8 in the control of eating behaviour.

Microvascular dysfunction increases the risk of type 2 diabetes mellitus: a meta-analysis

D. Muris, A. Houben, M.T. Schram, C.D.A. Stehouer;
Internal Medicine, Maastricht University Medical Centre, Netherlands.

Background and aims: Type 2 diabetes mellitus (DM2) is characterized by microvascular dysfunction. Recent data support the hypothesis that impairment of microvascular function may cause insulin resistance and thus contributes to the development of DM2. The aim of this meta-analysis is to investigate whether microvascular dysfunction contributes to the development of impaired glucose tolerance and DM2.

Materials and methods: We searched MEDLINE and EMBASE for studies published from 1989 to April 15th 2010. Prospective studies were included if they focused on microvascular measurements (retinal diameters, skin microvascular endothelium-dependent and -independent reactivity, capillary density, peripheral vascular reactivity, microalbuminuria, or plasma biomarkers of microvascular endothelial dysfunction) in a population-based sample of individuals without DM2 at baseline. We conducted a meta-analysis by use of RevMan5 to determine the associations of microvascular function with glucose tolerance status, using the generic inverse variance method. The pooled relative risk and 95%CI of the fully adjusted models were estimated by use of the random effects model.

Results: Twenty-three studies met our pre-specified inclusion criteria. One standard deviation (1SD) increase in retinal venular diameter was associated with a 15% higher risk of impaired fasting glucose (IFG) (95%CI [1.01-1.31], $p=0.03$), and 1SD decrease in retinal arteriolar/venular-ratio (AVratio) was associated with a 14% higher IFG risk (95%CI [0.98-1.32], $p=0.08$). Arteriolar diameter was not associated with the development of IFG ($p=0.84$). With respect to DM2, 1SD decrease in AVratio was associated with a 18% higher DM2 risk (95%CI [1.08-1.29], $p<0.001$), whereas increased venular diameters and decreased arteriolar diameters were not significantly associated ($p=0.21$ and $p=0.21$ respectively). For endothelial dysfunction, 1SD increase in microalbuminuria was associated with a 53% higher DM2 risk (95%CI [1.25-1.88], $p<0.001$), while 1SD increase in plasma levels of von Willebrand Factor (vWF) and soluble inter-cellular adhesion molecule-1 (ICAM-1) were associated with a 33% (95%CI [1.03-1.72], $p=0.03$) and 22% (95%CI [1.08-1.38], $p=0.002$) higher risk of DM2 respectively.

Conclusion: These data indicate that microvascular dysfunction, and in particular endothelial dysfunction, is associated with a higher risk of IFG and DM2. This suggests a role for microvascular dysfunction in the (early) pathogenesis of DM2.

291

Non-diabetic hyperglycaemia as a risk factor of gallstones

Y. Kabeya, K. Kato, M. Shirai, M. Tomita, T. Katsuki, Y. Oikawa, A. Shimada, Y. Atsumi;

Internal Medicine, Saiseikai Central Hospital, Tokyo, Japan.

Background and aims: Recent epidemiological evidence has suggested that patients with diabetes mellitus are associated with an increased risk of gallstones. However, an association between non-diabetic hyperglycemia and a risk of gallstones has not been thoroughly investigated at all or has been examined with a simple binary category (pre-diabetic or not). In the present study, we hypothesized that there could be a continuous association between non-diabetic hyperglycemia and a risk of gallstones and examined the hypothesis.

Materials and methods: We conducted a cross-sectional study in the medical check-up unit of one general hospital. All participants ($n=2,761$) who underwent a medical check-up focusing on metabolic syndrome from May 2008 to December 2010 were invited to the study. Blood samples and abdominal ultrasound images were obtained after an overnight fast. Those with known diabetes or those whose fasting plasma glucose (FPG) levels were more than or equal to 7.0 mmol/l were excluded ($n=439$). Ninety-two participants who had undergone cholecystectomy were also excluded. Data were not available among 8 subjects. Finally, a total of 2,222 participants were included in the analysis. A diagnosis of gallstones was confirmed by the ultrasound imaging.

Unconditional logistic regression was performed to examine the association between FPG levels and a risk of gallstones, having adjusted for possible confounders.

Results: Gallstones were identified among 212 participants (9.5%) but not among 2010 participants (90.4%). FPG levels were 5.58 ± 0.54 mmol/l among those with gallstones while 5.41 ± 0.52 mmol/l among those without ($p<0.001$). After adjustment for age, gender, BMI, WHR, systolic BP, diastolic BP, HDL-cholesterol levels, TG levels, smoking status and alcohol intake, a positive association between FPG levels and a risk of gallstones were found. Compared with individuals with an FPG of <5.0 mmol/l, the ORs of gallstones for those with an FPG of 5.0 to <5.5 mmol/l, those with an FPG of 5.5 to <6.0 mmol/l, those with an FPG of 6.0 to <6.5 mmol/l and those with an FPG of 6.5 to <7.0 mmol/l were 1.20 (95% CI = 0.73-1.98), 1.39 (95% CI = 0.83-2.32), 1.47 (95% CI = 0.82-2.63) and 2.31 (95% CI = 1.09-4.92), respectively (P for trend = 0.030). FPG levels were also analysed as a continuous variable, yielding a significant OR of 1.35 (95% CI = 1.01-1.81) for a 1 mmol/l increment in FPG levels.

Conclusion: The present study found that FPG levels were positively and continuously associated with an increased risk of gallstones among non-diabetic individuals. This association remained significant even after adjustment for possible confounders including BMI and WHR, suggesting that FPG levels could be associated with the formation of gallstones independently of obesity or other factors related to metabolic syndrome, which have been proposed as risks of gallstones. However, the causal association cannot be demonstrated in the present study because of the cross-sectional study design. Further studies are required in this area.

ORs of gallstones according to FPG levels

	Gallstones				Adjusted OR	95% CI	P for trend
	No n=2010	%	Yes n=212	%			
FPG (categorical)							0.030
FPG<5.0	394	19.6	23	10.9	1.00		
5.0≤FPG<5.5	759	37.8	70	33.0	1.20	0.73-1.98	
5.5≤FPG<6.0	565	28.1	70	33.0	1.39	0.83-2.32	
6.0≤FPG<6.5	236	11.7	35	16.5	1.47	0.82-2.63	
6.5≤FPG<7.0	56	2.8	14	6.6	2.31	1.09-4.92	
FPG (continuous)							
an increment in 1mmol/l					1.35	1.01-1.81	

ORs were adjusted for age, gender, BMI, WHR, systolic BP, diastolic BP, TG, HDL-cholesterol, smoking status and alcohol intake.

292

Analysis of hospital admissions for new-onset diabetes of the adult in the period 2003-2010 in a Mediterranean area: impact and characteristics of the non-Caucasian population

P. San Jose, I. Garcia-Martin, J. Caballero-Corchuelo, A. Boltaña, R. Insa, J. Soler, E. Montanya Mias, M. Perez-Maraver;
Endocrinology Unit, Hospital Universitari Bellvitge, L'Hospitalet de Llobregat, Spain.

Background and aims: Percentage of non-Caucasian population is increasing in Catalonia and particularly in Barcelona metropolitan area due to the growing of immigration in recent years. In other well-developed world areas with high percentage of non-Caucasian population like North-America, symptomatic diabetes onset in adults has differential characteristics in non-Caucasian compared with Caucasian patients, particularly in terms of autoimmunity and beta-cell function. Little is known about characteristics of symptomatic diabetes onset in non-Caucasian adult population in Mediterranean European countries. The aim was to evaluate the percentage of non-Caucasian patients in our unit admissions for new-onset symptomatic diabetes of the adult in the period 2003-2010 and to compare them with Caucasian subjects with regard to clinical, biochemical, immunological, and beta-cell function characteristics.

Materials and methods: Our study was a retrospective analysis. Patients admitted in our unit with the diagnosis of new-onset symptomatic diabetes in the period 2003-2010 were included if they were 18-40 years old and had no concomitant relevant illnesses. Annual prevalence of non-Caucasian popula-

tion was determined. Data from non-Caucasian patients were compared with those of Caucasian subjects in terms of clinical (gender, age, symptoms duration, weight loss, BMI, insulin dose at discharge, severity of metabolic situation), biochemical (glycemia, HbA_{1c}, pH, bicarbonate), immunological (GAD and IA-2 autoantibodies), and beta-cell function (glucagon test) characteristics. Groups were compared with parametric tests; statistical significance was defined as $p < 0.05$.

Results: 1052 patients were admitted in our unit in the period 2003–2010 with diabetes as the main diagnosis. Of those, 311 were diagnosed as new-onset diabetes, and 197 were 18–40 years old. Data with regard to autoimmunity and beta-cell function were available in 168 (85.3%), 136 Caucasians and 32 non-Caucasians. The global prevalence of non-Caucasians patients (mainly from Maghrib and South-America) was 23.9%, with progressive increase in recent years. Groups were comparable in terms of age (28.7 ± 5.8 vs. 30.5 ± 6.0 years, Caucasians and non-Caucasians respectively), BMI (23.4 ± 5.0 vs. 25.1 ± 5.1 kg/m²), duration of symptoms (7.8 ± 6.7 vs. 6.7 ± 5.9 weeks) and weight loss (8.2 ± 5.4 vs. 9.2 ± 4.8 kg). In contrast, differences between groups were significant in terms of pH (7.34 ± 0.11 vs. 7.38 ± 0.52 Caucasians and non-Caucasians respectively, $p < 0.01$), bicarbonate (23.7 ± 6.9 vs. 26.1 ± 3.9 mmol/L, $p < 0.05$), percentage of ketoacidosis (14.7% vs. 3.2%, $p < 0.05$), presence of autoantibodies (73.5% vs. 28.1%, $p < 0.01$) and stimulated C-peptide (0.42 ± 0.39 nmol/L vs. 0.70 ± 0.56 nmol/L, $p < 0.05$). The remaining clinical and biochemical parameters were comparable between groups.

Conclusion: The number and proportion of non-Caucasian patients has significantly increased in our hospital admissions for new-onset diabetes in adult population. These patients present with a lower presence of autoimmunity data and better preserved beta-cell function than Caucasian population. Evolution analyses are needed to clarify the pathological mechanisms involved.

293

STARDUST - study of the treatment and prevalence of renal disease in UK diabetes mellitus type 2 patients

S. Lee¹, R. Bilous²;

¹Boehringer Ingelheim Ltd, Berkshire, ²James Cook University Hospital, Middlesbrough, UK.

Background and aims: Kidney complications are common in patients with type 2 diabetes mellitus (T2DM). Treating T2DM patients with kidney impairment can pose a challenge for clinicians as many glucose lowering treatments are contraindicated in moderate and severe kidney impairment. This study aims to investigate antidiabetic treatments and insulin prescribed to T2DM patients with and without kidney impairment.

Materials and methods: The study was based on the UK General Practice Research Database (GPRD). Patients with eGFR < 60 mL/min/1.73m² were defined as having renal impairment, patients with eGFR > 60 mL/min/1.73m² were used for comparison. The nested case-control design was used to ensure both groups were comparable in terms of age, gender distribution and diabetes duration. Patients were included in the study if they had a diagnosis of type 2 diabetes and were 40 years or older at the time of diagnosis. Patients also had to have at least 12 months follow-up after the diagnosis and at least 1 record of serum creatinine or a diagnostic code of Chronic Kidney Disease (CKD) stage. Outcomes were category of glucose lowering therapies prescribed to patients with and without renal impairment.

Results: 168,265 patients met the inclusion/exclusion criteria, 75.54% of them had eGFR > 60 mL/min/1.73m², 24.46% had eGFR < 60 mL/min/1.73m². 9678 patients with renal impairment were matched with 59,168 patients without renal impairment. The average age was 75 and mean diabetes duration of 8.35 years. Nearly 80% of T2DM patients with renal impairment were diagnosed with hypertension compared to 37% of patients without renal impairment. Stroke, chronic obstructive pulmonary disease, coronary heart disease and hyperlipidaemia were also twice as common in patients with renal impairment compared to controls. Thirty-one per cent of patients without renal impairment were prescribed metformin compared to 48% ($P < 0.0001$) of patients with renal impairment. Amongst patients with renal impairment, 23% of patients with eGFR between 30 and 45 mL/min/1.73m² and 31.78% of patients with eGFR < 30 mL/min/1.73m² were prescribed with metformin. Number of prescriptions per patient was also higher in patients with renal impairment. On average, patients with renal impairment received 31 metformin prescriptions per person compared to 15 in patients without renal impairment. Prescriptions of sulphonylurea were also more common in patients with renal impairment, 34% versus 17% ($p < 0.0001$). However, the difference

was greatest for prescriptions of insulin, 8% of patients without renal impairment versus 22% ($p < 0.0001$).

Conclusion: Renal impairment is common in patients with T2DM. Patients with renal impairment were more likely to have comorbidities such as hypertension than patients without renal impairment. Treatments of T2DM were also very different amongst patients with and without renal impairment. Patients with renal impairment were more likely to receive prescriptions of glucose lowering treatments and were also receiving more prescriptions compared to the controls. In contradiction with the NICE guideline on type 2 diabetes, metformin remains to be commonly used in patients with eGFR < 30 mL/min/1.73m². Given similar duration of diabetes, prescriptions of insulin were two and half times as common in patients with renal impairment compared to patients without renal impairment. This may indicate a lack of choice in glucose lowering treatment for T2DM patients with renal impairment

The relationship between HbA_{1c} variability for 10 years and beta cell function and diabetic nephropathy in new onset type 2 diabetes

Y. Kim¹, J. Suk¹, B. Rhee², J. Park², M. Kim¹;

¹Internal medicine, Maryknoll General Hospital, ²Department of Internal Medicine, Inje University, Busan, Republic of Korea.

Background and aims: A1c is the important parameter for average glucose control but A1c may be fluctuating for long time and its degree can be so different in each diabetes patient. Insulin secretory function of type 2 diabetes has been known to be progressively deteriorated after diagnosed. The clinical meanings and the significance of the A1c variability on the chronic diabetic complications are still uncertain. We performed this study to see the A1c variability during the first 10 years after diagnosis of type 2 diabetes, and its relationship with beta cell function and diabetic nephropathy in clinical practice.

Materials and methods: Data were from 518 newly onset diabetes. Their mean age was 53.0 ± 12.2 years and the percent of male and female was 46.5% and 53.2%, respectively. A1cs, FBS, c-peptide, insulin levels, urine profiles and s-Cr were collected serially at least once in every year for 10 years since diagnosed as diabetes. Intrapersonal SD of serially measures A1c was considered a measure of variability of A1c.

Results: When the patients were divided by SD of A1c tertile, lowest SD group showed older age at diagnosis, lower HbA_{1c} at diagnosis and after 1-year and lower mean HbA_{1c} during the subsequent 9 years. Highest SD group showed lower fasting baseline c-peptide and HOMA- β values compared to lowest SD group, but there were no differences in HOMA-IR. The patients in highest SD group had higher decrease in c-peptide and HOMA- β during 10 years. Among the groups divided by diabetic nephropathy, normal group showed significantly lower mean A1c and mean SD of A1c compared with the group having overt proteinuria and abnormal serum creatinine values.

Conclusion: HbA_{1c} variability in newly diagnosed type 2 diabetes is inversely related with the marker of β -cell function at the time of diagnosis, and might have correlation with the development of diabetic nephropathy.

295

Trends in hospital admissions for diabetes and diabetes-related lower extremity amputations in the Republic of Ireland over a five year period

C. Buckley¹, A. O'Farrell², C. Bradley¹, R. Cavanagh³, D. De la Harpe², H. Johnson², T. Lynch¹, I.J. Perry¹;

¹University College Cork, ²Health Intelligence Unit, Dublin, ³St Vincent's Hospital, Dublin, Ireland.

Background and aims: Diabetes is a common chronic disease in the Republic of Ireland and the prevalence is rising. The WHO Global Burden of Disease study estimated a prevalence of 86,000 cases of diabetes in the Republic of Ireland in 2000, with a projected increase to 157,000 cases in 2030. Diabetes has many complications including Lower Extremity Amputation; a significant complication that is costly to the individual and the state. Lower extremity amputations are classified as major or minor based on anatomical location. Site of amputation affects quality of life and future functional capacity. The aims of this study are to identify in-patient hospital admissions of diabetic patients for any cause and for Lower Extremity Amputations (Total, Major and Minor) and to examine trends in admissions over a 5 year period. This is the first national estimate of diabetes-related Lower Extremity Amputation in the Republic of Ireland.

Materials and methods: This study is a retrospective review of hospital admissions using Hospital In-Patient Enquiry (HIPE) data, which includes major diagnoses and procedures performed during hospital admission. All in-patient admissions for which a diabetes diagnosis (ICD Codes E10-14) was recorded were extracted from the HIPE system for years 2005-2009 inclusive. The subgroup of these patients admitted for Lower Extremity Amputation was identified (ICD Codes 1484, 1505, 1533). Age standardised rates were calculated for each year and trend analysis carried out using Stats Direct.

Results: There were 283,332 hospital admissions pertaining to 122,714 patients with a diagnosis of diabetes over the 5 years. The direct standardised rates of hospital admissions in the diabetic population increased over time from 861/100,000 to 1,569/100,000 general population ($p=0.02$). From 2005-2009, there were 1,622 hospital admissions for diabetic patients receiving amputations. This involved 1,358 patients. The direct standardised rates of hospital admission for diabetes-related Lower Extremity Amputation increased from 7.5/100,000 to 8.7/100,000 general population over this period ($p=0.03$). The increase in amputations was mostly due to an increase in minor amputation rates.

Conclusion: This study found that as the prevalence of diabetes in the Republic of Ireland has increased over time, the number and rate of hospital admissions for diabetic patients and diabetes-related Lower Extremity Amputations has also increased. Fortunately, the rise in amputation rates is in line with the increase in diabetes prevalence and not in excess of it. Furthermore, while amputation rates have increased overall, major amputation rates have remained static and only minor amputation rates have increased. Minor amputations are not as clearly indicative of poor quality of care as major amputations. Thus, intervention strategies to improve foot-care may underlie the trends observed in this study. Improving diabetes care needs to continue to be prioritised in the Republic of Ireland to further reduce complication rates. Supported by: Health Research Board, Ireland

Type 2 diabetes and hypoglycaemia in the elderly: insights from the 6-month prospective DiaRegis follow-up

P. Bramlage¹, D. Tschöpe², C. Binz³, M. Krekler³, T. Plate⁴, E. Deeg⁵, A.K. Gitt⁵;

¹Institut für Kardiovaskuläre Pharmakologie und Epidemiologie, Mahlow,

²Herz- und Diabeteszentrum Nordrhein-Westfalen, Bad Oeynhausen,

³Bristol Myers Squibb, München, ⁴AstraZeneca, Wedel, ⁵Institut für Herzinfarktforschung Ludwigshafen an der Universität Heidelberg, Germany.

Purpose: Intensified glucose control in the elderly has been questioned because of complications associated with pharmacotherapy such as hypoglycaemia. **Methods:** Prospective registry of pts with type-2 diabetes and failure of oral mono- or dual antidiabetic therapy. Comparison of patients at an age of < 60 years ($n=1268$) with those ≥ 70 years ($n=1397$).

Results: Elderly patients had a substantially later diabetes onset and a better glucose control than the young (HbA1c 7.3 vs. 7.6%; $p<0.0001$; fasting blood glucose 138 vs. 146 mg/dl; $p<0.0001$; postprandial glucose 180 vs. 189 mg/dl; $p<0.0001$). Furthermore, cardiovascular disease was more frequent (CAD, stroke/TIA, heart failure). Elderly patients' cardiovascular pharmacotherapy was more intense and there was a higher use of sulfonylureas (SU, 34.8 vs. 22.0%; $p<0.0001$), while metformin and newer oral drugs (glitazones, DPP-4-inhibitors) were used less frequently. Any hypoglycaemia was a frequent complication in the elderly within 12 months prior to enrolment (12.7 vs. 9.1%; $p<0.01$). This led investigators to dismiss SUs in elderly patients with anamnestic hypoglycaemia (48.0% prior vs. 18.6% after therapy change). The use of DPP-4-inhibitors increased (5.1% prior vs. 30.5% at baseline) and insulin was started in 22.6%. Overall, therapy change led to improved HbA1c in both groups (6.9% in elderly and younger patients) at 6 months. In elderly patients with anamnestic hypoglycaemia HbA1c was only slightly reduced from 7.0 to 6.9% and 29% suffered from incident hypoglycaemic events vs. 5.9% in elderly patients without hypoglycaemia. Incident unstable angina, autonomous and peripheral neuropathy, non-proliferative retinopathy and clinically relevant depression were more frequent in elderly patients with anamnestic hypoglycaemia than in those without.

Conclusion: Elderly patients had a distinct risk profile and higher incidence of hypoglycaemia which may reasonably be attributed to the increased use of sulfonylureas. This was associated with a higher risk for incident morbidity in the following 6 months.

	Age < 60 years	Age ≥ 70 years	p-value
Coronary artery disease (%)	8.4	28.0	<0.0001
Post MI (%)	49.5	28.5	<0.0001
Stable angina (%)	19.8	33.7	<0.0001
Stroke / TIA (%)	2.5	6.8	<0.0001
Heart failure (%)	2.6	18.7	<0.0001
Incident events (6 months)	Age ≥ 70 years with anamnestic hypo	Age ≥ 70 years without anamnestic hypo	
Unstable angina (%)	2.4	0.6	<0.05
Autonomous neuropathy (%)	4.1	1.3	<0.01
Peripheral neuropathy (%)	10.7	4.7	<0.01
Non-proliferative retinopathy (%)	4.1	1.1	<0.01
Hypoglycaemia (%)	29.0	5.9	<0.0001

Diabetes, co-morbidities and long-term mortality after discharge from geriatric inpatient care

U.M. Vischer, E. Frangos, C. Graf, F.R. Herrmann, D. Zekry;

Dept of Internal Medicine, Rehabilitation and Geriatrics, Geneva University Hospitals, Thônex/Geneva, Switzerland.

Background: Many studies have demonstrated that diabetes is associated with an increase in both cardio-vascular (CV) and all cause mortality, even in older subjects. Patients in medical or geriatric care represent a particular population with a high prevalence of co-morbidities and functional disabilities. We have previously shown that diabetes in such patients is generally characterized by unexpectedly good glycemic control, albeit in the context of malnutrition and/or co-morbidities. It is unclear whether diabetes per se remains associated with a high prevalence of co-morbidities and long-term mortality in such a population.

Methods: We determined the prevalence of co-morbidities and functional disabilities according to diabetes status in a cohort of 444 patients (mean age 85.3 ± 6.7 ; 74.0% women) discharged from our geriatric service. Besides individual diseases, a global co-morbidity score (Chronic Illness Rating Scale, CIRS) was used. Functional disabilities were assessed using basic and instrumental activities of daily living (ADL and IADL). We further analysed the impact of diabetes, co-morbidities and functional disabilities on 4-year mortality using simple and multiple Cox proportional hazard models.

Results: Diabetic patients had a higher BMI (23.4 ± 4.7 versus 27.1 ± 4.9 kg/m² in controls, $p<0.001$) and a higher prevalence of hypertension (81.9 v. 65.1%, $p=0.003$) and ischemic heart disease (33.7 v. 22.2%, $p=0.033$), but there was no difference in the prevalence of stroke or renal insufficiency. They had a higher prevalence of co-morbidities according to the CIRS score (15.1 ± 4.5 v. 13.8 ± 4.8 , $p=0.016$). Diabetic patients also had more functional disabilities as evidenced by lower ADL and IADL scores. However, there were no significant differences in the prevalence of cognitive impairment and depression. In simple Cox models a low BMI, the CIRS score, low serum albumin and functional disabilities were associated with all-cause 4-year mortality. Diabetes was also associated with mortality (Hazard Ratio 1.42, 95%CI 1.02-1.99, $p=0.041$), but only after adjustment for age, sex and BMI (or obesity status). This association persisted after further adjustment for hypertension, ischemic heart disease, stroke, atrial fibrillation and renal insufficiency. However, it disappeared after adjustment for the CIRS score or ADL and IADL scores.

Conclusions: In older patients discharged from geriatric care, diabetes is associated with a high prevalence of co-morbidities and functional disabilities. It is also associated with 4-year mortality, but only after adjustment for the inverse association with the BMI. Diabetes-associated mortality is accounted for by global co-morbidities and functional disabilities, rather than by individual vascular co-morbidities. They imply that the active care of all - rather than selected - co-morbidities is the key to improving the prognosis of older diabetic patients.

The impact of treatment non-compliance on mortality in people with type 2 diabetes

M. Evans¹, C.J. Currie², M. Peyrot³, R.R. Rubin⁴, C.D. Poole⁵, S. Jenkins-Jones⁵, C. Burton⁶, C.L. Morgan⁵;

¹Department of Medicine, University Hospital of Wales, Cardiff, UK,

²Cardiff University, Cardiff, UK, ³Loyola University Maryland, Baltimore, USA,

⁴Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, USA, ⁵Pharmatelligence, Cardiff, UK, ⁶Point Of Care, Copenhagen, Denmark.

Background and aims: Poor compliance with scheduled appointments for diabetes-related monitoring and treatment has been linked to poor glucose control. The aim of this study was to determine if a diagnostic record of poor medication compliance and/or non-attendance at medical appointments was associated with all-cause mortality in insulin treated people with type 2 diabetes.

Materials and methods: Data were extracted from The Health Improvement Network (THIN) research database comprising data on patients served by over 350 primary care practices in the UK. Patients were included in the study if they had type 2 diabetes or they had previously received at least one prescription for an oral antidiabetic agent, and then initiated insulin therapy. Diagnostic codes indicating non-compliance with medication or non-attendance at medical appointments were assessed during a 30-month period prior to baseline. Relative survival was compared by determining the adjusted progression to all-cause mortality using Cox proportional hazard models.

Results: A total of 15,984 insulin-treated patients with type 2 diabetes were identified for inclusion into the study (age 64 ± 13 years, 54% male, BMI 31 ± 6 , HbA1c $8.3 \pm 1.6\%$). The number of patients receiving a specific medical diagnosis of non-compliance or missing at least one scheduled clinic appointment during the assessment period was 705 (4.4%) and 6,227 (39.0%), respectively. Non-attendance was higher among those who were non-compliant with medication (odds ratio [OR] = 2.45; 95% CI 2.10–2.86). Following adjustment for age, gender, smoking status, HbA1c, BMI, systolic blood pressure, renal disease and the number of previous contacts with the primary care practitioner in the preceding 12 months, both the diagnosis of medication non-compliance (HR=1.28; 95% CI 1.00–1.63) and visit non-attendance (HR=1.24; 95% CI 1.11–1.38) were found to be independently associated risk factors for all-cause mortality.

Conclusion: Medication non-compliance and visit non-attendance - as assessed during routine care by primary care physicians - were independently associated with increased all-cause mortality in patients with type 2 diabetes receiving insulin. The small proportion of patients with a diagnostic code of medication non-compliance is likely to reflect the most obvious or severe cases. A more systematic investigation of the effects of varying levels of medication non-compliance on treatment outcome is indicated.

Risk of osteoporosis and fracture incidence in female type 2 diabetic patients in Korea

J. Kim¹, H.-J. Kim¹, S. Yu², H. Lee¹, J. Jung¹;

¹Internal Medicine, Eulji University Hospital, ²Internal Medicine, Hallym University Hospital, Seoul, Republic of Korea.

Background and aims: Several of the previous epidemiologic studies suggested that type 2 diabetes are at increased risk of osteoporotic fractures. However, there are no published data on fracture risk and related clinical features in patients with diabetes in Korea. In this study, we compared fracture incidence of type 2 diabetic female patients with that in non-diabetic hypertensive cohort.

Materials and methods: We conducted a retrospective cohort study in a secondary referral hospital. The incidence of fracture in a type 2 diabetic cohort was compared with that in a non-diabetic hypertensive cohort for 6 years. Female type 2 diabetics who visited our endocrinology department and non-diabetic female hypertensive patients who visited our cardiology department from Jan 2004 to April 2004 were assigned to the diabetic cohort and the non-diabetic hypertensive cohort, respectively. Patients with end-stage renal disease, malignancy were excluded. The data on the fracture event was obtained. Surveys on the use of anti-osteoporosis medications and bone mineral density (BMD) using DEXA scanning were done.

Results: The incidences of fracture were 111 in the female diabetic cohort (n= 1362, 60.9 ± 11.5 years) and 66 in the female non-diabetic hypertensive cohort (n=1082, 61.9 ± 11.8 years). The estimated annual incidences per 1000 persons were 14.9 and 10.5, respectively. The relative risk (RR) in diabetic cohort was 1.39 (P = 0.33; 95% CI, 1.03–1.90). The increased fracture risk in diabetes remained still significant after adjusting for age (RR 1.57; 95% CI, 1.15–2.14). There existed a difference in the fracture site between the two group; in diabetic cohort, vertebral/hip/distal radial/any other site fracture were 35.3%, 19.8%, 12.9, 31.9%, respectively; in hypertensive cohort, 51.5%, 22.7%, 18.2%, 7.6%, respectively (P=0.002). According to BMD criteria, the prevalence of osteoporosis and osteopenia in diabetic cohort (21.6% and 50.5%, respectively) was comparable that of hypertensive cohort (24.2% and 54.1%, respectively). Use of any osteoporosis medication was more common in diabetic cohort (12.1%) than in hypertensive cohort (4.3%) (P<0.001), while the proportion of bisphosphonate, sex hormone, and raloxifen use was similar between the two groups.

Conclusions: In our study, significantly higher incidence of fracture was observed in female type 2 diabetics as compared to non-diabetic female hypertensive patients despite they had similar BMD. Special concern for this fracture risk group is warranted for diabetes professionals.

Impact of introducing HbA_{1c} into the diagnostic criteria and cardiovascular risk profiles of individuals with newly diagnosed diabetes

S. Hara¹, Y. Heianza^{2,1}, K. Fujiwara², H. Tsuji¹, S.D. Hsieh¹, S. Kodama^{2,1}, K. Saito^{2,1}, Y. Arase¹, N. Yamada², H. Sone^{2,1};

¹Health Management Center, Toranomon Hospital, Tokyo, ²Department of Endocrinology and Metabolism, University of Tsukuba Mito Medical Center, Japan.

Background and aims: Evidence has indicated that the glycation and oxidation of lipids may contribute to the development of atherosclerosis in diabetic individuals. Although glycated hemoglobin A1c (HbA1c) was newly introduced into the new criteria for diagnosing diabetes, its performance has not been evaluated in detail, especially among diverse ethnic groups. We aimed to evaluate the impact of introducing HbA1c for diagnosis of diabetes and to investigate whether individuals with diabetes diagnosed by HbA1c criterion have different cardiovascular risk profiles than those diagnosed by fasting plasma glucose (FPG) criterion in a large cohort of Japanese individuals.

Material and methods: This cross-sectional study involved 26884 participants without known diabetes aged 20–91 years who underwent a routine medical checkup at the Health Management Center, Toranomon Hospital. Subjects were categorized into 4 groups according to the presence or absence of FPG ≥ 7.0 mmol/L and/or HbA1c $\geq 6.5\%$.

Results: Prevalence of undiagnosed diabetes by FPG and/or HbA1c was 3.6% among participants. When only HbA1c or FPG was used for diagnosis, almost equal numbers of diabetic individuals were missed (26.5% or 26.0% respectively). HbA1c $\geq 6.5\%$ criterion yielded high specificity (99%) and low sensitivity (64%) for identifying diabetes diagnosed by FPG criterion. The distribution of clinical metabolic markers such as adiposity, blood pressure, and lipids did not increase in parallel within each diagnostic group. Compared with individuals with diabetes according to FPG ≥ 7.0 mmol/L and HbA1c $< 6.5\%$, individuals with diabetes according to HbA1c $\geq 6.5\%$ and FPG < 7.0 mmol/L were characterized as older, more likely to be women, and having lower systolic blood pressure, diastolic blood pressure, and gamma-glutamyltransferase values. Individuals with discordantly diagnosed diabetes by HbA1c had unfavorable lipids profiles, such as low HDL cholesterol levels and high LDL or non-HDL cholesterol levels. A similar association was observed that we investigated characteristics of pre-diabetes defined by HbA1c (5.7–6.4%) and/or FPG criteria (5.6–6.9 mmol/L) among non-diabetic individuals. HbA1c $\geq 5.7\%$ and FPG < 5.6 mmol/L was associated with low levels of HDL-C and high levels of LDL-C and non-HDL-C. Unfavorable lipid abnormalities did not depend on the specific cutoff value of HbA1c $\geq 6.5\%$.

Conclusions: After introducing HbA1c into the diagnosis, large numbers of previously undiagnosed cases of diabetes in Japanese men and women were detected. These newly diagnosed patients had unfavorable lipid profiles, reflecting an atherosclerotic trait. Understanding the difference in risk profiles of diabetic patients by clinicians will be of great importance.

A new cardiovascular score including diabetes for the low risk and aged southern European population: the erice risk score

R. Gabriel, C. Brotons, M. Tormo, A. Segura, F. Rigó, R. Elosúa, J.A. Carbayo, J. Tuomilehto, I. Moral, A. Ortega, J. Muñoz;
Clinical Epidemiology, Hospital Universitario La Paz, Madrid, Spain.

Background and aims: The impact of diabetes mellitus (DM) on cardiovascular disease (CVD) risk is an important aspect to be considered in risk assessment. The European SCORE did not consider the overall impact of DM on CVD risk. Also, it appears that true effect of DM in Europe is greater than in risk estimation systems based on the Framingham cohort where DM is included. To develop a new cardiovascular disease risk prediction tool, including the information on DM status, to accurately estimate the individual cardiovascular risk in Southern Europe, where people have a relatively low CV risk, but a relatively high prevalence of DM.

Materials and methods: The project assembled a pool of 7 Spanish cohort studies including middle-aged (30–74 years) and elderly individuals (> 75 years). There were 11,800 persons free of CVD at baseline (5,413 men and 6,387 women) representing 108,569 person years of follow-up. DM was de-

fined as FPG ≥ 7.0 mmol/L, random capillary FG ≥ 11.1 mmol/L or treatment with any anti-diabetic drug at baseline. Cox regression analyses were conducted to examine the contributions of the different variables to CVD forming the potential basis for the development of the CVD risk-score (ERICA-score). **Results:** Overall prevalence of DM at baseline was 8.6% (8.8 in males, and 8.4% in females). A total of 1,214 cardiovascular events were identified, of which 633 were fatal. Age was the strongest risk factor for CVD. With regard to modifiable risk factors, in men, high SBP was the strongest predictive factor of CVD followed by DM and smoking with similar impact. In women, DM plays a crucial role followed by smoking and high SBP. The contribution of high Cholesterol levels to the CVD risk was small, both in men and women, in this Southern population, when considering all age-groups. The multivariate adjusted hazard ratios of CVD in people with DM were 1.37 in men and 1.59 in women, compared to non-diabetics. The individual contribution of DM to the global CVD risk was higher in this Southern European population than in the Framingham population.

Conclusion: Separate risk charts are given for diabetics and non-diabetics, because at every level of a risk factor or at any combination of risk factors the absolute risk is increased in diabetic patients. The individual contribution of DM to the CVD risk is important in the Southern European population. However the Euro Heart SCORE risk function does not include DM as a risk factor score and the Framingham algorithm underestimate its impact.

Predicting changes in risk factors in type 2 diabetes in the post-UKPDS era: longitudinal analysis of the Swedish national diabetes register

A. Ahmad Kiadaliri^{1,2}, P.M. Clarke³, U.G. Gerdtham¹, P.M. Nilsson¹, B. Eliasson⁴, S. Gudbjörnsdottir⁴, K. Steen Carlsson¹;

¹Lund University, Sweden, ²Tehran University of Medical Sciences, Islamic Republic of Iran, ³University of Sydney, Australia, ⁴University of Gothenburg, Sweden.

Background and aim: The results based on the seminal UKPDS study have been the standard for health economic models for the past decade. Our aim was to provide an update accounting for changes in treatment standards and population characteristics for the application in health economic models by predicting changes of five major risk factors (HbA_{1c}, systolic BP, BMI, total cholesterol: HDL cholesterol ratio and LDL cholesterol) in persons newly diagnosed with type 2 diabetes.

Materials and methods: Observational data from the Swedish National Diabetes Register (NDR) were analyzed using Generalized Methods of Moments estimation for dynamic panel models (N=5020, aged 25–70 years at diagnosis in years 2001–2004). Temporal validation was performed using persons diagnosed in 2005 (n = 414). Results were compared to corresponding predictions based on time path equations estimated for the UKPDS outcome model.

Results: The value of the risk factor in the previous year was the main predictor of the current value of the risk factor in all equations. These coefficients were below 1 (range 0.35–0.81) and it implied that initial high risk-levels were reduced over time while low risk-levels would increase. The rate of convergence was significantly lower for BMI than for other risk factors. BMI was associated with elevations in all other risk factors. Females had lower levels of HbA_{1c}, total: HDL cholesterol ratio and systolic BP than males. The results from the model validation showed that the predicted values corresponded well with the observed ones (Figure 1). Our updated equations predicted the current data more precisely than previous equations based on UKPDS outcome model (lower root mean squared error for NDR vs. UKPDS: HbA1c 12.6 vs. 15.2; total: HDL cholesterol ratio 13.7 vs. 16.1; systolic BP 19.0 vs. 20.2).

Conclusion: Our findings indicate new time-patterns for risk factors in the post-UKPDS era and the validation analysis confirmed the importance of updating the equations as new data become available. We suggest that the results from UKPDS trial may have affected the management of type 2 diabetes and ignoring this effect may seriously bias the results of health economic analyses of current therapies.

Figure 1. Predicted and observed time path of HbA_{1c} for non-smoker males in validation sample.

Equation shows the regression of observed values on predicted ones for this group

Is type 2 diabetes equivalent to a cardiovascular event?

S. Canivell¹, J. Ortiz², J. Mitjavila², X. Otero², E. Sánchez³, J.M. Sotoca², M. Pinyol², A. Sisó², R. Gomis¹;¹Hospital Clinic-IDIBAPS.CIBERDEM, ²GESCLINIC, ³CAPSE, Barcelona, Spain.

Background and aims: There is on-going debate whether type 2 diabetes should be considered as a cardiovascular risk factor equivalent to a cardiovascular event itself. The aims of this study were to compare the mortality and comorbidity between type 2 diabetic patients with no previous cardiovascular events and patients with previous cardiovascular events considering therapy, diabetes and cardiovascular events duration, glycemic and cardiovascular risk factors control.

Materials and methods: A prospective cohort study with 3-year follow-up was performed in 2,588 patients: 1,430 with a previous cardiovascular event (from which 24% had type 2 diabetes) and 1,158 with type 2 diabetes recruited from a primary health care center in Southern Europe. Cardiovascular event was defined as a previous episode of CHD, stroke or peripheral arterial disease registered in the clinical database. The study was approved by the local ethics committee and obeyed all the laws according to the Declaration of Helsinki. As of recruitment, information was collected on cardiovascular risk factors, diabetes control, therapy, deaths and comorbidity (which was assessed through the Charlson index). Results are expressed as means \pm SD, if continuous variables, or as %, if categorical variables. X2 tests were performed for the comparison between categorical variables and ANOVA in case of continuous variables using STATA.11 software. The significance level was set up at $p < 0.05$ (two-sided).

Results: At baseline, results showed that all patients had a similar duration of diabetes and cardiovascular event since diagnosis registered in the database. At three years of follow-up, there are 855 patients with a previous cardiovascular event and without type 2 diabetes (CVnoDM), 301 with a previous cardiovascular event and type 2 diabetes (CVDM) and 1,012 with type 2 diabetes (DM). Blood pressure, LDL and total cholesterol serum levels, physical activity performed and HbA_{1c} levels in diabetics are similar in the three groups. All patients are overweight (BMI > 25), 63% are men, aged 73 years in average and an 11% are smokers. DM receive in a minor proportion flu vaccine compared to CVnoDM and to CVDM (12% vs 63% vs 74% respectively, $p < 0.001$). DM have more comorbidity associated compared to CVnoDM (Charlson's index of 2.09 (95%CI 2.00-2.18) in DM and of 1.83 (95%CI 1.72-1.93) in CVnoDM, $p = 0.02$). CVnoDM and CVDM are in a higher proportion on anticoagulation or antiplatelet therapy (67% and 77%, respectively) compared to DM (47%, $p < 0.01$). Treatment with ACEIs or ARAII is intensified in CVDM patients (64% of use) compared to CVnoDM patients (43% of use, $p = 0.003$). No significant differences in the proportions of deaths during the last year in DM (1.1%) and CVDM (3.2%) were found compared to CVnoDM (2.2%) and neither comparing DM with CVDM ($p = 0.3$). There is almost the double of cardiovascular death (27.3% vs 14.4%, $p = 0.02$) in CVDM compared to CVnoDM. There is a similar proportion of cardiovascular death comparing CVnoDM with DM (14.4% vs

16.7%, $p = 0.7$). A similar ratio of cancer death has been found in all groups (18% on average).

Conclusion: Type 2 diabetes generates more morbidity itself than cardiovascular disease without diabetes. Patients with a previous cardiovascular event have double the risk of cardiovascular death if they suffer additionally from type 2 diabetes compared to those who do not.

The hypertriglyceridaemic-waist phenotype in relation to carotid artery atherosclerosis in Chinese patients with type 2 diabetes

L. Zhang^{1,2}, Y. Dong^{1,2}, N. Wang¹;¹Qingdao Endocrine & Diabetes Hospital, Qingdao, China, ²Weifang Medical University, Weifang, China.

Background and aims: High waist circumference plus hypertriglyceridemia has been proposed as a useful tool to identify patients with increased cardiovascular risk in general populations. We examined the relationship between the hypertriglyceridemic-waist phenotype and the risk of carotid artery atherosclerosis (CAA) in Chinese patients with type 2 diabetes.

Materials and methods: 2625 consecutive diabetic in-patients (mean age 56 ± 11 years, 55% women) were included. CAA was determined by Color Doppler Ultrasonography and defined by the formation of detectable carotid artery plaques. Logistic regression analysis was applied to relate hypertriglyceridemic-waist phenotype to CAA.

Results: The prevalence of elevated waist circumference (≥ 90 cm in men or ≥ 80 cm in women) plus elevated triglycerides (≥ 1.7 mmol/L) was 26.7% and 45.2% respectively in patients with and without CAA. Compared with participants who had a waist circumference and triglycerides level below the threshold, those with the hypertriglyceridemic-waist phenotype had higher levels of systolic blood pressure (140.1 mmHg vs. 133.7 mmHg, $p < 0.05$), HbA_{1c} (8.7% vs. 7.7%, $p < 0.01$), apolipoprotein B (1.09 g/L vs. 0.97 g/L, $p < 0.05$), C-reactive protein (8.2 mg/L vs. 4.9 mg/L, $p < 0.01$), TNF- α (26.5 pg/ml vs. 16.8 pg/ml, $p < 0.05$) and mean intima-media thickness (0.08 cm vs. 0.07 cm, $p < 0.05$), but lower levels of apolipoprotein A-I (1.20 g/L vs. 1.33 g/L, $p < 0.05$). The hypertriglyceridemic-waist phenotype was associated with CAA (OR 1.30, 95% CI 1.07-1.56), after adjusting for age, sex, duration of diabetes, body mass index, smoking, HbA_{1c}, apolipoprotein B and C-reactive protein.

Conclusion: Among diabetic patients, simultaneous measurement of waist circumference and triglycerides could be used as inexpensive approach to identify individuals with increased cardiovascular risk.

305

Serum peroxiredoxin 4 and cardiometabolic outcomes in the general population

A. Abbasi^{1,2}, E. Corpeleijn¹, D. Postmus¹, R.T. Gansevoort², P.E. de Jong², R.O.B. Gans³, J. Struck³, J. Schulte³, H.L. Hillege¹, P. van der Harst⁴, R.P. Stolk¹, G. Navis², S.J.L. Bakker²;¹Epidemiology, University Medical Center Groningen, Netherlands, ²Internal Medicine, University Medical Center Groningen, Netherlands, ³Research, BRAHMS AG (Part of Thermo Fisher Scientific), Hennigsdorf, Germany, ⁴Cardiology, University Medical Centre Groningen, Netherlands.

Background and aims: Previous studies suggest a role of oxidative stress in the development of metabolic and cardiovascular diseases (CVD). Recently, circulating levels of peroxiredoxin 4 (Prx4), a hydrogen peroxide degrading peroxidase, have been proposed as a novel biomarker of oxidative stress. Levels of Prx4 and its potential association with cardiometabolic conditions in the general population are unknown.

Material and methods: We included 7295 participants (aged 28-75 years; women 52.6%) from the Prevention of Renal and Vascular End-stage Disease (PREVEND) study. Prx4 was measured by a novel immunoluminometric assay at baseline. Metabolic syndrome (MS) was defined according to the Adult Treatment Panel III criteria. Type 2 diabetes (T2D) was ascertained if one or more of the following criteria were met: (1) fasting plasma glucose ≥ 7.0 mmol/L, (2) non-fasting sample plasma glucose ≥ 11.1 mmol/L, (3) self-report diagnosis by a physician, (4) use of antidiabetic agents.

Results: Prx4 levels were significantly higher in individuals with prevalent MS (median [IQR], 0.85[0.55-1.38] vs. 0.65[0.41-1.05] U/L; $p < 0.001$), prevalent CVD (1.01[0.57-1.63] vs. 0.67[0.43-1.08] U/L; $p < 0.001$) and prevalent T2D (1.01[0.63-1.49] vs. 0.68[0.43-1.09] U/L; $p < 0.001$). During 10-years of

subsequent follow-up, we observed 407 (5.6%) incident cases of T2D, 642 (8.8%) CVD events and 460 (6.3%) deaths. In a model adjusted for age, lipids, BMI, waist circumference, systolic blood pressure, and parental diabetes, OR (95% CI) for T2D per doubling of Prx4 levels was 1.18 (1.01–1.37; $p=0.03$) in men versus 0.87 in women (0.71–1.06, $p=0.16$). In a model adjusted for Framingham risk factors, HR (95% CI) was 1.16 (1.07–1.27; $p<0.001$) for cardiovascular events and 1.21 (1.10–1.34; $p<0.001$) for all-cause mortality in the overall population. By adding Prx4 to above models, the integrated discrimination improvement, as a measure of reclassification, was 0.002 ($p=0.06$) for incident T2D in men, 0.003 ($p=0.003$) for CVD events and 0.004 ($p=0.02$) for all-cause mortality in the overall population.

Conclusion: Elevated Prx4 levels are associated with prevalent MS, CVD, and T2D. Prx4 improved prediction of future risk of cardiovascular events and all-cause mortality above Framingham risk score.

Modifiable predictors of cardiovascular disease and mortality in Chinese with impaired glucose tolerance: 23-year follow-up of the Daqing diabetes prevention study

G. Li¹, P. Zhang², J. Wang³, Y. An¹, Q. Gong¹, E. W. Gregg², G. Roglic⁴, W. Yang¹, B. Zhang¹, Y. Hu³, P. H. Bennett⁵

¹Endocrinology, China-Japan Friendship Hospital, Beijing, China, ²Division of Diabetes Translation, Centers for Disease Control and Prevention, Atlanta, USA, ³Cardiology, Daqing First Hospital, China, ⁴Chronic Disease and Health Promotion, WHO, Geneva, Switzerland, ⁵Phoenix Epidemiology and Clinical Research Section, National Institute of Health, USA.

Background and aims: Diabetes and impaired glucose tolerance (IGT) increase the risk of cardiovascular disease (CVD) and mortality. Thus, prevention of diabetes and the related excess CVD incidence and mortality is critical, and data about modifiable predictors of CVD and mortality in Chinese adults with IGT are needed. We examined the development and predictors of CVD and mortality among Chinese with IGT.

Materials and methods: 576 adults with IGT participated in the Daqing Diabetes Prevention Study - a clinic-randomized trial testing the effectiveness of a 6-year lifestyle intervention (1986–1992) to prevent type 2 diabetes. CVD events, defined as the first event including myocardial infarction, heart failure, sudden death, stroke or amputation, and all-cause mortality were ascertained in 542 (94%) participants over a 23-year period until December 31st, 2009. Proportional hazard analyses were used to determine predictors of each outcome.

Results: Among 488 participants who had complete data on the variables needed for this analysis, there were 186 first CVD events, 65 CVD deaths, and 141 all-cause deaths. Age, sex, smoking and changes in 2-hour plasma glucose (2hPG) from baseline to the end of 6-year lifestyle intervention (C2hPG) were significantly associated with all-cause mortality after controlling for baseline body mass index (BMI), systolic blood pressure (SBP) and 2hPG. After adjusting for baseline BMI, smoking, 2hPG, age and sex, only baseline SBP and C2hPG were significantly positively associated with CVD mortality and first CVD event. The relative risk (RR) for baseline SBP (per 10mmHg increment) was 1.13 (95%CI 1.04–1.24) for CVD mortality, and 1.07 (95%CI 1.01–1.13) for first CVD event, while the RR for C2hPG (per 1 mmol/l increment) was 2.74 (95% CI 1.00–7.49) for CVD mortality, and 2.88 (95% CI 1.67–4.99) for first CVD event. In a subset of the population with baseline lipid determinations, total cholesterol was not associated with all-cause and CVD mortality or first CVD event.

Conclusion: Changes in 2hPG at the end of the 6-year lifestyle intervention significantly predicted first CVD events, and CVD and all-cause mortality, and along with baseline SBP significantly predicted first CVD events and CVD mortality. Lifestyle interventions in IGT can prevent diabetes and better prevention outcomes for CVD events and mortality may be achievable by combining lifestyle intervention with optimal blood pressure control.

Persistent lipid abnormalities in statin-treated patients: Portuguese diabetic sub-population of the Dyslipidemia International Study (DYSIS) P.M. da Silva¹, S.M. Cardoso²

¹Internal Medicine, Santa Marta Hospital, Lisbon, ²Epidemiology, Coimbra University School of Medicine, Portugal.

Background and aims: Diabetes mellitus (DM) is a well-established risk factor for cardiovascular disease (CVD). DM patients often experience multiple lipid abnormalities. This study aimed to evaluate the prevalence and type of persistent lipid abnormalities in Portuguese diabetic sub-population treated with lipid modifying therapies (predominantly statins).

Materials and methods: The Dyslipidemia International Study (DYSIS) was a multicenter, epidemiologic cross-sectional study, conducted in 12 European countries and Canada. Entry criteria included patients ≥ 45 years old, with a lipid profile assessment performed in the previous 6–12 months while on statin therapy for at least 3 months. In Portugal, along with the other countries, data concerning demographic characterization, cardiovascular risk factors and lipid modifying treatment were collected between April 2008 and February 2009 in primary care centres and private practice.

Results: In Portugal, 916 patients were recruited of which 348 (38.0%) had DM. Patients with DM had significantly lower LDL-c levels than patients without DM, however, there were no differences between the two populations regarding triglyceride and HDL-c values (Table 1). The percentage of diabetic patients that did not meet the ESC guidelines for total cholesterol and LDL goal levels was lower than the observed in patients without DM (61.8% vs 72.5%; $p<0.001$; 57.9% vs 66.3%, $p<0.05$, respectively). On the other hand, there were more DM patients with low HDL-c according to ESC guidelines (27.7% vs 18.8%, $p<0.01$). There were no differences in hypercholesterolemia treatment between patients with and without DM: the most frequently used statin was simvastatin in both groups (54.9% vs 56.5%, $p=0.64$).

Conclusion: The Portuguese results of DYSIS show that total cholesterol, triglyceride and HDL-c remain outside the recommended levels in more than 50% of statin-treated patients with DM. Although this is a high risk population for CVD events, lipid management strategies did not differ from the general population. This is in line with the international findings of this study. These patients remain at increased CVD risk and supplementary treatment may be indicated.

Table 1. Biochemical and historical results for DYSIS in Portugal.

	Patients with DM N=348 (38.0%)	Patients without DM N=568 (62.0%)
LDL-c (mmol/L)	2.7 (2.1–3.3)	3.2 (2.6–3.9)*
[Median and Quartiles]		
LDL-c <2.59mmol/L	42.1% (118/280)	24.5% (105/429)*

The clustering of components of metabolic syndrome, duration of onset of diabetes and coronary artery disease in type 2 diabetes mellitus based on the diabetes case management program 2001, Taiwan

M.M. Fuh¹, P.-C. Chen², C.-I. Li¹, H. Su³, C.-T. Chang¹, C. Chen¹, C.-C. Lin¹; ¹China Medical University Hospital, Taichung, ²Department of Healthcare Management, Yuanpei Cyber University, Hsinchu, ³Taipei Medical University Hospital, Taiwan.

Background and aims: In order to evaluate the relationship between clustering of components of metabolic syndrome (MetS) and coronary artery disease (CAD) in different duration of T2DM for the ensuing development of CAD prevention program in high risk people.

Materials and methods: From Jan. 2006 to Jun. 2009, 3543 cases of T2DM, age over 20 were cumulatively enrolled in DCMP 2001. All patients were having the general anthropometric data collected, fasting blood samples taken and then metabolic variables measured. CAD in participants was evidenced by history of CAD and myocardial infarction and regular follow-up in CV clinics and other evidences resulting from coronary angiogram and/or echocardiogram. Duration of diabetes was calculated by subtracting time of onset of diabetes from the current age. The MetS defined was based on the criteria mentioned in the ATP III. Patients were obligatorily classified under 6 groups, MetS with waist component, waist required and non-waist required; MetS without waist component, with 2 other components and with more than 2 components; Non-MetS with waist and without waist component. All patients with CAD in 6 groups with different ranges of duration of diabetes were presented by case number and percentage distribution. By using the logistic regression analysis with Non-MetS without waist in newly developed T2DM as a reference group, the odds ratio (OR) for occurrence of CAD among 6 groups was analyzed.

Results: The case number and percentage distributions of CAD occurring in these 6 groups with different duration of diabetes were demonstrated in Table 1. The ORs for occurrence of CAD were statistically significant all the way from newly onset of diabetes to the duration of diabetes over 15 years in both non-waist required MetS with waist component ($p < 0.038-0.001$) and MetS without waist with over 3 components ($p < 0.004-0.000$) in this T2DM cohort (Table 2). The ORs for the occurrence of CAD of other 4 groups were also presented.

Conclusion: The clustering of different components of MetS rather than waist in subjects with MetS would be higher in the prevalence rate of CAD in this T2DM cohort.

Table 2. The distribution of odds ratio for the occurrence of coronary artery disease in metabolic and non-metabolic syndrome with different ranges of duration of disease in type 2 diabetes mellitus

Modelling integrated care for diabetes based on observational data: the MICADO model

A.A.W. van der Heijden¹, R.T. Hoogenveen², T.L. Feenstra^{2,3}, L.W. Niessen^{4,5}, M.C. de Bruijne¹, J.M. Dekker¹, C.A. Baan^{2,1}, G. Nijpels¹;

¹The EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, Netherlands, ²National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands, ³University Medical Center Groningen, Netherlands, ⁴Department of Health Policy and Management, Erasmus University Rotterdam, Netherlands, ⁵Department of International Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, USA.

Background and aims: Simulation models can assist in comparing the cost-effectiveness of various interventions. Already known models concentrate on known diabetes patients. However, the MICADO model was developed for the evaluation of long-term cost-effectiveness of interventions in both diabetes patients and the general population. We describe the modelling of the incidence and progress of microvascular complications in MICADO. This model combines the modelling of macro- and microvascular complications for the general population and for diabetes patients, which makes the model rather unique.

Materials and methods: The already existing and tested RIVM Chronic Disease Model was modified and extended with modules for microvascular complications (nephropathy, diabetic foot and retinopathy) in persons with type 1 or type 2 diabetes (Figure). The resulting MICADO model is a Markov-type, multistate transition model linking risk factors to incidence of diabetes and micro- and macrovascular complications. Outcomes are prevalence of complications, quality of life, costs and cost-effectiveness. Validation was performed by comparing the prevalence or incidence of microvascular complications estimated by the model to empirical data of these complications. To account for uncertainty in the transition probabilities, we performed probabilistic sensitivity analysis.

Results: The incidence of End Stage Renal Disease (ESRD) (247 (95% Interquartile Range (IR): 120 to 363)) was similar to the registered incidence of ESRD in the Netherlands in 2005 (268). The model estimated 592 (95% (IR): 291-842) amputees annually, which compared well to the registered number of diabetes related amputees in the Netherlands in 2003 (728). The prevalence of diabetes related blindness was probably slightly underestimated by our model (720 (95% IR: 690 to 748)).

Conclusions: Validation to independent empirical data showed that the model in its current form performed well. The MICADO model can be used for the simulation of a population to describe the natural course of diabetes and its complications and to evaluate the long-term (cost-) effectiveness of diabetes-related interventions aiming to reduce the risk of vascular diseases.

Circulating levels of palmitoleic acid correlate with beta cell function in obese children and adolescents

J. Staaf¹, K. Ubhayasekera², D. Veljkovic¹, A. Forslund³, P. Bergsten¹;
¹Medical Cell Biology, ²Physical and Analytical Chemistry, ³Women's and Children's Health, Uppsala University Hospital, Sweden.

Background and aims: The prevalence of obesity is increasing exponentially on a global scale, not only afflicting adults but children and adolescents as well. Pathogenesis of type 2 diabetes mellitus (T2DM) is associated with obesity and is a consequence of inadequate beta-cell function and peripheral insulin resistance. In obese individuals levels of free fatty acids are elevated. Such elevated levels, in particular of palmitic acid, have detrimental effects on beta-cells. Recent studies show that another circulating free fatty acid, palmitoleic acid, has positive effects on beta-cell function and survival. In addition, the palmitoleic acid level has been shown to correlate positively with insulin sensitivity in adults. To what extent palmitoleic acid levels are altered early in development of obesity and precipitating beta-cell dysfunction and T2DM is not known. The aim of this study was to measure circulating levels of palmitoleic acid in young obese patients and correlate the fatty acid levels with beta-cell function and insulin resistance.

Material and methods: Fasting blood samples were obtained from 24 obese children, 12 boys and 12 girls, between 3 and 16 years old belonging to the Uppsala Longitudinal Study of Childhood Obesity. All children had normal fasting glucose levels and HbA1c. Six free fatty acid levels, palmitoleic acid included, were quantified by GS/MS. In addition fasting glucose, insulin and additional metabolic parameters were obtained. In half of the patients an oral glucose tolerance test was performed. To obtain a qualitative measurement of beta-cell function, the disposition index was derived from the Insulinogenic index and the Matsuda index. Insulin resistance was estimated by the homeostatic model assessment of insulin resistance (HOMA-IR).

Results: Fasting insulin levels varied between 5.3 to 53 µU/ml in the study group and 17% of the patients showed normal fasting insulin levels. Palmitoleic acid constituted on average 6% of the total free fatty acid amount and correlated with the total amount of free fatty acids ($P<0.01$). The relative amount of palmitoleic acids was found to correlate negatively with basal insulin secretion ($P<0.05$) and HOMA-IR ($P<0.05$), in essence relatively high levels of palmitoleic acid was associated with lower basal insulin secretion at normal glucose levels. Total amount of free fatty acids was neither found to correlate with beta-cell function nor insulin resistance. Moreover, a significant relationship was established between the amount of palmitoleic acid and the disposition index ($P<0.05$), indicating a potentially important role of circulating palmitoleic acid levels in beta-cell function.

Conclusion: We conclude that palmitoleic acid may play a role in promoting beta-cell function and thereby serve in a protective manner against onset of T2DM in young obese individuals.

BMI cut-offs in childhood may not be valid predictors of metabolic risk: a 9-year longitudinal study

L.D. Voss, B.S. Metcalf, A.N. Jeffery, J. Hosking, T.J. Wilkin;
 Endocrinology & Metabolism, Peninsula Medical School, Plymouth, UK.

Background and aims: Categorical cut-offs at the 85th and 95th centiles, denoting overweight and obesity respectively, are widely applied to paediatric BMI charts. They imply that BMI tracks during childhood, and their aim is to alert the clinician to health risk. Although validated in adults, such cut-offs have not been evaluated for health risk in children. The aim of this study was to establish 1. How closely metabolic status tracks through contemporary childhood and 2. How well early BMI predicts later metabolic outcome

Materials and methods: BMI (SDS and $\geq 85^{\text{th}}$ centile, both derived from 1990 UK growth standards) and a composite metabolic risk z-score, combining insulin resistance (HOMA-IR), fasting triglycerides, total/HDL cholesterol ratio and mean arterial BP, were measured annually from 5-14y in 239 children (137 boys) from the EarlyBird cohort. Consistency (tracking) of BMI SDS and metabolic risk z-score were evaluated separately from 5y to 14y

by Pearson correlation (r), and across all annual time-points (by intra-class correlation coefficient (ICC). The ability of BMI at 5y to predict future metabolic status was established using linear regression.

Results: BMI SDS tracked moderately over the nine years of observation (all years: ICC=0.84, 5y v 14y: $r=0.62$, $p<0.001$), but the metabolic risk z-score tracked relatively poorly (all years: ICC=0.54, 5y v 14y: $r=0.30$, $p<0.001$). Although metabolic risk at 14y was slightly higher in children deemed overweight/obese at 5y than in those deemed normal weight at that age (0.25 v -0.07 z-scores, $p<0.01$), BMI at 5y only weakly predicted metabolic risk at 14y ($\beta=0.10$, $r=0.14$, $p=0.03$).

Conclusion: Truly longitudinal analyses of this kind have not been conducted before in contemporary children. Categorical cut-offs drawn on BMI centile charts, denoting overweight and obesity, give the impression of consistency and predictive value that may not exist in practice. This prospective cohort study suggests that metabolic status tracks poorly and that an early measure of BMI will not reliably predict later metabolic outcome. Use of such cut-offs, particularly in early childhood, may stigmatise unnecessarily and trigger inappropriate management.

The prevalence of the metabolic syndrome is comparable using the nation specific IDF, WHO and NCEP-ATP III criteria in Turkey

N. Dinççag¹, I. Satman¹, S. Kalaça², B. Omer³, K. Karşıdağ¹, T. Yılmaz¹, Y. Tütüncü¹, S. Genç³, S. Gedik¹, F. Türker¹, B. Cambaz¹, J. Toumlehto⁴, TURDEP Study Group;

¹Department of Endocrinology and Metabolism, İstanbul University, Turkey, ²Department of Public Health, Marmara University, İstanbul, Turkey, ³Department of Clinical Biochemistry, İstanbul University, Turkey, ⁴Department of Public Health, Helsinki University, Finland.

Background and aims: The metabolic syndrome (MS) is a term for a cluster of risk factors that increase the risk of developing cardiovascular diseases (CVD) and type 2 diabetes mellitus. However, the prevalence of MS in Turkey remains largely unknown. The aim of this study is to estimate the prevalence of MS using the nation-specific IDF criteria and compare it with the modified WHO and NCEP-ATP III criteria in a large Turkish survey.

Materials and methods: Data derived from a recently completed population-based survey of 26,499 adults (age ≥ 20 years, women 63%, response rate 89%) who participated in the cross-sectional 'Turkish Diabetes, Obesity, Hypertension Epidemiology Survey-II (TURDEP-II)'. After an overnight fast, blood glucose, lipid profile, insulin, and other biochemical parameters were measured, HOMA-IR calculated, blood pressure and anthropometrics were measured, and an OGTT was performed.

Results: First of all, population-specific cut-off values of waist in male and female were calculated by plotting waist against prevalent CVD using the ROC curve. We identified 95.5 cm for male and 90.5 cm for female as the best predictive cut-points for waist (sensitivity 70%, specificity 45%, both sexes). We used these values in the IDF criteria. The WHO criteria was slightly modified by excluding microalbuminuria. Results are summarized in the table below.

Conclusion: MS is one of the major public health problems in Turkey. When population specific adjustments are made, the prevalence is comparable by different methods proposed. However, MS may differ by age, sex and living environment. Thus, one strategic approach may not fit for all.

The prevalence of MS by different criteria in the adult population of Turkey (%)			
	IDF	WHO	NCEP-ATP III
Average	29.0	25.1	22.8
Male/Female	27.7/30.6*	25.1/25.0*	17.3/26.5*
Urban/Rural	30.2/27.6*	25.5/23.6*	23.7/21.8*

Relation between smoking habit and presence of metabolic syndrome: effect of gender and of previous increase in body weight

F. Tesi, G. Fabbri, C. Nardò, G. Petrini, G. Seghieri;
Dpt. of Internal Medicine, Spedali Riuniti, Pistoia, Italy.

Background and aims: Since previous population studies have shown that smoking habit is related to the presence of metabolic syndrome (MS), the aim of this study was to answer the following questions: first: is there any gender difference in the relation linking smoking habit and MS? And second: given that, as known, there is an inverse relationship between body weight and smoking, does the eventual association smoking-MS remain significant after adjustment for body weight increase during the previous decades?

Materials and methods: For the purposes of this study we used a database containing the data of 1429 subjects (527M/902F) who consecutively came to the dietetic outpatient clinic of our hospital in order to obtain dietetic prescription because suffering from overweight or obesity. In all subjects MS was assessed according to the presence of MS-ATP III criteria. The records of the database also provided the annotation of body weight at the age of approximately 18 years (BMI-18) as well as of smoking habit. Former smokers from a period of less than one year were excluded and all others were included in the group of non-smokers.

Results: Prevalence of MS was significantly higher among males, compared to females (27.5% vs. 15.2%; $p=0.0001$), similar to what happened to the prevalence of smokers (28% vs. 21%, $p=0.004$). Age and increase in body weight since age of 18yr were on average similar in both sexes (45 ± 14 (SD)yr in males and 46 ± 14 yr in females; $p=ns$, and 22 ± 12 Kg in males vs. 22 ± 13 Kg in females; $p=ns$), while BMI-18 was significantly higher among males, compared to females (24 ± 3 Kg/m² vs. 22 ± 3 Kg/m²; $p=0.0001$). When comparing smokers vs. non smoking subjects, the increase in body weight since age of 18yr resulted to be lesser in the group of smoking females (19 ± 12 Kg vs. 22 ± 12 Kg; $p=0.0001$), but not among males (22 ± 13 Kg vs. 22 ± 12 Kg; $p=ns$). After adjusting for age, BMI-18, increase in body weight and family history of diabetes the relative risk for MS was significantly associated to smoking habit equally in both sexes (OR:1.77;95%CI: 1.05-2.99 among males, and OR:1.78;95%CI:1.08-2.94 among females).

Conclusion: In this population of overweight-obese patients, smoking increases the relative risk of MS by about the 80% in both genders. Such increase seems to be independent of previous body weight changes from the age of approximately 18yr.

An altered activity in the autonomic nervous system assessed by 24-h Holter-ECG is related to both insulin resistance and visceral adiposity in healthy subjects with or without a family history of diabetes

M.K. Svensson¹, U. Wiklund², P. Rask³, J. Kullberg⁴, L. Johansson⁴, J.W. Eriksson^{5,6}, S. Lindmark⁷;

¹Dept of Molecular and Clinical Medicine/Nephrology, Sahlgrenska University Hospital Nephrology, Sahlgrenska University Hospital, Gothenburg, ²Dept of Biomedical Engineering & Informatics, Umeå University Hospital, ³Dept of Clinical Physiology, Örebro University Hospital, ⁴Dept of Radiology, Oncology and Radiation Science, Uppsala University, ⁵Dept of Molecular and Clinical Medicine, Sahlgrenska University Hospital, Gothenburg, ⁶AstraZeneca, R&D, Mölndal, ⁷Dept of Medicine, Umeå University Hospital, Sweden.

Background and aims: The aim of this study was to evaluate the role of the autonomic nervous system in the development of insulin resistance and type 2 diabetes (T2D).

Materials and methods: 23 healthy individuals with first-degree relatives with T2D (R) were compared with 24 control subjects without family history of diabetes (C). The groups were matched for age (46.8 ± 12.0 vs. 47.2 ± 11.7 years), BMI (25.1 ± 3.8 vs. 25.0 ± 3.1 kg/m²) and sex (M/F; 12/11 vs. 13/11). Insulin sensitivity was assessed by a hyperinsulinemic euglycaemic clamp (56 mU/m²/min). To assess the activity of the autonomic nervous system, power spectrum analysis of heart rate variability (HRV) was calculated from 24-h Holter-ECG recordings (fast Fourier transformation of R-R intervals related to normal-to-normal interbeat intervals). Computed tomography was performed to determine abdominal adipose tissue distribution.

Results: Insulin sensitivity, (M-value; mg/kg lbm/min), HbA1c, fasting blood glucose, serum insulin and adipose tissue distribution did not differ between

R and C. Total HRV spectral power (P_{tot}) and very low-frequency (P_{VLF}) power was lower in R during the 24 h ECG-recordings ($R\ 3.50\pm 0.17$, $C\ 3.61\pm 0.25$, $p=0.02$ and $R\ 3.28\pm 0.15$, $C\ 3.38\pm 0.21$, $p=0.03$, respectively). Insulin sensitivity (M-value) was negatively associated with low /high-frequency power ratio ($P_{LF/HF}$) ($r=-0.40$, $p=0.005$). The amount of visceral adipose tissue was positively associated with $P_{LF/HF}$ during the 24 h ECG-recordings ($r=0.34$, $p=0.03$). **Conclusion:** An increased ratio of sympathetic to parasympathetic nervous activity, assessed as $P_{LF/HF}$ in 24-h Holter-ECG recordings is associated with insulin resistance and visceral adiposity, and may contribute to the development of type 2-diabetes, which may be genetically linked to a reduced overall autonomic nerve activity.

315

Successful implementation of a community program of screening and three year primary prevention of type 2 diabetes with lifestyle modifications: DE-PLAN study

T. Acosta, A. Fernandez, M. Sanchez, M. Alonso, J. Pinilla, R. Tuesta, L. Sanchez, C. Martin, P. Marques, J. Tuomilehto, R. Gabriel;
IdiPAZ, Madrid, Spain.

Objectives: To detect individuals with high risk of type-2 diabetes (T2D) in primary care setting in Spain. To implement a lifestyle modification program to prevent T2D in high risk individuals.

Methods: 1) Screening program in individuals 45-74 years old using the FINDRISC. 2) Assessment of glucose metabolism status by OGTT in those with high risk (FINDRISC >14). 3) Lifestyle intervention (diet and physical activity): 3-month intensive program plus continuous programme). Setting: health centers of Madrid, Gredos, Arévalo, Segovia, Aranda de Duero (Castilla y León), and Talavera de la Reina (Castilla la Mancha) in Spain Year evaluations: OGTT, lifestyle and cardiovascular risk changes.

Results: In the total study population, screening with the FINDRISC was completed in 3056 individuals and 956 (31.4%) of them were classified as high risk (FINDRISC>14) for developing T2D. Among the high-risk people, screened-detected T2D (SD-T2D) was observed in 99 individuals (18.9%). The prevalence of any dysglycaemic condition (IFBG or IGT or SD-T2D) in the population was estimated around .59.5 %. The 76.9% of those classified as high risk (SD-T2D excluded) were enrolled in the intervention program.

Conclusion: Prevalence of both high risk for T2D, screening-detected T2D and dysglycemic status are quite high in the Spanish population. The FINDRISC questionnaire is a useful screening tool to detect these people. After 3 follow-up years the intervention program is still ongoing. The Primary Prevention of T2D is feasible to implement at Primary Care level in Spain.

316

Delay in incidence of type 2 diabetes among high-risk Spanish individuals following lifestyle intervention in real-life primary care

B. Costa¹, F. Barrio¹, J.-J. Cabré¹, J.-L. Piñol¹, X. Cos¹, B. Bolibar¹, J. Basora¹, C. Castell², J. Lindström³, J. Tuomilehto⁴, The DE-PLAN-CAT Research Group;

¹Diabetes and Metabolism Area, Jordi Gol Primary Care Research Institute. Catalan Health Institute, Reus-Tarragona-Barcelona, Spain, ²Department of Health, Generalitat de Catalunya, Barcelona, Spain, ³Diabetes Prevention Unit, National Institute for Health and Welfare, Helsinki, Finland,

⁴Department of Public Health, University of Helsinki, South Ostrobothnia Central Hospital, Seinäjoki, Finland.

Background and aims: Based on clinical trials, type 2 diabetes (T2D) can be prevented or delayed. The aim of this study was to assess the effectiveness of an active real-life primary care strategy in high-risk individuals for developing T2D.

Materials and methods: Multicenter, longitudinal cohort assessment (4 years) conducted in 18 primary health-care centres. Caucasian individuals without known diabetes aged 45-75 years were screened using (first step) the last version of the Finnish Diabetes Risk Score (FINDRISC; 0 to 26 points). A 2-hour 75 g OGTT test was carried out (second step). People with diabetes (FPG \geq 7 mM or 2hPG \geq 11.1 mM) at baseline were excluded. High-risk screenees with FINDRISC \geq 14 and/or prediabetes (IFG or IGT) based on the OGTT were invited to participate in lifestyle intervention: either (1) general information on diet and cardiovascular health without individualized programme, or (2) intensive DE-PLAN educational program (individualized or collective) periodically reinforced. OGTT was repeated yearly to determine T2D incidence.

An attempt was made to ascertain the T2D status also in people who dropped out from the programme prematurely, and they were included in the intention-to-treat (ITT) analysis. Median follow-up time was 36 months.

Results: A total of 2054 subjects were screened (81% response); 552 of them classified as having high T2D risk (26.9%), of whom 219 (39.7%) were included in the information group and 333 (60.3%) to the intensive education group. The two groups were comparable in terms of age (62/62 yrs), sex (64/68% women), BMI (31.2/31.1 kg/m²), FINDRISC score (16/16 points), FPG (5.3/5.2 mM) and 2hPG (7.1/6.9 mM). Drop-out rate was higher in the information group (11.6% vs. 9.4%, $p < 0.05$). At study close, 52 (44.4%) in the information group and 53 (25.6%) people in the intensive education group had developed T2D (42.3% relative risk reduction (RRR), $p < 0.001$). Respectively, 64 (54.7%) and 75 (36.2%) worsened their glucose status (relative decrease = 33.8%) and 6 (5.1%) and 27 (13%) shifted from prediabetes to normal glucose metabolism (relative increase = 155%). In the ITT analysis ($n = 552$ –3 deaths) the cumulative T2D incidence was 28.9 vs. 18.4% (36.3% RRR, $p = 0.004$).

Conclusion: A substantial reduction in T2D incidence can be obtained in real-life primary health care setting by intensive lifestyle intervention among high-risk subjects identified with the simple FINDRISC tool.

Long term high dose fish oil supplementation does not alter glucose disposal in older subjects with impaired glucose regulation

L.F. Clark¹, M. Thivierge¹, S.C. McGeoch², P. Abraham², D.W.M. Pearson², G.E. Lobley¹

¹Rowett Institute of Nutrition and Health, University of Aberdeen,

²Department of Diabetes, Aberdeen Royal Infirmary, UK.

Introduction: Animal studies have shown improvements in insulin sensitivity and glucose tolerance with long chain (LC) n-3 polyunsaturated fatty acids (PUFA) in some species. Possible mechanisms for improving insulin sensitivity with fish oils include increasing the fluidity of membranes (by incorporation of LC n-3 PUFA) and by reducing inflammation. Human studies have reported a range of responses to LC n-3 PUFA. In a review of 21 studies assessing changes in insulin sensitivity with LC n-3 PUFA in humans, 2 showed a positive effect, 9 responded negatively and 10 were unchanged. Most studies with negative results reported on people with type 2 diabetes treated with oral hypoglycaemic therapy. Such variability in human studies may be due to differences in the quantity and duration of supplementation used in the experimental models and the extent of metabolic decompensation. Recent animal studies have reported that muscle membranes need to be enriched to 14% with LC n-3 PUFA for insulin sensitivity to show a significant improvement. We sought to establish the effects of 9 months of high dose LC n-3 PUFA supplementation on insulin sensitivity to glucose in a group of individuals with impaired glucose regulation (IGR).

Methods: 33 subjects (20 men, 13 women, mean age: 61 years, range: 51–68) with IGR (impaired fasting glycaemia $n = 8$, impaired glucose tolerance $n = 13$, type 2 diabetes, diagnosed at screening not requiring medication for glycaemic control and HbA1c $< 7\%$, $n = 5$ or a random glucose > 5.5 mmol/l, $n = 7$) were enrolled for a paired placebo controlled double-blind study. Mean BMI was 32.8 kg/m² (SD: 5.9 kg/m²). Subjects were paired according to sex, glucose disposal during clamp 1 and body composition. After pairing they were supplemented with 6g fish oil (3g LC n-3 PUFA) or 6g maize oil (control) daily. The dose of fish oil used in this study is the highest recommended by the UK Food Standards Agency. At the beginning and end of the study (clamps 1 and 2), subjects underwent a 2h period of glucose kinetics to assess fasting endogenous glucose production (EGP) using D-[6,6-²H₂]glucose followed immediately by 3h hyperinsulinaemic-euglycaemic clamp (40 mU/m²/min). The dextrose used in the clamp was also labelled with D-[6,6-²H₂]glucose to allow the suppressed EGP to be determined. Statistical analysis was performed using the restricted maximum likelihood approach.

Results: Mean total glucose disposal (infused plus non-suppressed EGP) did not differ between clamps 1 and 2 (6.37 vs. 6.95 mg/kg fat free mass (FFM)/min; $P = 0.18$) or the different oil supplements ($P = 0.88$) or gender ($P = 0.27$). Overall, there were no changes in fasting EGP between clamps (2.74 vs. 2.68 mg/kg FFM/min; $P = 0.33$). EGP was also not affected by supplement ($P = 0.56$) or sex ($P = 0.22$). Overall, suppressed EGP during the clamp decreased during the study (76.7% vs. 68.7%; $P < 0.01$). Men showed no differences between the two oils but in women the suppressed EGP decreased by 11.3% on fish whilst suppressed EGP did not change in the maize oil group ($P =$

0.047). The mean proportion of total glucose disposal accounted for by non-suppressed EGP was only 13.7% (SD: 9.5%).

Conclusion: Our results indicate that long term, high dose LC n-3 PUFA supplementation does not alter fasting endogenous glucose production or glucose disposal in subjects with impaired glucose regulation.

High dietary niacin intake strongly and independently predicts decrease in liver fat during a lifestyle intervention in humans

C. Ketterer¹, R. Wagner¹, K. Dudziak¹, K. Kantartzis¹, J. Machann², F. Schick², M. Graf¹, S. Kümmerle¹, H.-U. Häring¹, A. Fritsche¹, N. Stefan¹

¹Division of Endocrinology, Diabetology, Nephrology, Vascular Disease and Clinical Chemistry, ²Section on Experimental Radiology, University Hospital Tübingen, Germany.

Background and aims: Nicotinic acid (niacin) has well known favourable effects on serum lipids in humans. This is thought to be mediated mainly through the inhibition of adipose tissue lipolysis and, thereby, the flux of fatty acids to the liver. In addition, niacin directly inhibits the activity of diacylglycerol acyltransferase 2, which catalyzes the final step in triglyceride synthesis and putatively increases hepatic lipid oxidation. Thus, it may be a promising tool to treat nonalcoholic fatty liver disease (NAFLD). Hence, we hypothesized that a high dietary intake of niacin may be associated with a larger decrease in liver fat during a lifestyle intervention.

Materials and methods: A total of 202 nonalcoholic, apparently healthy subjects at risk for type 2 diabetes and cardiovascular disease underwent a lifestyle intervention with increase in physical activity and diet modification and provided information about their diet. The composition of the diet was estimated with a validated computer program using 2 representative days of a 3-day diary. Total-, subcutaneous abdominal- and visceral adipose tissue was measured by magnetic resonance tomography and liver fat by magnetic resonance spectroscopy at baseline and after 9 months of follow-up.

Results: During the intervention total-, subcutaneous abdominal- and visceral adipose tissue and liver fat decreased (all $p < 0.0001$). The largest decrease was found for liver fat (-32%, $p < 0.0001$). However, there was a large variability in this change. A high intake of niacin strongly and independently of age, gender, body fat and energy intake predicted a larger decrease in liver fat ($p < 0.0001$) and subjects in the highest (4th) quartile of niacin intake had the largest decrease in liver fat (1st: -22%; 2nd: -21%; 3rd: -39%; 4th: -41%). This relationship was also independent of high cardiorespiratory fitness ($p = 0.0004$), another strong predictor of change in liver fat during the intervention. Furthermore, among 58 subjects with NAFLD at baseline, a resolution of NAFLD was found in 23 individuals, and for 1 standard deviation increase in niacin intake at baseline the odds ratio for resolution of NAFLD was 1.77 (95% CI, 1.00–3.43).

Conclusion: In conclusion, high niacin intake at baseline strongly predicted the decrease in liver fat during a lifestyle intervention in humans. In addition, niacin intake was associated with change in liver fat independently of adiposity, total energy intake and cardiorespiratory fitness, suggesting specific effects of niacin on hepatic lipid metabolism.

319

Leisure time physical activity limits inflammation in individuals with impaired glucose tolerance

M.I. Hellgren¹, P.-A. Jansson², C.A. Larsson³, L. Rastam³, U. Lindblad^{1,4}

¹Department of Primary Health Care, University of Gothenburg, ²The Wallenberg laboratory, University of Gothenburg, ³Department of clinical sciences, Lund University, Malmö, ⁴Skaraborg Institute, Skövde, Sweden.

Background and aims: Inflammatory markers have been associated with type 2 diabetes (T2D) and impaired glucose tolerance (IGT). There is evidence that lifestyle interventions, using weight loss and physical activity, prevent or postpone progression to T2D in individuals with IGT. However, it is unknown whether leisure time physical activity (LTPA) is associated with inflammation among patients with IGT in a representative population.

Methods: Questionnaires, including data concerning LTPA (4-graded scale; 1+2 defined as sedentary, 3+4 defined as physically active), anthropometric measures, an oral glucose tolerance test (OGTT), and C-reactive protein (CRP) were collected from a random sample of 2816 individuals, 30–75 years old, in a cross-sectional study from the South-west of Sweden.

Results: The prevalence of IGT was 7.6% (n=213). CRP was significantly higher in women with IGT compared to women with normal glucose tolerance; mean difference 1.5 (CI 0.7:2.3), $p<0.001$. However, this was not seen in men, $p=0.290$. Also in sedentary women with IGT levels of CRP were significantly higher; $\Delta 1.8$ (0.8:2.8), but not in those who were physically active $\Delta -0.4$ (-1.5:0.8). Correspondingly, CRP was higher in sedentary men with IGT $\Delta 1.3$ (0.03:2.6), but not in physically active men $\Delta 0.4$ (-1.1:1.8). Self-reported LTPA was inversely associated with CRP ($p=0.024$), which was supported by a consistent association between resting heart rate (proxy for fitness) and CRP ($p=0.001$). All tests were adjusted for differences in age, BMI, and smoking.

Conclusion: In an unselected population physical activity is associated with low systemic inflammation in individuals with IGT.

Risk factors in the Portuguese population with diabetes: diabetes prevalence study in Portugal

J.F. Raposo¹, L. Gardete-Correia¹, S. Massano-Cardoso², A.C. Mesquita¹, J.M. Boavida^{3,4};

¹Portuguese Diabetes Association, Lisbon, ²Hygiene and Social Medicine Institute, Coimbra, ³Portuguese Diabetes Programme, Lisbon, ⁴Portuguese Society of Diabetology, Lisbon, Portugal.

Background and aims: The objectives of this study were to determine the prevalence of risk factors in type 2 diabetes in the Portuguese population aged between 20 and 79 years

Materials and methods: Taking into account the number and distribution of inhabitants (7,657,529 people aged between 20 and 79 years), 122 representative units were selected. The total sample participating in the study comprised 5,167 subjects. Data were standardized for the Portuguese population aged 20–79 years. Arterial hypertension (IDF/ESC/EASD) systolic values ≥ 130 mm hg and diastolic ≥ 80 mm hg were considered hypertension. Excess weight and obesity - were defined using the BMI (body mass index), IDF/ESC/EASD criteria: Excess weight ≥ 28 kg/m² and obesity ≥ 30 kg/m². Abdominal perimeter ≥ 94 in men and 80 in women was considered abnormal (IDF criteria).

Results: Arterial hypertension - (TA $\geq 130/80$) was found in 70.9% (95% CI 68.0% to 74.0%) of diabetic people in both sexes, 75.9% in males and 66.4% in females. Only 46.8% of the men and 58.4% of the women with arterial hypertension were taking anti-hypertensive medication. LDL cholesterol - Only 10.8% (95% CI 7.8% to 13.0%) of the women with diabetes had LDL Cholesterol <100 mg/dl and only 15.5% (95% CI: 12.4% to 19.1%) of the men with diabetes had LDL Cholesterol <100 mg/dl. Triglycerides - were < 150 mg/dl in 57.7% (CI 95%: 54.4%-60.8%) of people with diabetes, with or without medication. HDL - Cholesterol - 39.7% (95% CI: 35.3% to 44.4%) of the female population had values < 50 mg/dl and 21.2% (95% CI: 17.7% to 25.2%) of the males had values < 40 mg/dl. Abdominal perimeter (AP) - The average abdominal perimeter in diabetic men was 102.4 cm (95% CI 101.3 to 103.4); median = 103. It was > 94 cm in 77.1% of the total. The average AP in non-diabetics was = 97 (95% CI 96.4 to 97.6) median 97, with AP > 94 cm in 59.6% of the total. In diabetic women, the average abdominal perimeter was 101.1 (95% CI 99.9 to 102.2); median = 101. In 96.3% of all diabetic women it was > 80 cm. The average AP of non-diabetic women was = 92.8 (95% CI 92.3 to 93.3) median 92.2. Body Mass Index (BMI) - A significant difference was detected between the figures in diabetic people and non-diabetics and also between men and women. Non-diabetic men have an average BMI of 27 (95% CI 27.3 to 27.7), diabetic men - average BMI 29.3 (95% CI 29.0 to 29.7), variance analysis - $F=65.247$; $p<0.0001$; the figures for women are: average BMI in non-diabetic women 28.2 (95% CI 28.0 to 28.4) and in diabetic women 31 (30.5 to 31.5) - variance analysis - $F=105.6253$; $p<0.0001$.

Conclusion: Diabetes is a chronic disease with a high prevalence in Portugal, one of the highest in Europe. In addition to glycemic control there is a marked failure in the control of risk factors particularly blood pressure, dyslipidemia and obesity. A significant number of people take medication but remain uncontrolled. Strategies to underline these factors must be implemented not only among patients but also among health professionals.

Prevalence of abnormal glycaemia and its associated risk factors in rural adult Bangladeshi population

J. Akter¹, A. Akhter², K. Fatema², A. Afroz³, L. Ali⁴, A. Hussain⁵;

¹Department of Reproductive and Child Health, ²Department of Epidemiology, ³Department of Biostatistics, ⁴Department of Biochemistry and Cell Biology, Bangladesh Institute of Health Sciences (BIHS), Dhaka, Bangladesh, ⁵Department of International Health, University of Oslo, Norway.

Background and aims: Substantial racial heterogeneity in diabetes leads to the necessity of conducting epidemiological studies in different communities. Such studies are still inadequate in Bangladeshi population, particularly in

truly respective rural areas. The objective of the present study was to explore the prevalence of diabetes, prediabetes and their associated risk factors in a rural adult Bangladeshi population.

Materials and methods: This population based cross-sectional study was conducted through diabetes screening camps arranged in remote rural areas of North Western Bangladesh, which included a total of 836 participants (468 male, 368 female), aged at or above 30 years. Clinical and anthropometric data were collected by using appropriate techniques. WHO guideline for Asian population was used to identify overweight and obese. Diabetes, impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) were diagnosed by WHO criteria after a 2 sample OGTT. Serum glucose was estimated by glucose oxidase method. Multiple regression analysis was used with adjustment for potential confounders.

Results: The prevalence of diabetes and prediabetes (both IGT & IFG) were 7.2% (95% CI 5.4–9.0) and 6.5% (95% CI 4.8–8.2) respectively. It differs between male and female, but it increased with age. The mean BMI was significantly higher in the diabetic (23.9 ± 4.7) and prediabetic (23.1 ± 4.4) groups compared to the nondiabetic group (21.7 ± 3.6 ; $p < 0.006$ – 0.002). A similar difference was found in case of WHR (0.97 ± 0.09 in diabetic, 0.92 ± 0.06 in prediabetic and 0.89 ± 0.07 in nondiabetic groups, $p < 0.05$). On Pearson's correlation analysis FBG ($r = 0.119$, $p = 0.001$) and 2HBG ($r = 0.125$, $p = 0.001$) both showed significant correlation with BMI. FBG ($r = 0.226$, $p = 0.001$) and 2HBG ($r = 0.125$, $p = 0.001$) also showed significant correlation with WHR. On multiple regression analysis when the confounding effects of age and sex were adjusted, BMI and WHR showed significant association for the occurrence of diabetes in this population.

Conclusion: A high prevalence of both diabetes and prediabetes exists in rural population and it seems to be associated with obesity. Preventive programs, particularly targeted to body weight management through lifestyle modification should be strengthened even in remote rural areas.

Incidence trend of type 2 diabetes in children and adolescents in Germany

J. Rosenbauer¹, A. Stahl¹, C. Baechle¹, K. Castillo¹, R.W. Holl², G. Giani¹, German Pediatric Surveillance Unit (ESPED), the DPV-Science Initiative, Competence Network Diabetes mellitus;

¹Institute of Biometrics and Epidemiology, German Diabetes Centre, Düsseldorf, Germany, ²Institute of Epidemiology, Ulm University, Germany.

Background and aims: An increasing incidence of type 2 diabetes in children and adolescence has been observed in native populations. A rising occurrence of type 2 diabetes is also under discussion in Europe. Aim of the present study was to estimate incidence and time trend of type 2 diabetes in children 5–19 years of age in the large risk population of the German federal state North Rhine-Westphalia (NRW) during 2002–2009.

Materials and methods: During the study period the average risk population was 2.94 million children. The North Rhine-Westphalian diabetes incidence register ascertains newly diagnosed cases of type 2 diabetes by means of three data sources: the prospective hospital-based active surveillance system ESPED, annual inquiries among paediatric, internal and general medical practices, and the computer-based documentation system DPV founded for quality control and scientific research in paediatric diabetes care. Completeness of ascertainment was estimated by the capture-recapture-method. Point and interval estimates (95%-CI) of incidence rates (per 100,000 person-years) were based on Poisson distribution and corrected for ascertainment. Age- and sex-standardized rates were estimated by the direct method using equal weights. Poisson regression analysis was applied to assess time trends.

Results: During 2002–2009 a total of 233 newly diagnosed diabetic children aged 5–19 years (98 boys, 135 girls) were registered. Ascertainment was estimated to be 82.3% (95%-CI: 74.2%–92.5%) complete. The age- and sex-standardized overall incidence rate was 1.20 (1.07–1.34). The age-standardized incidence among boys (1.03, 0.85–1.21) was lower than among girls (1.38, 1.17–1.59, $p = 0.005$). Incidence depended significantly on age ($p < 0.001$). Age-specific estimates for age groups 5–9, 10–14, and 15–19 years were 0.26 (0.15–0.38), 1.24 (1.00–1.49), and 2.1 (1.79–2.41), respectively. Annual incidence rates ranged between 0.80 in 2008 and 1.74 in 2009. No significant time trend in the incidence was observed, the average annual incidence increase was estimated as 0.2% (–4.9%–5.6%, $p = 0.934$). The incidence did also not significantly change over time in boys (annual increase: 1.8% (–6.0%–10.2%, $p = 0.669$), girls –0.1% (–7.6%–6.3%, $p = 0.790$), and the three age-groups (5–9

years: –13.9% (–30.2%–6.1%, $p = 0.160$), 10–14 years: 2.9% (–5.8%–12.3%, $p = 0.530$), 15–19 years: 0.4% (–6.3%–7.6%, $p = 0.913$).

Conclusion: Based on a large risk population, no significant change in the incidence of type 2 diabetes in children and adolescents could be observed in this study. However, since the annual number of newly diagnosed type 2 diabetic patients is very small, the trend should be followed for a longer time period. Undiagnosed cases of type 2 diabetes were not covered by this study, thus the incidence level is underestimated to a certain extent. But the under-coverage can be assumed not to affect the incidence trend seriously. Based on the actual incidence estimate, about 150 children in the age-group 5–19 years are newly diagnosed with type 2 diabetes per year in Germany.

Racial disparities in the age of diagnosis of type 2 diabetes mellitus and impaired glucose regulation in a multi-ethnic high-risk population in Singapore

J. Khoo, B. Ng, E. Tan, T.-L. Tay, J.-P. Foo, S.-B. Soh, L.-W. Cho, V. Au, R. Chen;

Changi General Hospital, Singapore.

Background and aims: The prevalence of type 2 diabetes mellitus has been increasing rapidly in Asia. Asians, especially individuals of Indian (South Asian) descent, are at greater risk of developing diabetes and cardiovascular disease. However, the effect of ethnicity on age of diagnosis of diabetes in Southeast Asia has not been established. We aimed to compare the prevalence and age at diagnosis of impaired fasting glucose (IFG), impaired glucose tolerance (IGT) and diabetes in different races in a high-risk Southeast Asian population in Singapore.

Materials and methods: All patients without a history of diabetes who had a 75g oral glucose tolerance test and concurrent HbA1c performed in our tertiary hospital from January 2001 to October 2009 were included in the study. All patients were deemed to be high-risk due to positive family history of diabetes, previous gestational diabetes, random plasma glucose level > 7.0 mmol/L, obesity or polycystic ovarian syndrome. Data was obtained through review of case records and laboratory databases. Diabetes mellitus, IFG and IGT were diagnosed based on the World Health Organization criteria. Differences between races were tested with one-way analysis of variance and multiple comparisons with post-hoc Bonferroni correction in SPSS 16.0. All values are given as mean \pm SD. A p value < 0.05 was considered significant.

Results: There were 659 patients (70.7% Chinese, 19.7% Malays, 9.6% Indians) (343 males, 52.0%). Mean age was 54.2 ± 15.4 years (range 14–96) and mean body mass index (BMI) 26.2 ± 5.8 kg/m² (range 14.7–52.7). Five hundred and thirty four patients (81.0%) had impaired glucose regulation (IGR) or diabetes. Patients of Indian ethnicity were diagnosed with diabetes and IGR at a significantly younger age than Chinese and Malay patients, and had higher fasting plasma glucose (FPG) ($p = 0.02$) and HbA1c ($p = 0.04$) than the Chinese majority (Table 1).

	Chinese (n = 369)	Malay (n = 111)	Indian (n = 54)	p value (Malay vs Indian)	p value (Chinese vs. Indian)
Prevalence (%) of diabetes and IGR	77.2 (369/466)	85.3 (111/130)	85.7 (54/63)	NS	NS
Age	56.7 ± 15.5	52.4 ± 13.3	47.6 ± 13.6	0.02	< 0.001
BMI (kg/m²)	25.4 ± 4.8	28.8 ± 7.1	27.0 ± 5.5	NS	NS
FPG (mmol/L)	7.14 ± 2.49	7.29 ± 2.22	7.87 ± 2.66	NS	0.02
2HPG (mmol/L)	14.04 ± 5.10	13.52 ± 5.74	14.33 ± 5.17	NS	NS
HbA1c (%)	6.97 ± 1.55	7.14 ± 1.53	7.37 ± 2.02	NS	0.04

Table 1. Comparison of age, BMI, FPG, 2HPG and HbA1c between the races in Southeast Asian subjects diagnosed with diabetes and IGR (n = 534). 2HPG = 2-hour post-load plasma glucose. NS = not significant.

Conclusion: Indian patients with risk factors for diabetes present at a younger age with more severe dysglycaemia compared with Chinese and Malay patients, despite no significant difference in BMI, and may need earlier screening. It is important to consider the racial disparities and differing risks of developing diabetes amongst different races when screening a high-risk multi-ethnic population.

324

Diabetes epidemic in Turkey: results of the second population-based survey of diabetes and risk characteristics in Turkey (TURDEP-II)

I. Satman¹, B. Omer², Y. Tutuncu¹, S. Kalaça³, S. Gedik¹, N. Dinççağ¹, K. Karsıdag¹, T. Yılmaz², S. Genç², A. Telci³, B. Çakır⁴, J. Tuomilehto⁵, TURDEP Group;

¹Endocrinology and Metabolism, İstanbul University, Turkey, ²Department of Clinical Chemistry, İstanbul University, Turkey, ³Department of Public Health, Marmara University, İstanbul, Turkey, ⁴Department of Endocrinology and Metabolism, Atatürk Education and Research Hospital, Ankara, Turkey, ⁵Department of Public Health, Helsinki University, Finland.

Background and aims: Because of the rapid change in lifestyle in Turkey, there is concern of emerging diabetes epidemic. We conducted the 2nd Turkish Diabetes Epidemiology Study (TURDEP-II) to determine the prevalence of diagnosed and undiagnosed diabetes (DM), preDM and their time trends, and to identify risk factors associated with DM in adult Turkish population. The field survey was performed from Jan to July 2010, approx. 12 yrs after the 1st survey, TURDEP-I

Materials and methods: A population-based random sample of 26,499 adults (≥20 yrs, women 63%, response rate 89%) participated in this cross-sectional survey. After an overnight fast, fasting blood glucose (FBG), and other biochemical parameters were measured in all participants, then an OGTT was performed to identify undiagnosed DM and preDM (impaired fasting glucose, IFG or impaired glucose tolerance, IGT) in non-diabetic participants.

Results: The prevalence of DM was 16.5% (undiagnosed 7.5%), translating to 6.5 million adults with DM in Turkey. The prevalence of DM age-standardized to TURDEP-I, world and European populations was 13.7%, 17.1% and 15%, respectively. The prevalence was higher in women than in men ($p=0.004$). The prevalence of isolated IFG, IGT and combined preDM was 14.5%, 7.9%, and 8%, respectively, and that of obesity 34.2% and hypertension (HT) 31.3%. Compared to TURDEP-I; DM, IGT, and obesity increased by 90%, 106% and 40%, respectively. During the 12 yrs weight and waist increased on average by 8 kg and 7 cm in men, and by 6 kg and 6 cm in women. Multiple logistic regression analysis revealed that in female; age (OR; 95%CI: 1.046; 1.041–1.050), waist (1.019; 1.014–1.024), BMI (1.016; 1.005–1.028), HT (2.008; 1.635–2.465), and living in regions other than the North were independently associated with prevalent DM, while living in rural (0.883; 0.798–0.977), less number of meals (0.347; 0.270–0.445), high education level (0.454; 0.343–0.599), and quit smoking (0.700; 0.522–0.939) were associated with less risk of DM. On the other hand, in male; age (1.048; 1.042–1.054), waist (1.011; 1.004–1.019), BMI (1.048; 1.027–1.070), HT (1.797; 1.334–2.420), living in the South and the West (1.358; 1.109–1.663), sedentary lifestyle (1.379; 1.128–1.685), family history of DM (2.522; 2.196–2.897) were independently associated with prevalent diabetes; whereas living in rural (0.769; 0.670–0.882), less number of meals (0.321; 0.231–0.447), and being widowed or divorced (0.531; 0.304–0.927) were associated with less risk of DM.

Conclusion: These results from one of the largest nationally representative survey carried out thus far indicate that DM has rapidly become a major public health challenge in Turkey and underline the urgent need for the development of national strategies aimed at the prevention, detection, and treatment of DM in the general Turkish population.

Hospital Universitario Central de Asturias, Oviedo, ¹¹EAP Raval Sud,

Institut Català de la Salut. Red GEDAPS. Primary Care. Unitat de Suport a

la Recerca (IDIAP – Fundació Jordi Gol), Barcelona, ¹²Endocrinology and

Nutrition, Hospital de Cruces, Baracaldo, Spain.

Background and aims: The Di@bet.es study is a national, cross-sectional population-based survey of diabetes, obesity and other cardio metabolic risk factors and their association with lifestyle, promoted by the Spanish National Diabetes Strategy and carried out by the Spanish Society of Diabetes (SED) and CIBER of Diabetes and Related Metabolic Diseases (CIBERDEM).

Design: Population-based, cross-sectional, cluster sampling. Target population: The entire Spanish population. Sample: 5728 subjects in 100 clusters (health centers or the equivalent in each region) randomly selected with a probability proportional to population size. Participation: 57%. Variables: Clinical and demographic structured survey, lifestyle survey (physical activity and food consumption frequency questionnaires), quality of life survey, physical examination (weight, height, BMI, waist, hip, blood pressure), oral glucose tolerance test (75g) (WHO 1999 criteria).

Results: About 30% of the population had some carbohydrate disturbance. The overall prevalence of DM adjusted for age and sex was 13.8% (CI95%= 12.8–14.7%). Of these, about half had unknown diabetes: 6.0% (CI95%= 5.4 to 6.7%). The age and sex adjusted prevalences of isolated IFG, isolated IGT and combined IFG-IGT were 3.4% (CI95%= 2.9–4.0%), 9.2% (CI95%= 8.2–10.2%) and 2.2% (CI95%= 1.7–2.7%) respectively. The prevalence of diabetes and other disorders increased significantly with age ($p < 0.0001$) and was higher in men than in women ($p < 0.001$).

Conclusion: The di@bet.es study shows, for the first time, prevalence results of Diabetes and Impaired glucose regulation in a representative sample of the Spanish population.

Comparison of measures of general adiposity and body fat distribution as predictors of type 2 diabetes in Korean adults

C.-H. Kim¹, H.-K. Kim², J.-Y. Park³, K.-U. Lee³;

¹Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Kyeonggi-do, ²Health Promotion Center, Asan Medical Center, Seoul,

³Internal Medicine, University of Ulsan College of Medicine, Seoul, Republic of Korea.

Background and aims: Not only general measures of obesity, such as body mass index or percent body fat, but also measures of central body fat distribution, such as waist circumference or waist-to-height ratio, are strongly associated with the risk of type 2 diabetes. However, it is not clear which anthropometric measurements of obesity best predict risk of type 2 diabetes. We compared various anthropometric measures of obesity and body fat distribution for their ability to predict development of diabetes, and investigated whether BMI modified the effect of body fat distribution on diabetes risk in Koreans.

Materials and methods: We analyzed the anthropometric and laboratory data of 9,432 Korean adults (age 20–79 years, 6,260 men and 3,172 women) who underwent routine medical check-ups in 2005 (baseline) and in 2010 (follow up). After excluding patients with diabetes at baseline, 8,748 subjects (5,707 men and 3,041 women) were included for the analysis. Body weight, height, waist circumference, and bioelectrical impedance (to calculate fat mass and percent body fat) were measured at baseline. Diabetes was defined as fasting plasma glucose ≥ 7.0 mmol/l, HbA1c $\geq 6.5\%$, or taking anti-diabetic medica-

tions. Receiver-operating characteristic (ROC) analysis was used to compare the ability of the parameters to predict development of type 2 diabetes.

Results: Among the 8,748 participants who were non-diabetic at baseline, a total of 308 subjects (242 men and 66 women) developed diabetes during 5 years. Each of the anthropometric parameters of general obesity (body mass index [BMI], fat mass, percent body fat) and central body fat distribution (waist circumference [WC] and waist-to-height ratio [WHtR]) was a good predictor of type 2 diabetes. However, when area under the ROC curves (AUCs) were compared, BMI (0.697, 0.669–0.725 [95% CI]), WC (0.709, 0.682–0.736), and WHtR (0.718, 0.692–0.743) were better predictors of diabetes risk than fat mass (0.672, 0.643–0.700) or percent body fat (0.657, 0.628–0.686). There was no significant difference between BMI, WC, and WHtR. When the participants were divided into 3 subgroups according to BMI, WHtR and WC were better predictors than BMI or fat mass in the low BMI (< 23 kg/m²) group. In the group with BMI > 27 kg/m², there was no significant difference between WHtR, WC, and BMI.

Conclusion: Throughout its range, BMI, WC, and WHtR were excellent predictors of type 2 diabetes in Koreans. However, in subjects with low BMI, measures of central body fat distribution is more useful than measures of general obesity in predicting type 2 diabetes risk. Table. Area under the ROC curves (AUC) for each of the anthropometric parameters in predicting type 2 diabetes

	AUC (95% CI)		
	BMI < 23 kg/m ²	BMI 23–27 kg/m ²	BMI > 27 kg/m ²
WHtR	0.706 (0.630–0.782) ^{a,b}	0.610 (0.570–0.650) ^{a,b,c}	0.593 (0.532–0.653) ^{b,c}

Risk determinants for type 2 diabetes

L. Gardete-Correia¹, J.M. Boavida¹, J.F. Raposo¹, A.C. Mesquita¹, S. Massano-Cardoso²

¹Portuguese Diabetes Association, Lisbon, ²Hygiene and Social Medicine Institute, Coimbra, Portugal.

Background and aims: Diabetes is a growing worldwide problem. In 1995 the prevalence of diabetes in Portugal was estimated to be about 5.1% of the population. In 2010 the first national study on the prevalence of diabetes (PREVADIAB) revealed a prevalence of 12.3% of the adult population aged between 20 and 79 years old. With this subsequent analysis we aimed to find risk determinants for type 2 diabetes.

Materials and methods: Using the 2001 Portuguese Census, a random sample of people aged between 20 and 79 years was selected from 122 locations representative of the distribution of the Portuguese population. Demographic characteristics were registered and an OGTT was performed. Diabetes WHO criteria were used for the diagnosis of diabetes.

Results: The total sample consisted of 5167 people that corresponds to an 83.8% response rate. A total prevalence of diabetes (diagnosed and undiagnosed) of 12.3% (CI 10.8–12.6%) was found with 43% of undiagnosed cases. The highest prevalence was in male gender (14.6% vs 10.2% in females) and in older groups (2.0% in the group 20–39 years, 12.8% in the group 40–59 years old and 27.1% in the 60–79 years old). People with the lowest level of literacy (not finishing first level of education) had a prevalence of 30.3%, different from the ones with the first level (19.4%) and the secondary level (7.9%) and university level (6.6%). In the group with BMI >30 the diabetes prevalence was 19.5%, also different from the group with BMI between 25–30 (12.1%) and the group with normal BMI (5.5%).

Conclusion: The diabetes growing prevalence raises governments' and health systems' concerns. In this study we showed an average prevalence of 12.3% in an adult population. As in other countries gender differences were found, higher in men than women. According to the known physiopathology of type 2 diabetes, we also found that the prevalence of diabetes has a strong correlation with BMI. However, the greatest difference between groups was the literacy level, showing that the lowest level of literacy was related to the highest prevalence of type 2 diabetes. This could be one of the greatest risk determinants for type 2 diabetes.

Vitamin D levels and type 2 diabetes in a Spanish population

F.C. Soriguer¹, I. Gonzalez-Molero¹, S. Morcillo¹, S. Valdes¹, P. Botas², E. Delgado², G. Rojo¹, E. Menendez², G. Oliveira¹

¹Carlos Haya Hospital.Endocrinology and Nutrition Service, Málaga,

²Asturias Central Hospital.Endocrinology and Nutrition Service, Oviedo, Spain.

Background and aims: Several studies suggest a complex relationship between the presence of insulin resistance or diabetes and vitamin D / iPTH levels. The aim of this study has been to evaluate the relationship between vitamin D and iPTH levels and the status of carbohydrate metabolism in a representative sample of the Spanish population.

Materials and methods: The study was conducted in two population of northern and southern Spain, evaluated in the same period of time and with a similar methodology: The Pizarra study (Málaga) and Asturias study. Subjects in both groups underwent clinical and anthropometric assessment survey, a blood test (fasting glucose and insulin, creatinine, calcium, phosphorus, 25OH vitamin D, iPTH) HOMA-IR (homeostatic model assessment-Insulin resistance) and an OGTT (oral glucose tolerance test). The number of subjects included was 1182. To calculate the statistical difference between the means of continuous variables we used the ANOVA test for quantitative and the Chi2 test for qualitative variables. The strength of association between two variables was measured using the Odds Ratio (OR).

Results: The mean age of participants was 50.3 ± 14.4 years (range: 20–83 years), with 57% female and 43% male. The mean of 25-hydroxyvitamin D and iPTH were: 22.46 ng / mL and 42.29 pg / mL, respectively. 65.6% had normal fasting glucose and OGTT, 6.45% had impaired fasting glucose, 8.15% carbohydrate intolerance, 9.85% new diagnosed diabetes and 9.93% known diabetes. 25-hydroxyvitamin D levels in these groups were, respectively: 23.43, 21.45, 22.97, 21.82 and 23.22 (p 0.034) and iPTH : 45.1, 48.26, 45.99, 49.31 and 41.08 (p0.001)both adjusted for age, sex, BMI and season. The percentage of patients with 25- hydroxyvitamin D levels below 20 ng / ml was different in the five groups: 30.9%, 35.5%, 37.5%, 49.1% and 36.8%(p0.014). Vitamin D levels were significantly different for different values of HOMA-IR: for quartile 1 (Homa <1.07): 25.85; for quartile 2 (Homa 1.07– 1.73): 22.94; for quartile 3 (1, 74– 2.95): 22.54 and for quartile 4 (> 2.95): 22.05 (p 0.041, all adjusted for age, sex, BMI and season).

Conclusion: 1. One-third of the subjects studied have 25 hydroxyvitamin D levels below 20 ng / mL, 2. The higher the insulin resistance (measured by HOMA-IR) the lower the levels of vitamin D, 3. Patients with undiagnosed diabetes have 25hydroxyvitamin D levels significantly lower and iPTH significantly higher than normal population

PS 008 HbA_{1c} in prediction and diagnosis

329

The OGTT is a better tool for detection of diabetes, impaired glucose regulation and impaired insulin secretion and action than HbA_{1c}: the GENFIEV study

C. Bianchi¹, R. Miccoli², G. Penno¹, S. Del Prato², GENFIEV Study Group;

¹Department of Endocrinology and Metabolism, Azienda Ospedaliero-Universitaria Pisana, ²Department of Endocrinology and Metabolism, University of Pisa, Italy.

Background and aims: HbA_{1c} (A1c) has been proposed for the diagnosis of diabetes (DM) and identification of individuals at risk of DM. Very few studies evaluated whether A1c performs better than OGTT for categorization of impaired glucose regulation (IGR: IFG, IGT, IFG+IGT) and associated metabolic abnormalities. Therefore, aims of the study were to compare these indices in their ability to identify IGR and DM and evaluate the relation of these measures to other metabolic characteristics, particularly insulin resistance and β -cell function.

Materials and methods: We have examined 844 consecutive subjects (44% men; age 49.5 \pm 11 years; BMI 29 \pm 5 Kg/m²) enrolled into the Genetics Physiopathology and Evolution of Type 2 diabetes (GENFIEV) study. Plasma glucose and C-peptide were determined during OGTT to assess β -function while lipid profile; HOMA-IR and A1c (HPLC) were evaluated in fasting condition.

Results: Based on ADA criteria 43% had normal glucose tolerance (NGT), 42% IGR and 15% DM on OGTT, while IGR and DM were 38 and 11% on A1c with a concordance rate between of 54% and 44%, respectively. A1c specificity was 74% and 95% for IGR and DM. In non-diabetic subjects (NGT+IGR) both A1c and 2h-postload glucose were correlated with lipid profile, blood pressure, obesity, although the 2-h glucose correlation was stronger (triglycerides: $r=0.21$ vs. 0.11 ; HDL-Ch $r=0.19$ vs. -0.10 ; SBP $r=0.25$ vs. 0.15 ; DBP $r=0.20$ vs. 0.07 ; all $p<0.04$) with the exception of BMI: $r=0.08$ vs. 0.13 ($P=NS$). In a logistic regression analyses adjusted for age, sex, and BMI, individuals with IGR and even more DM by OGTT had greater chance to have insulin resistance and impaired insulin secretion (Odd Ratio for HOMA-IR: IGR-OGTT 3.33 (95%CI 2.32-4.78) vs. IGR-HbA_{1c} 2.52 (1.77-3.58), DM-OGTT 8.02 (4.78-13.45) vs. DM-HbA_{1c} 3.95 (2.30-6.77); OR for Insulinogenic Index: IGR-OGTT- 3.08 (2.15-4.40) vs. IGR-HbA_{1c} 2.88 (2.03-4.09), DM-OGTT 14.24 (8.49-23.89) vs. DM-HbA_{1c} 8.56 (5.00-14.64)). Finally, IGR and DM by OGTT were more associated with metabolic syndrome (ATP III) than IGR and DM by HbA_{1c} (IGR-OGTT 2.80 (1.90-4.14) vs. IGR-HbA_{1c} 2.08 (1.42-3.04); DM-OGTT 4.31 (2.55-7.31) vs. DM-HbA_{1c} 3.36 (1.92-5.88)).

Conclusion: A1c identifies a smaller proportion of individual at-risk and even smaller with DM than OGTT and has a weaker correlation with pathogenetic defects of hyperglycemia as well as of other metabolic abnormalities. Clinical Trial Registration Number: NCT00879801

Screening using various cutoffs of HbA_{1c} and impaired fasting plasma glucose for predicting future diabetes: the Toranomon hospital health management center study

C. Horikawa¹, Y. Heianza^{1,2}, S. Hara², Y. Arase², K. Saito^{1,2}, K. Fujiwara¹, A. Sugawara¹, H. Tsuji², S. Kodama^{1,2}, S.D. Hsieh², H. Shimano¹, N. Yamada¹, H. Sone^{1,2};

¹Department of Endocrinology and Metabolism, University of Tsukuba Mito Medical Center, ²Health Management Center, Toranomon Hospital, Tokyo, Japan.

Background and aims: Complex histories in the diagnosis of non-diabetic hyperglycemia or pre-diabetes make it difficult to target persons most likely to progress to diabetes, and thereby to efficiently enable early intervention. We aimed to evaluate the performance of different screening criteria for pre-diabetes as predictors for diabetes to identify which combination of impaired fasting glucose (IFG) and elevated HbA_{1c} criteria is the most predictive of future type 2 diabetes in a large cohort of Japanese individuals.

Material and methods: The study enrolled 4670 men and 1571 women aged 24-82 years without diabetes (diabetes: fasting plasma glucose (FPG)

≥ 126 mg/dl, HbA_{1c} $\geq 6.5\%$, or self-reported clinician-diagnosis diabetes). Diagnosis of pre-diabetes was made according to IFG (FPG 100-125 mg/dl, IFG100; or FPG 110-125 mg/dl, IFG110) or elevated HbA_{1c} (5.7-6.4%, HbA_{1c}5.7; or 6.0-6.4%, HbA_{1c}6.0). A combination of two tests with alternative cut-offs was used for diagnosing pre-diabetes. The follow-up duration was a median of 5.0 years on an annual basis, during which 338 incident cases of diabetes occurred.

Results: The prevalence of pre-diabetes was 33.5% by a combination of HbA_{1c}5.7/IFG100 criteria, 28.0% by HbA_{1c}6.0/IFG100, 16.7% by HbA_{1c}5.7/IFG110, and 8.2% by HbA_{1c}6.0/IFG110. Screening by the IFG100/HbA_{1c}5.7 criteria yielded the highest sensitivity of 86%, but the lowest specificity of 70% for predicting future diabetes. Among the individuals classified as having pre-diabetes by any of the four combined criteria, 28.1-32.0% reverted to normoglycemia at the last follow-up examination. At 170.3 months (5.6 years) after a baseline examination, however, pre-diabetic individuals who fulfilled both (1) HbA_{1c}5.7 and IFG100 showed 50% cumulative risk of diabetes, both (2) HbA_{1c}5.7 and IFG110 or (3) HbA_{1c}6.0 and IFG100 showed 80%; and both (4) HbA_{1c}6.0 and IFG110 showed 100% cumulative risk (see Figure 1). Pre-diabetic individuals who fulfilled the (1), (2), (3) and (4) criteria showed 50% of cumulative incidence rate at 5.6 years, 3.9 years, 3.9 years and 2.0 years after the baseline examination, respectively.

Conclusions: Screening for pre-diabetes using a combination of HbA_{1c} 5.7-6.4% and FPG 100-125 mg/dl criteria substantially reduced the likelihood of missing future cases of diabetes. Targeted screening of pre-diabetic individuals who strictly fulfill both HbA_{1c} 6.0-6.4% and FPG 110-125 mg/dl criteria would predict definite progression to diabetes. Figure: Cumulative incidence of diabetes during follow-up time according to the baseline diagnosis of pre-diabetes using elevated HbA_{1c} and IFG (Normoglycemia*: HbA_{1c} <6.0% and FPG <110 mg/dl, Normoglycemia*: HbA_{1c} <5.7% and FPG <100 mg/dl)

Does the HbA_{1c} cut-off point of 6.5% fit for Asia? A meta-analysis and system review

S. Yan, S.Y. Liu, Y.S. Zhao, W.C. Zhang, J.N. Li; Harbin Medical University, China.

Background and aims: Hemoglobin A1c (HbA_{1c}) $\geq 6.5\%$ was confirmed to be a criteria for diabetes diagnosis by 2010 ADA. There was still not, however, a guideline fit for Asia Pacific. To comprehensively evaluate the validity of 6.5% for diagnosing diabetes for Asian population, the systematic review and meta-analysis of cross sectional research on the accuracy of HbA_{1c} cut-off point in Asian population was performed.

Materials and methods: Electronic literature searching on MEDLINE, EMBASE and COCHRANE on the diagnostic accuracy of HbA_{1c} cut-off point published before February 2011 and handing search the reference lists of identified articles. Extract the data of optimal thresholds of HbA_{1c} for diabetes diagnosis posed by each study and calculate their medians. The summary sensitivities, specificities of each cut-off point described in these studies were calculated and the SROC curves were performed. Calculate the mean values

of HbA_{1c} and look for a cut-off point with highest specificity in confidence interval.

Results: Nine studies with uniform quality control published in English from 1989 to 2011 met the inclusion criteria. The total sample size was 18,543. The medians of optimal cut-off points posed by each study is 5.75%. The cut-off of 6.3% had the highest Youden's index was found in our study for Asian population with the corresponding sensitivity and specificity 69.0% (95%CI: 64.2%–73.5%) and 95.9% (95%CI: 95.3%–96.5%), respectively. The mean value of HbA_{1c} was 5.4±0.34%. In the confidence interval of mean±3SD, the cut-off point of 6.42% has the highest specificity. It was similar to 6.5% posed by ADA criteria. Meantime in our analysis, the cut-off point of 6.5% had higher specificity of 96.2% (95%CI: 95.8%–96.6%) and a higher area under SROC (0.8697) and its sensitivity was appropriate (41.8%, 95%CI: 38.6%–45.0%).

Conclusion: The cut-off point 6.42% with high specificity was similar to the ADA criteria. The HbA_{1c} cut-off point of 6.5% has a higher specificity and its sensitivity is not low either. Therefore we recommend that the HbA_{1c} cut-off point of 6.5% fits for diabetes diagnosis in Asian Pacific.

Optimal HbA_{1c} cut-off points conducted by 3 methods

Method/Value	Mediant of optimal cut-off point (%)	Cut-point with the highest Youden's index (%)	Mean value+3SD of HbA _{1c} (%)
value	5.75	6.3	6.42

A comparison of determinants and progression rates of impaired glucose regulation (IGR) to type 2 diabetes using an oral glucose tolerance test (OGTT) and HbA_{1c} diagnostic criteria

S.A. Mostafa¹, B. Srinivasan¹, K. Khunti², L.J. Gray², T. Yates¹, D. Webb¹, M. Davies¹

¹Cardiovascular Sciences, University of Leicester, ²Health sciences, University of Leicester, UK.

Background and aims: International organisations have included HbA_{1c} as a diagnostic criterion to detect T2DM. We investigated the progression rate of IGR (impaired glucose tolerance, IGT, and/ or impaired fasting glycaemia, IFG, using WHO 2011 criteria) to T2DM using HbA_{1c} or an OGTT during annual follow-up. Furthermore, we assessed the risk of developing diabetes with baseline HbA_{1c} categories and various risk factors.

Materials and methods: Analysis of the ADDITION-Leicester (UK) population based diabetes screening study from 2004–2010. Primary Care participants with IGR (n=909) detected at baseline were invited for an annual OGTT and HbA_{1c} measurement. Logistic regression analysis was used to produce adjusted odds ratios (OR) for progression to diabetes for risk factors in a stepwise procedure.

Results: For a median follow-up of 3 years (interquartile range 1–4), the progression rate to T2DM was 13.9% (95% CI 11.8–16.3%) and 14.3% (12.0–16.9%) using the OGTT and HbA_{1c}≥6.5% criteria respectively. However, only 5.5% had diabetes on both OGTT and an HbA_{1c}≥6.5%, suggesting major discordance between the two criteria. At follow-up, people with HbA_{1c}≥6.5% but without diabetes on OGTT were more likely to be of South Asian ethnicity (p<0.0001), have a lower BMI (p<0.0001), waist circumference (p<0.0001), waist:hip ratio (p=0.004) and diastolic BP (p=0.003) compared to individuals with T2DM on OGTT and HbA_{1c}<6.5%. 2-hour plasma glucose (2hpg, per 0.5mmol/l OR 1.3 (1.1–1.6)) and HbA_{1c} (per 0.5%, 1.6 (1.1–2.4)) were significant baseline predictors of progression from isolated-IGT to diabetes on OGTT, whilst age (per year, 0.95 (0.91–0.98)) produced an inverse association. For progression from isolated-IFG, fasting plasma glucose (FPG per 0.5mmol/l, 3.9 (1.1–14.1)), waist circumference (per cm, 1.1 (1.0–1.1)), 2hpg (1.6 (1.2–2.1) and history of CVD 6.2 (1.1–36.2) were significant predictors. For combined IGT/IFG, FPG (9.4 (2.4–37.0)), HbA_{1c} (1.7 (1.0–3.0)) and albumin: creatinine ratio (1.3 (1.0–1.7)) were significantly related to progression. Other anthropometric measures, sex, ethnicity, BP, lipids, family history of diabetes, current smoking status, fasting insulin, HOMA1-IR, leptin, adiponectin and Vitamin D were not significant. When HbA_{1c} criteria was applied at follow-up the significant baseline predictors of diabetes for isolated-IGT were HbA_{1c} (OR: 6.2 (3.3–11.6)); for isolated-IFG, HbA_{1c} (11.8 (2.9–48.6)) and South Asian ethnicity (5.1 (1.4–18.7)) and for combined IGT/IFG, HbA_{1c} (2.7 (1.0–7.1)) and FPG (5.0 (1.5–16.8)). Using a comparator of baseline HbA_{1c}<5.0%, the risk of progressing to HbA_{1c}≥6.5% over 3

years was significant (p<0.05) with baseline category HbA_{1c} 6.0–6.4% but not 5.5–5.9%, OR: 10.9 (3.1–37.7) and 3.3 (0.9–11.8).

Conclusion: Progression rates for people with IGR to diabetes was similar using an OGTT or HbA_{1c}, suggesting re-screening IGR using either test in clinical practice is feasible, however they detect different people with different clinical characteristics. The most consistent determinants of IGR progression to diabetes were glucose blood tests, with a limited scope for non-invasive measures, basic demographics and biomarkers. The risk of developing diabetes on HbA_{1c} criteria was significant only for people with HbA_{1c}≥6.0%.

333

5-year temporal change in HbA_{1c} and its risk factors in the Japanese general population

Y. Yamamoto¹, T. Nakagami¹, Y. Iwamoto², Y. Uchigata¹, N. Yoshiike³

¹Diabetes Center, Tokyo Women's Medical University Medical Center

School of Medicine, ²Tokyo Women's Medical University Medical Center,

³Department of Nutrition, Aomori University of Health and Welfare, Japan.

Background: Because of aging and obesity, the number of people with diabetes (DM) is increasing rapidly worldwide. In Japan, the prevalence of DM has been monitored based on A1C ≥6.5% since 1997 and has been repeated with a 5-year interval as the Japan National Diabetes Survey. There are very few data available on temporal trends in the distribution of A1C at population level and on factors explaining temporal changes. The aim of this study is to examine 5-year temporal change in A1C from 1997 to 2002 and risk factors for A1C in Japan, by using cross-sectional data from the Japan National Diabetes Survey conducted in 1997 and 2002.

Methods: The study comprises 4,439 men and 6,716 women aged 20 years and older. The demographic and clinical data and proportions of people classified by five groups on A1C (<5.6, 5.6–5.9, 6.0–6.4, ≥6.5%, medicated DM) were compared between two surveys years. The step-wise multivariate regression model with age (10 years), body mass index (BMI) (1 kg/m²), systolic blood pressure (SBP) (10 mmHg), total cholesterol (TC) (1 mmol/l), survey year (2002 vs. 1997), antihypertensive medication, regular exercise habits, step/day (1,000 steps/day), current smoking status, and current alcohol habits as independent variables was fitted to identify risk factors for HbA_{1c} in people without medicated DM.

Results: In men, mean age, BMI and the proportion of people on antihypertensive medications were significantly higher, while mean step/day and the proportion of current smokers were significantly lower in 2002 than 1997. In women, mean age, TC and the proportion of people having regular exercise habits were significantly higher in 2002 than 1997. The crude proportion for men and women with A1C ≥6.5% and for men with medicated DM did not change, but the crude proportion for men and women with A1C 5.6–6.4% was significantly increased for 5-years (men: 23.9→34.6%, women: 28.3→40.1%, p<0.001). The median A1C shifted from 5.3 to 5.5% for 5 years in men and women without medicated DM. When adjusting for age, mean A1C was significantly higher in 2002 than 1997 in the group of men and women with BMI <30 kg/m². When adjusting for BMI, mean A1C was significantly higher in 2002 than 1997 in the group of men <40 years old and women <50 years old. Table 1 shows beta coefficient and its standard error of risk factors for 1% increase of A1C. The survey year was identified as an independent risk factor for increase of A1C as well as established risk factors of DM.

Conclusions: The median A1C increased by 0.2% from 1997 and 2002 in Japan. This may be partly due to an elevation of A1C in young-middle aged or non-obese individuals. However, the temporal increase of A1C in Japan was not fully explained by established risk factors of DM in this study.

Multivariate regression analysis for 1% increase in A1C in people without medicated DM

	Men			Women		
	B	SE	P-value	B	SE	P-value

Predictive value of HbA_{1c} for the occurrence of diabetes in normoglycaemic people: the REDIA cohort - Reunion Island 1999-2001 / 2006-2009

F. Favier^{1,2}, A. Fianu^{1,3}, R. Grimoire^{1,4}, C. Dalban¹, N. Naty¹, S. Porcherat¹, J.-B. Picaud¹, X. Debussche², N. Le Moullec³, A. Fagot-Campagna⁴;

²Diabétologie, CHR de la Réunion, Saint Denis, Réunion, ³Endocrinologie-

diabétologie, CHR de la Réunion, Saint Pierre, Réunion, ⁴Institut de Veille Sanitaire, Saint Maurice, France.

Background and aims: The glycated hemoglobin (HbA_{1c}) is a parameter commonly used for glycaemic monitoring in diabetic patients. Recently it has been proposed as a diagnostic criterion for diabetes at the threshold $\geq 6.5\%$. Aims: to verify that among non diabetic normo-glycaemic adults, the gradient of increasing HbA_{1c} values below 6.0% is predictive of diabetes or glucose abnormalities detected several years after.

Materials and methods: Among 4610 persons aged 18-69, residing in three cities of Reunion Island and recruited in the REDIA survey on diabetes in 1999-2001, 3096 participated in a follow-up cohort in 2006-2009. At the inclusion, 2025 persons unknown as diabetics were diagnosed normo-glycaemic by capillary blood glucose test (<1.00 g / l fasting / 1.40 g / l non-fasting) and capillary HbA_{1c} test ($<6.0\%$). The predictive value of HbA_{1c} on the onset of diabetes (treated or detected) and glycemia (HbA_{1c} $\geq 6.0\%$) was assessed by: 1) the area under the ROC curve (AUC), 2) the relative risks estimated by modified Poisson regression models.

Results: Participants were followed for 7.4 years (median). Whatever the glycaemic event considered, the discriminatory value of the initial HbA_{1c} was satisfactory (AUC ~ 0.75). After taking into account gender, age, BMI, hypertension, family history of diabetes and monitoring delay, the risk of abnormal glucose control (HbA_{1c} $\geq 6.0\%$) increased exponentially with Initial HbA_{1c} ($p < 0.0001$), whereas at the threshold of 6.5% the risk increased only from 5.4-5.9% ($p < 0.0001$). In people with no direct family history of diabetes, the risk of diabetes increased linearly with HbA_{1c} ($p < 0.0001$), whereas among those reporting a direct family history of diabetes, the risk increased only from 5.4-5.9% ($p = 0.0004$).

Conclusion: Our populational study in Reunion island shows that the probability of incident type 2 diabetes increases with HbA_{1c} measured at inclusion, even at an initial risk level lower than that usually seen in the general population (ie $\geq 6.0\%$) and during a relatively short period (< 10 years).

Changes in glucose and HbA_{1c} prior to the diagnosis of diabetes: a 10-year follow-up of the Hoorn Study

E. van't Riet¹, M. Alsema¹, T. Teerlink², G. Nijpels³, C.D.A. Stehouwer⁴, J.M. Dekker¹;

of Clinical Chemistry, ³EMGO Institute and dep. of General Practice,

VU University Medical Center, Amsterdam, Netherlands, ⁴Department

of Internal Medicine and Cardiovascular Research Institute, Maastricht

University Medical Center, Netherlands.

Background and aims: It is unknown whether early changes in glucose levels prior to the diagnosis of diabetes, as shown in previous studies, are accompanied by changes in A1c. To evaluate this, we compared changes in fasting glucose, postload glucose and A1c levels over a 10-year period in participants of the Hoorn Study who did and did not develop diabetes.

Materials and methods: For the analysis we used data of 565 non-diabetic participants of the Hoorn Study between 50-75 years of age who had an OGTT and A1c determination at baseline (1989), first (1996) and second (2000) follow-up. Diabetes was diagnosed at follow-up based on fasting glucose ≥ 7.0 mmol/L, and/or postload glucose ≥ 11.1 mmol/L, and/or A1c $\geq 6.5\%$, and/or use of diabetes medication. Three groups were created: participants without diabetes during follow-up ($n = 418$), participants with incident diabetes in 1996 ($n = 99$) and participants with incident diabetes in 2000 ($n = 48$). Curves were plotted to compare the time course of glycemic measures in the three groups. To test whether the time-dependent changes in glycemic measures differed between participants with diabetes and those without diabetes during follow-up, linear mixed models were used.

Results: In Figure 1, the time course of glycemic measures in participants who did and did not develop diabetes is shown. Participants who developed diabetes already had higher fasting and postload glucose levels and A1c as compared to those who did not develop diabetes. In participants with incident diabetes in 1996 (top lines in Figure 1), mean fasting glucose, A1c and postload glucose increased significantly from 1989 to 1996 as compared to participants without diabetes (bottom lines in Figure 1). After the diagnosis in 1996, all glycemic measures stabilized towards 2000. Mean levels of fasting glucose and postload glucose in participants with incident diabetes in 2000 (dotted lines in Figure 1) increased gradually between 1989 and 1996, but not significantly different from those without diabetes ($p > 0.10$). In contrast, A1c levels already showed a significant increase in future diabetes patients between 1989 and 1996 compared to those without diabetes ($p < 0.001$). Between 1996 and 2000, rapid increases in fasting glucose, and especially postload glucose and A1c were seen in those who developed diabetes in 2000 as compared to those without diabetes (all $p < 0.001$).

Conclusion: Future diabetes patients already have increased levels of glucose and A1c 10 years before the diagnosis of diabetes. These levels rapidly increase a few years before the diagnosis, with an earlier increase in A1c as compared to glucose.

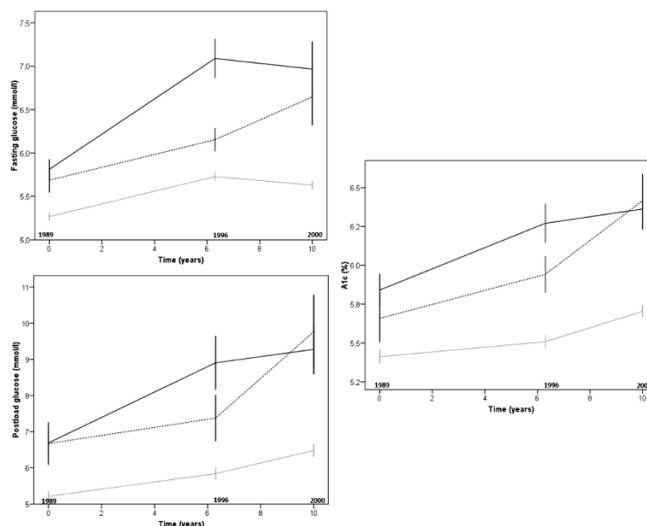

Figure 1. Changes in fasting and postload glucose and A1c in those with incident diabetes in 1996 (top lines, N=99), those with incident diabetes in 2000 (dotted lines, N=48) and those who did not develop diabetes during 10 years of follow-up (bottom lines, N=418). Data are presented as the mean and 95% confidence intervals at all time points.

Diagnosis of diabetes with HbA_{1c} value screens different population between genders in terms of glucose tolerance and insulin secretory reaction

S. Okahata¹, M. Yamakado², K. Sakamoto¹, M. Yano², Y. Ishizaka², T. Shiba¹;
¹Toho University Ohashi Medical Center, ²Mitsui memorial hospital, Tokyo, Japan.

Background and aims: Diagnostic criterion of diabetes mellitus recommended by WHO or ADA adopted HbA_{1c} as well as the plasma glucose at OGTT. We have characterized the diagnosis of diabetes using HbA_{1c} from the view point of glucose tolerance and insulin secretion observed at OGTT.

Methods: In order to evaluate the validity of diagnosing of diabetes with HbA_{1c}, cross-sectional analysis was performed in 3,142 Japanese subjects (men 66 %) with the examination of 75g OGTT and HbA_{1c}. Serum IRI was also measured in OGTT. These subjects were divided into 4 groups, categorized as low risk (HbA_{1c}<6.0: A), high risk (6.0≤HbA_{1c}<6.5: B), mild diabetes (6.5≤HbA_{1c}<6.9: C) and overt diabetes (HbA_{1c}≥6.9: D), depending on their HbA_{1c} value and the results of 75g OGTT were compared between genders in each categories. In Japan, cases with more than 6.9% of HbA_{1c} were formally diagnosed as diabetes. Statistical analysis was conducted with two-way ANOVA and multiple regression analysis using commercially available computer software, JMP 7 (SAS Institute, Cary, NC, USA).

Result and discussion: We recognized significant and unignorable differences of plasma glucose level at each time point in OGTT between genders by up to 32 mg/dL in group C. Regarding FPG (mg/dL) and FIRI (μU/ml) women showed significantly lower level than men by 4.9 and 1.0 in group A, by 7.7 and 1.5 in group B, respectively. In group C, only FPG was significantly lower in women by 5.6. As shown in table, 2h-post challenge plasma glucose (2hPG) level showed significant larger difference between genders. Insulin secretory response was also explored at OGTT. Significant lower 2h-post challenge IRI was observed in women by 5.5 in group A, and by 7.4 in group B. HOMA-IR showed significant lower value in women in group A and B, which might cause the gender difference of glucose profile; while this wasn't so evident in group C or D. As for HOMA-β, in contrast, women had significant higher value in group C. Multiple regression analysis explored some indices decisive of 2hr postchallenge glucose. Both HOMA-IR and HOMA-β contributed significantly to 2hPG in all groups of A, B, C and D, with HOMA-IR positively and HOMA-β negatively. Insulinogenic index at 1 hour (1hr I.I) affected significantly and negatively to 2hPG in groups B, C and D although not significantly between genders. To be female was negative factor to determine 2hPG in group A, B, and C.

Conclusion: A significant gender difference was recognized in the glucose and insulin level at OGTT, when glucose tolerance was categorized with HbA_{1c} value. These data suggest diagnosis of diabetes with OGTT or HbA_{1c} screens different population between genders, which results in over-diagnosis of the stages of glucose intolerance in women. Data are shown in the form of mean ± SD, *: <0.05 **: < 0.01 ***: <0.0001, HOMA-IR: Homeostasis model assessment-Insulin Resistance, HOMA-β: Homeostasis model assessment beta cell model, 1h I.I: [(1hrIRI)-(FIRI)]/[1(hPG)-(FPG)]

Haemoglobin susceptibility to glycosylation may partly explain discordance between HbA_{1c} measurement and oral glucose tolerance test to diagnose dysglycaemia

E. Cosson, S. Chiheb, I. banu, M. Nguyen, E. Hamo-Tchatchouang, N. Charnaux, P. Valensi;
 AP-HP, Jean Verdier Hospital, Bondy, France.

Background and aims: The aim was to assess whether the poor consistency for dysglycemia diagnosis of HbA_{1c} and oral glucose tolerance test (OGTT) may be explained by hemoglobin glycosylation susceptibility (GS).

Materials and methods: We included 1033 consecutive overweighted or obese patients without renal failure, abnormal thyroid function or known diabetes, and having had fructosamine (glycosylated proteins; colorimetry) and HbA_{1c} (turbidimetric immuno-assay) measurement and an OGTT. Predicted HbA_{1c} from albumin corrected-fructosamine (Alb-F) was calculated from the following regression: predicted HbA_{1c} = 0.002 x Alb-F + 4.56 (r=0.185, p<0.0001). Three groups were determined: "High-GS" / "Low-GS" (5% / 5% of patients having the greatest / lowest measured HbA_{1c} as compared to predicted HbA_{1c}) and "Intermediate-GS" (90% remaining patients).

Results: On the basis of the OGTT and HbA_{1c} measurement respectively, 267 (25.8%) and 443 (42.8%) patients had intermediate hyperglycemia and 66 (6.4%) and 95 patients (9.2%) had diabetes (American Diabetes Association criteria 2011). The results were inconsistent for dysglycemia diagnosis in 31.1% and for diabetes diagnosis in 19.6% of the patients. In the "High-GS" subjects, the proportion of false positive results of HbA_{1c} as compared with OGTT was 59.6% for diabetes and 30.8% for dysglycemia; versus 3.8 and 32.5% in the "Intermediate-GS" and 0 and 0% in the "Low-GS" patients (p<0.0001). In mirror, the "Low-GS" subjects had more false negative results of HbA_{1c} as compared with OGTT. Multivariate analysis showed that body mass index (odds ratio 1.06 [95% confidence interval 1.01-1.12], p=0.015), fasting plasma glucose (per mmol/l, OR 1.83 [1.22-2.75], p=0.003) and 2h-plasma glucose (OR 1.17 [1.02-1.34] 0.023) were independently associated with high-GS.

Conclusion: Discordant results of HbA_{1c} and OGTT for diagnosing dysglycemia may be partly explained by hemoglobin GS, which increases with higher body mass index and glucose values even in subnormal range.

338

Determinants of HbA_{1c} in non-diabetic Dutch adults: genes, environment and their interactions in the LifeLines cohort study
R.P. Stolk¹, H. Jansen¹, I.M. Nolte¹, I.P. Kema², B.H.R. Wolffenbuttel³, H. Snieder¹;

¹Department of Epidemiology, ²Department of Laboratory Medicine,

³Department of Endocrinology, University Medical Center Groningen, Netherlands.

Background and aims: HbA_{1c} is associated with cardiovascular risk in persons without diabetes, and its use has been recommended for diagnosing diabetes. Therefore, it is important to get better insight in determinants of HbA_{1c}. In this study we investigate the effect of environmental factors, genetic loci and gene-environment interactions on HbA_{1c} in non-diabetic adults.

Materials and methods: BMI, waist circumference, HbA_{1c}, fasting plasma glucose (FPG) and erythrocyte indices were measured in 2,921 non-diabetic adults participating in the population-based LifeLines study. Data on current smoking and alcohol consumption were collected by questionnaires. Genome-wide genotyping was performed, 12 previously identified SNPs were selected for replication and categorized in “glycaemic” and “non-glycaemic” SNPs according to the presumed way they act on HbA_{1c}. Genetic risk scores (GRSs) were calculated by adding up the weighted effect of HbA_{1c}-increasing alleles.

Results: Age, gender, BMI, FPG, mean corpuscular haemoglobin (MCH), mean corpuscular haemoglobin concentration (MCHC), current smoking and alcohol consumption were independent predictors of HbA_{1c}, together explaining 26.2% of the variance in HbA_{1c}, with FPG only contributing 10.9%. We replicated three of the previously identified SNPs, namely rs1402837, rs4737009 and rs1046896 and the GRSs were also independently associated with HbA_{1c}. We found a smaller effect of the “non-glycaemic GRS” in females compared to males and an attenuation of the effect of the “glycaemic GRS” with increasing BMI.

Conclusion: Our results suggest that a substantial part of HbA_{1c} is determined by non-glycaemic factors, raising serious questions about the use of HbA_{1c} as a diagnostic test for diabetes.

Association of skin intrinsic fluorescence with cumulative glycaemic exposure in the DCCT/EDIC study

P. Cleary¹, B. Braffett¹, J. Maynard², C. Cowie³, R. Gubitosi-Klug⁴, T. Orchard⁵;

¹The George Washington University, Rockville, ²VeraLight, Albuquerque,

³National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda,

⁴Case Western Reserve University, Cleveland, ⁵University of Pittsburgh, USA.

Background and aims: We have previously demonstrated that dermal advanced glycation end products (AGEs) are associated with microvascular complications in a subset of the Diabetes Control and Complications Trial/ Epidemiology of Diabetes Interventions and Complications (DCCT/ EDIC) cohort. Other studies have shown a correlation of AGEs with skin intrinsic fluorescence (SIF). In addition, DCCT/EDIC has shown that glycemic exposure as expressed by overall mean HbA_{1c} is strongly associated with microvascular complications. We thus performed a substudy to evaluate the relationship of SIF and glycemic exposure.

Materials and methods: SIF was measured noninvasively on the volar forearm of 1,080 participants. SIF was quantified using the SCOUT device after an average DCCT/EDIC follow-up of 23.5 years. SIF had a log normal distribution, thus was log transformed for analysis. Glycemic exposure was expressed as time weighted mean HbA_{1c}.

Results: The proportion of variation (R²) in log SIF explained by mean HbA_{1c} (Table 1) over various periods was low (< 9%), but statistically significant for all measures of mean HbA_{1c}, except ‘DCCT only’ for the intensive therapy group. The correlation of the DCCT mean HbA_{1c} with SIF was less than that for the EDIC mean HbA_{1c}; the overall mean HbA_{1c} had the strongest correlation.

Table 1	Combined	INT	CONV	INT vs. CONV
N	1,080	561	519	
Mean HbA_{1c}	Unadjusted R ² with log SIF			p-value ~
Time Span				
Last 5 yrs EDIC	0.030	0.024	0.037	0.4676
Last 10 yrs EDIC	0.041	0.034	0.049	0.3864
EDIC only	0.056	0.048	0.067	0.2541
DCCT only	0.011	0.005 #	0.028	0.3392
DCCT+EDIC	0.053	0.038	0.074	0.1192
Overall *	0.065	0.050	0.083	0.1890

* Overall HbA_{1c} is calculated by summing [DCCT/EDIC eligibility HbA_{1c} x duration of diabetes at study baseline], [DCCT mean HbA_{1c} x years of follow-up in DCCT], [EDIC mean HbA_{1c} x years of follow-up in EDIC].

P=0.0993. All other correlations are significant at p=0.01.

~ P-value for interaction in a model with treatment group, HbA_{1c}, and their interaction

The R² in the intensive (INT) group was slightly less than that in the conventional (CONV) group for the EDIC periods but substantially less for the DCCT period (Table 1). Log SIF was not significantly different between the DCCT intensive and conventional treatment groups after adjusting for the significant effects of skin tone as measured by the SCOUT device, age, smoking status, and clinic latitude (above/below 37°) (geometric means 22.2 AU vs. 22.3 AU, p=0.67). In the combined cohort, the association of overall mean HbA_{1c} with log SIF was 0.068 (semipartial R²) after adjustment for skin tone, age, smoking status, and clinic latitude. The overall model explained 30% of the variation in log SIF. The model for men explained a higher proportion of the variation in log SIF compared to that for women (model R² 37% vs. 23%). SIF was associated with overall mean HbA_{1c}, subject age, smoking status, skin tone, and clinic latitude among both males and females. Overall, mean HbA_{1c} and subject age had a stronger association with log SIF among males than females.

Conclusion: Over the 23.5 years of DCCT/EDIC, glycemic exposure as represented by the overall mean HbA_{1c} along with subject age and smoking status, explained the most skin intrinsic fluorescence variance in both the combined and gender stratified analysis.

Non-invasive skin fluorescence age trends in subjects with normal health are gender dependent

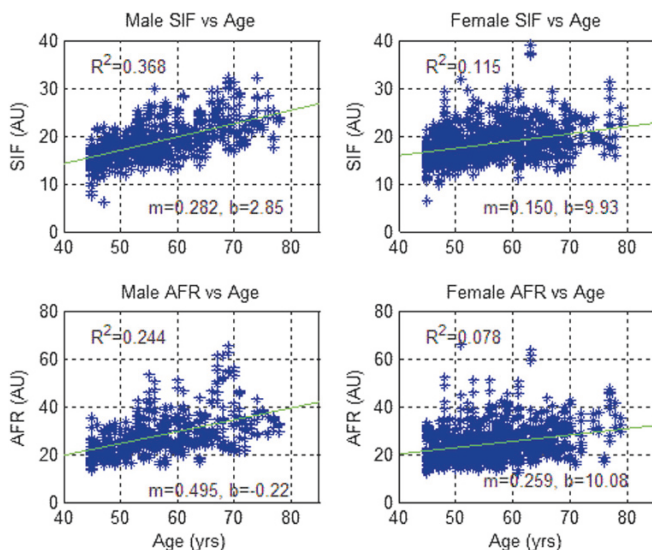

J. Maynard, N. Matter;
VeraLight, Inc., Albuquerque, USA.

Background and aims: Non-invasive skin intrinsic fluorescence (SIF) and the autofluorescence ratio (AFR) are both associated with the accumulation of advanced glycation endproducts (AGEs) and have been used to assess risk of diabetes complications. SIF has also been investigated as a screening test for pre-diabetes and type 2 diabetes. AGEs have been shown to increase as a function of age in normal health and at a faster rate in subjects with diabetes. We studied 777 subjects in normal health to estimate the change in SIF and AFR as a function of age and gender.

Materials and methods: Subjects without a pre-existing diagnosis of diabetes were recruited for a non-invasive diabetes screening study involving two visits to the clinic. The first visit required an overnight fast (> 8 hrs), while the second visit was in a random fasting state. During the first visit, subjects gave informed consent, answered a health and demographics questionnaire and had blood pressure measured. Fasting plasma glucose (FPG), A1c and 2 hour post challenge glucose (2HPG) after a 75 gram oral glucose tolerance test were also measured. At each visit, SIF and AFR were measured on the left volar forearm near the elbow using a SCOUT device that quantifies both skin reflectance and fluorescence in the 360 to 660 nm spectral range. Skin fluorescence was excited by a 375 nm LED. A white LED was used to measure skin reflectance. SIF and AFR were calculated over 435 to 655 nm using algorithms described in the literature. Subjects with skin reflectance > 1 absorbance unit were excluded from the AFR age trend analysis because AFR is overestimated in these cases. Least-squares linear fits of SIF and AFR versus age were calculated by gender for subjects in normal health that were 45 to 80 years old and not current smokers. Normal health was defined as FPG < 6.1 mmol and 2HPG < 7.8 mmol and A1c < 6.0% and no renal compromise, cardiovascular disease or hypertension.

Results: 273 men and 504 women satisfied the normal health criteria. Ethnic distribution was 594 white, 80 Hispanic, 86 African American and 17 other. The median age was 54 ± 7.7 years and median A1c was $5.5 \pm 0.3\%$. Figure 1 shows the correlations (R^2), slopes (m), and intercepts (b) between SIF and AFR vs. age for each gender; all correlations were significant ($p < 0.0001$). For both SIF and AFR, the male slope was 1.9 times greater than the female slope, while females had a larger intercept. To test if the age and gender interaction is significant, SIF and AFR linear regression models for the entire cohort were constructed using age, gender and age x gender as the independent variables. The age x gender interaction was significant ($p < 0.0001$) for SIF and AFR.

Conclusion: For subjects in normal health, SIF and AFR demonstrate significant, gender dependent trends with increasing age. Non-invasive screening for pre-diabetes and type 2 diabetes or assessing risk of diabetes complications with SIF or AFR may be confounded by these underlying trends and performance improvements may be possible if they are accounted for.

Clinical Trial Registration Number: NCT00614783

341

Which factors determine performance of skin autofluorescence-based decision tree for detection of impaired glucose tolerance and diabetes?

A.J. Smit¹, J.M. Smit², G.J. Botterblom^{1,2}, T. van Bommel², R. Graaff³;
¹Department of Vascular Medicine, University Medical Center Groningen,
²Medicine, Gelre Ziekenhuis, Apeldoorn, ³Department of Biomedical Engineering, University Medical Center Groningen, Netherlands.

Background and aims: Noninvasive skin autofluorescence (AF) is a marker of tissue accumulation of advanced glycation endproducts (AGE) which has been proposed as a carrier of glycometabolic memory. Skin AF has been reported to be superior to fasting plasma glucose (FPG) and HbA1c for the detection of impaired glucose tolerance IGT and diabetes in studies in naive persons, and in patients at intermediate-high risk of diabetes. Further improvement in the diagnostic performance of skin AF has been obtained in a decision tree (Diab-Spot), incorporating the items calendar age, BMI, number of 1st degree relatives with diabetes, and conditional questions on recent hospital admissions and on kidney disease. We analysed the relative contributions of these and other clinical items on the misclassification rates of this decision tree in persons at intermediate high risk of IGT or diabetes.

Materials and methods: Diagnostic performance (for IGT/suspicion diabetes, and for diabetes, respectively) and misclassification rates/numbers were assessed against WHO-GTT cutoff values in a 2-hour GTT in persons with 2 metabolic syndrome criteria. This was done for age-corrected skin AF alone, and using factor analysis for addition of the further items in Diab-Spot. Results were compared to those for glycemic criteria FPG and HbA1c (using WHO and IEC 2009 cutoff values, respectively).

Results: 218 persons, age 56 yr (33 <45, 23 >70), 128M/90 F, s-creatinine 82 (40-166) $\mu\text{mol/L}$, participated, 93 with previous cardiovascular events. With GTT-based WHO criteria 28 had diabetes, 46 IGT, 41 IFG, 103 normal glucose tolerance (NGT). With HbA1c-based IEC-2009 criteria, 13 had diabetes, 87 suspicion, and 117 NGT. Using AF alone to detect GTT-based diabetes/IGT, 57 were misclassified (23 false positives, 34 false negatives), with 68.5% sensitivity (S) and 86% specificity (SP). Factor analysis revealed that addition of BMI and family history contributed most in improving S, and questions on hospital admissions SP, to overall 83% and 90%, respectively. Items on sex, smoking, known kidney disease, use of antihypertensives did not add significantly. For FPG, using IEC criteria for DM (suspicion), S and SP were 64 and 83%, respectively, for HbA1c 80 and 75%.

Conclusion: Skin AF-based decision model has superior performance compared with FPG or HbA1c in intermediate risk persons to detect diabetes/IGT. Other relevant factors include age, BMI, family history. Noninvasive skin AF is promising for diabetes screening and further supported by its previously proven additive value in predicting diabetic complications.

342

Utility of glycated albumin for the diagnosis of diabetes mellitus in a Japanese population study: results from the Kyushu and Okinawa Population Study (KOPS)

N. Furusyo¹, T. Koga¹, M. Ai², S. Otokozawa³, H. Ikezaki¹, M. Unno¹, K. Okada¹, T. Kohzuma⁴, E.J. Schaefer³, J. Hayashi¹;
¹Department of General Internal Medicine, Kyushu University Hospital, Fukuoka, Japan, ²Life Science and Bioethics Research Center, Tokyo Medical and Dental University, Japan, ³Lipid Metabolism Laboratory, Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University, Boston, USA, ⁴Diagnostics Department, Asahi-Kasei Pharma Corp, Tokyo, Japan.

Background and aims: Glycated albumin (GA) is a measure of the mean plasma glucose level over approximately 2–3 weeks. We determined reference values for GA, and assessed the utility of GA in the diagnosis of diabetes mellitus (DM) in the general population.

Materials and methods: We studied 1,575 men and women (mean age, 49.9 years; range, 26–78 years) participating in a periodic health examination in a suburban Japanese town. Glycohemoglobin A1c (HbA1c) and fasting plasma concentrations of glucose (FPG), and GA were measured. Participants with FPG 7.0 or more mmol/L or HbA1c 6.5 % or more were diagnosed as having DM. The GA assay has the benefits of being well standardized, with excellent coefficients of variation and can be run using high throughput automated analyzers. Moreover the assay does not require whole blood.

Results: GA levels were significantly correlated with HbA1c level ($r = 0.766$, $P < 0.001$) and FPG ($r = 0.706$, $P < 0.001$). The presence of DM was significantly

higher in participants with GA levels between 15.0 and 15.9 % than in those with GA less than 14 % ($P = 0.037$), and was markedly increased in those with GA values more than 16 %. Receiver operating characteristic curve analysis indicated that a GA level of 15.5 % or more was optimal for the diagnosis of DM, with a sensitivity of 83.3% and a specificity of 83.3%.

Conclusion: We recommend a GA value 15.5 or more % as an optimal cut-point for the diagnosis of DM in the general population.

343

The relationship between plasma glycated albumin level and atherosclerosis: results from the Kyushu and Okinawa population study (KOPS)

H. Ikezaki¹, N. Furusyo^{1,2}, T. Koga², M. Ai^{3,4}, S. Otokozawa⁵, T. Kohzuma⁶, E.J. Schaefer⁵, J. Hayashi^{1,2};

¹Department of Environmental Medicine and Infectious Disease, Kyushu University, Fukuoka, Japan, ²Department of General Internal Medicine, Kyushu University Hospital, Fukuoka, Japan, ³Lipid Metabolism Laboratory, Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA, ⁴Life Science and Bioethics Research Center, Tokyo Medical and Dental University, Tokyo, Japan, ⁵Lipid Metabolism Laboratory, Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA, ⁶Diagnostics Department, Asahi-Kasei Pharma Corp., Tokyo, Japan.

Background and aims: Glycated albumin (GA) is a recognized indicator of glycemic control. This study was done to assess the hypothesis that GA can serve as well as glycohemoglobin A1c (HbA1c) as a risk marker of atherosclerosis.

Material and methods: HbA1c and fasting plasma concentrations of GA and high-sensitive C-reactive protein (hs-CRP) were measured for 1,575 residents (mean age, 49.9 years; range, 26–78 years) of a suburban Japanese town. Carotid artery intima-media thickness (IMT) was measured by ultrasound for each subject. Obesity was defined as body mass index $> 25 \text{ kg/m}^2$.

Results: The hs-CRP and max-IMT of participants with GA $> 19 \%$ were significantly higher than the values of those with GA $< 14 \%$ (hs-CRP: 0.121 ± 0.148 vs. $0.060 \pm 0.101 \text{ mg/L}$, $P < 0.01$; max-IMT 1.109 ± 0.562 vs. $0.757 \pm 0.317 \text{ mm}$, $P = 7.0 \%$ were significantly higher than the values of those with HbA1c $< 5.0 \%$ (hs-CRP: 0.154 ± 0.192 vs. $0.040 \pm 0.083 \text{ mg/L}$, $P < 0.01$; max-IMT 1.094 ± 0.559 vs. $0.702 \pm 0.268 \text{ mm}$, $P = 16 \%$ were significantly higher in than the values of those with GA $< 16 \%$. Among subjects with GA of 16 to 19 %, the hs-CRP and max IMT were significantly higher for obese subjects than for non-obese subjects.

Conclusions: Similar to HbA1c, a high plasma GA level was associated with inflammation and atherosclerosis. GA may be useful as a risk marker for atherosclerosis. Persons with a high GA level are at risk of developing atherosclerosis, especially if they are obese.

344

Characteristics of 24-hour glycaemic excursions revealed by continuous glucose monitoring in subjects with normal glucose tolerance and impaired glucose tolerance

M. Yu, J. Xia, L. Chen, J. Zhu, S. Zeng; Endocrinology, Putuo Hospital attached to Shanghai University of Traditional Chinese Medicine, China.

Background and aims: Continuous glycemic monitoring provides much more information about shifting glycemic levels throughout the day. In this study, continuous glucose monitoring system (CGMS) was used to further investigate the characteristics of 24-hour glycemic excursions in subjects with normal glucose tolerance (NGT) and impaired glucose tolerance (IGT).

Materials and methods: The glycemic excursions and tendency of 51 newly diagnosed IGT subjects (aged 59 (31–80) yrs, 25M/26F) and 41 NGT subjects (aged 42 (25–69) yrs, 21M/20F) were measured by the CGMS for 3 days. The CGMS took the glycemic measurements for a total of 288 values every 24 hours.

Results: IGT group in comparison with NGT group showed significantly higher values (means \pm SEM) of body mass index ($25.3 \pm 0.5 \text{ kg/m}^2$ vs $22.8 \pm 0.4 \text{ kg/m}^2$), systolic blood pressure ($130 \pm 3 \text{ mmHg}$ vs $119 \pm 2 \text{ mmHg}$), HbA_{1c} ($6.13 \pm 0.08 \%$ vs $5.53 \pm 0.09 \%$) and triglyceride ($1.80 \pm 0.20 \text{ mmol/l}$ vs $1.15 \pm 0.13 \text{ mmol/l}$) (all $P < 0.01$). The profiles of the CGMS showed: There were significant differences in the average glycemic level ($5.31 \pm 0.08 \text{ mmol/l}$

vs $6.48 \pm 0.11 \text{ mmol/l}$), the standard deviation of 24-hour glycemic values ($0.88 \pm 0.04 \text{ mmol/l}$ vs $1.48 \pm 0.08 \text{ mmol/l}$), and the maximal amplitude of glycemic excursions ($3.91 \pm 0.25 \text{ mmol/l}$ vs $7.10 \pm 0.37 \text{ mmol/l}$) between NGT group and IGT group ($P < 0.01$). 60.8% diurnal glycemic peaks occurred in 6am–10am period, but no glycemic peaks were observed during 9pm–5am period in IGT group. The values of postprandial glycemic peaks, time to postprandial glycemic peaks, the postprandial amplitude of glycemic excursions and the area under the curve (AUC) of postprandial glucose in IGT group were $10.17 \pm 0.30 \text{ mmol/l}$, $74.6 \pm 4.5 \text{ min}$, $4.13 \pm 0.27 \text{ mmol/l}$, $0.27 \pm 0.02 \text{ mmol/l-24h}$ in breakfast; $9.15 \pm 0.30 \text{ mmol/l}$, $93.0 \pm 4.9 \text{ min}$, $3.76 \pm 0.32 \text{ mmol/l}$, $0.37 \pm 0.03 \text{ mmol/l-24h}$ in lunch; $8.96 \pm 0.27 \text{ mmol/l}$, $86.6 \pm 4.9 \text{ min}$, $3.31 \pm 0.26 \text{ mmol/l}$, $0.33 \pm 0.03 \text{ mmol/l-24h}$ in supper; respectively, which were all significantly higher than those in NGT group (all $P < 0.01$). The glycemic peak of post-breakfast was higher than those of post-lunch and supper, but the AUC of post-lunch glucose was higher than those of post-breakfast and supper.

Conclusion: Continuous glucose monitoring offers advantages to revealing more details about the glycemic excursions and tendency throughout the day in IGT subjects. The glycemic profiles from the CGMS have a valuable role in identifying the characteristics of glycemic excursions and making the optimal treatment decisions in IGT.

345

Beyond the morphology of the glucose curve following an oral glucose tolerance test in obese youth

M. Manco¹, M.R. Spreghini¹, G. Morino¹, G. Nolfè²;

¹Bambino Gesù Hospital, Rome, ²Institute of Cybernetics, National Research Council of Italy-CNR, Pozzuoli, Italy.

Background and aims: The morphology of the glucose curve following an oral glucose tolerance test may predict the risk of altered glucose metabolism and harbor metabolic information not captured by the level of glycaemia alone. Aim of the present study was to describe any association between morphology of the glucose curve during the OGTT and insulin action, insulin secretion and glucose tolerance in obese children and adolescents.

Materials and methods: OGTT data of 553 young obese patients were analyzed. Subjects were divided in groups based on morphology of the glucose curve (i.e., monophasic, biphasic, triphasic and upward monotonous curves). Insulin sensitivity/resistance was estimated by the homeostasis model assessment (HOMA-IR), the insulin sensitivity (ISI), the muscular insulin sensitivity (MISI) and the hepatic insulin resistance (HIRI) indexes, and the oral glucose insulin sensitivity (OGIS). Insulin secretion was estimated by the insulinogenic index (IGI). Areas under glucose (AUC_G) and insulin (AUC_I) curves were computed.

Results: The prevalent morphology of the glucose curve was monophasic ($N=285$, 54%). Monophasic morphology was associated with the highest concentration of 1-hour plasma glucose (1HPG, $P < 0.0001$) and AUC_G ($P < 0.0001$). Individuals with biphasic morphology had lower OGIS ($P=0.01$) and greater AUC_I ($P < 0.0001$) than those observed in subjects with monophasic morphology. Triphasic morphology was associated with the highest values of HIRI ($P=0.02$) and IGI ($P=0.007$). By combining either morphologies of the glucose curve and time of glucose peaking or morphologies of the insulin curve, a deeper characterization of different phenotypes of glucose metabolism emerged.

Conclusion: Morphologies of the glucose curves seem reflecting different metabolic phenotypes of insulin action and insulin secretion in the class of normo-tolerant individuals. Findings of this study may deserve validation in a cohort study, in which glucose metabolism would be estimated by using gold-standard techniques.

The assessment of 1-h plasma glucose during an oral glucose tolerance test in a group of Romanian subjectsR. Dinu¹, S. Popa¹, M. Mota¹, E. Mota², M. Cruce³;¹Diabetes, Nutrition, Metabolic Diseases ²Nephrology, ³Molecular and Cell Biology, University of Medicine and Pharmacy Craiova, Romania.

Background and aims: Type 2 diabetes mellitus (DM) is one of the most common forms of chronic disease globally. In 2010, it was estimated that 285 million people worldwide have diabetes. Many important clinical trials demonstrated that early diagnosis and treatment can prevent or delay the onset of diabetes complications. The golden criterion for the diagnosis of DM remains the oral glucose tolerance test (OGTT) with 75g glucose. If the diagnosis is based upon 2-h plasma glucose value, the 1-h value is taken in consideration only for the diagnosis of gestational diabetes but not for DM. The aim of our study was to evaluate the 1-h plasma glucose value during OGTT in the diagnosis of diabetes.

Materials and methods: The study comprised of 412 subjects that performed a 2-h OGTT. According to the glucose values recorded during OGTT, the subjects were divided in 5 groups: without DM, IFG, IGT, IFG+IGT, DM. The statistical analysis was performed using SPSS 17.0 for Windows and the p-value under 0.05 was considered significant.

Results: The 1-h glucose value for each group was 163.34±38.16, 164.34±42.29, 184.83±46.86, 201.03±39.17 and 247.03±64.36 (p<0.001). The post-hoc analysis revealed that the 1-h glucose value for the subgroup without DM and, respectively, with DM were significantly different from the other subgroups. Using the receiver operating characteristic (ROC) curve, we tried to determine the cut-off value for the 1-h glucose value in diagnosing diabetes. The area under ROC curve was 0.853 (95%CI=0.806-0.897). The value of 215.5 mg/dl (sensitivity: 69.1%, specificity: 86.1%) was the point on the ROC curve with maximum Youden index and with shortest distance value from the point (0,1). When comparing the subjects without DM with all the subjects with impaired glucose metabolism, 168.5 mg/dl (sensitivity: 73.8%, specificity: 77.2%) had the maximum Youden index and 179.5 mg/dl (sensitivity: 63.8%, specificity: 87.8%) had the shortest distance value from the point (0,1).

Conclusion: These data indicate that the 1-h glucose value is a good predictor for diabetes. The value from the subjects without DM is significantly different from the value of the subjects with impaired glucose metabolism. The value of 215.5mg% can be considered a cut-off for the diagnosis of diabetes. Further research is needed to determine the role of the 1-h glucose value during the OGTT.

PS 010 Genetics of type 1 diabetes

347

Genome-wide association study on obesity in patients with type 1 diabetesE. Fagerholm^{1,2}, N. Sandholm^{1,2}, C. Forsblom^{1,2}, L. Thorn^{1,2}, M. Saraheimo^{1,2}, D. Gordin^{1,2}, P.-H. Groop^{1,2}, FinnDiane Study Group;¹Folkhälsan Institute of Genetics, ²Department of Medicine, Division of Nephrology, Helsinki University Central Hospital, Finland.

Background and aims: Several single nucleotide polymorphisms (SNPs) have been identified for obesity in large genome-wide association studies on obesity in the general population. However, no such studies have been performed in patients with type 1 diabetes, a population also affected by obesity. Therefore, our aim was to study which SNPs affect the susceptibility to obesity in patients with type 1 diabetes using a genome-wide approach.

Materials and methods: Genotype data as well as data on BMI and covariates (age and sex) were available for 3211 adult Caucasian patients with type 1 diabetes. All patients participated in a nationwide multi-center study on diabetic complications. After quality control of the genotype data (Hardy-Weinberg equilibrium, minor allele frequency, genotyping rate, missingness and bad clustering), 509 938 SNPs remained. BMI was analysed with linear regression using PLINK v 1.07 and adjusted for age and sex. Results were corrected for multiple testing with Bonferroni correction.

Results: In this patient cohort, the prevalence of obesity, defined as BMI over 30 kg/m², was 10.3%, while 38.3% of the patients were overweight (BMI between 25 and 30 kg/m²). No SNP was significant ($P < 1.0 \times 10^{-7}$) after Bonferroni correction. However, five suggestive hits ($P < 1.0 \times 10^{-5}$) were observed on chromosomes 3p21, 14q31, 16p12, 18q21 and 20p11. The strongest association was in CST1 gene on chromosome 20 and increased BMI with 0.50 kg/m² per C allele ($P = 8.9 \times 10^{-7}$). Only one of the observed top hits was located in a gene previously associated with obesity (NRXN3 on chromosome 14). The other top hits were located in genes not previously associated with obesity; one exonic missense SNP (Trp > Arg) in CCDC71 (3p21) and intronic SNPs in XYLT1 (16p12), CTIF (18q21) and CST1 (20p11). However, although not among the top hits, the generally well replicated SNP in the first intron of FTO (rs8050136) was associated with BMI also in patients with type 1 diabetes and increased BMI with 0.31 kg/m² per A allele ($P = 6.1 \times 10^{-4}$).

Conclusion: In this preliminary analysis, we provide suggestive evidence for five new loci associated with obesity in type 1 diabetes. Only modest overlap was seen with results from genome-wide association studies in the healthy population suggesting partially different genetic causes for obesity in type 1 diabetes. Replication will be required to validate these loci.

The transcriptional modulation involving mRNAs and microRNAs during development of T cells is associated with the emergence of type 1 diabetes mellitus in NOD miceT.A. Fornari¹, P.B. Donate¹, C. Macedo¹, E.T. Sakamoto-Hojo^{1,2}, E.A. Donadi³, G.A.S. Passos^{1,4};¹Genetics, University of São Paulo - Faculty of Medicine of Ribeirão Preto - FMRP/USP, ²Biology, University of São Paulo - Faculty of Philosophy, Sciences and Letters of Ribeirão Preto - FFCLRP/USP, ³Medical Clinic, University of São Paulo - Faculty of Medicine of Ribeirão Preto - FMRP/USP, ⁴Morphology, University of São Paulo - Faculty of Dentistry of Ribeirão Preto - FORP/USP, Ribeirão Preto, Brazil.

Background and aims: As early as one month of age, non-obese diabetic (NOD) mice feature pancreatic infiltration of autoreactive T lymphocytes, which destruct insulin-producing beta cells, leading to autoimmune diabetes mellitus (T1D) within eight months. Thus, we hypothesized that during the development of T1D, the transcriptional modulation of immune reactivity genes, as well as, modulation of microRNAs (miRNAs) may occur during thymocytes mature into peripheral CD3+ T lymphocytes. Our aim is to analyze the transcriptional modulation of mRNA and microRNAs during development of thymocytes into peripheral CD3+ T lymphocytes in the context of the emergence of T1D.

Materials and methods: Thymocytes and peripheral CD3+ T lymphocytes were obtained from pre diabetic and diabetic NOD mice, which were used to

prepare total RNA samples. The mRNA and miRNA fractions were labeled with Cy3 fluorochrome and hybridized with Agilent platform and the profilings of these cells were obtained through bioinformatics data analysis using GeneSpring software pipeline.

Results: The transcriptome of thymocytes and peripheral CD3+ T lymphocytes from pre diabetic and diabetic mice analyzed through microarray hybridizations identified 2771 differentially expressed genes. Hierarchical clustering grouped mice according to age/T1D onset and genes according to their transcription profiling. The transcriptional activity of thymocytes developing into peripheral CD3+ T lymphocytes revealed sequential participation of genes involved with CD4+/CD8+ T cell differentiation (Themis), tolerance induction by Tregs (Foxp3) and apoptosis (Fas) soon after T cell activation (IL4), while the emergence of T1D coincided with the expression of cytotoxicity (Crtam) and inflammatory response genes (Tlr) by peripheral T lymphocytes. Further analysis on post-transcriptional regulation of these genes showed involvement of the microRNAs miR-181a, miR-181c, miR-363 and let-7f, which were modulated in the course of T1D. Similarly to mRNAs the expression profiling of miRNAs were associated to the development of T1D.

Conclusion: These results are evidence for the association between the transcriptome (mRNA) and mirnome (miRNAs) of T lymphocytes and the manifestation of autoimmune diabetes mellitus.

Association between interferon-induced helicase 1 (IFIH1) Ala946Thr polymorphism and the seasonal variation in the onset of type 1 diabetes

A. Jermendy¹, I. Szatmari¹, A. Korner¹, R. Hermann², L. Madacsy¹

¹1st Department of Pediatrics, Semmelweis University, Budapest, Hungary,

²Immunogenetics Laboratory, University of Turku, Finland.

Background and aims: The onset of type 1 diabetes is determined by an interplay between genetic and environmental factors. Among the environmental factors viral infections display a seasonal pattern contributing to the seasonal variation in the onset of type 1 diabetes. Previously we observed that the rs1990760 (A>G, Ala946Thr) polymorphism of the interferon-induced helicase 1 (IFIH1), a virus recognition receptor, confers a modest susceptibility to type 1 diabetes, namely the major A allele is associated with increased disease risk. The aim of the present study was to evaluate a possible association between the IFIH1 Ala946Thr polymorphism and the seasonal variation in the onset of type 1 diabetes.

Materials and methods: The IFIH1 Ala946Thr polymorphism was genotyped in 1056 patients of Eastern European ancestry with type 1 diabetes mellitus (age at diagnosis of diabetes: 8.6±5.1 years [range: 0.6 - 30.9 years], 539 males, 517 females). Type 1 diabetes onset was recorded in monthly intervals. Diabetes was classified based on clinical data; autoimmune markers were determined only if difficulties occurred in classification. Seasonality was characterized by cosinor test. The association between IFIH1 rs1990760 genotypes (AA, AG, GG) and trends in monthly manifestation of type 1 diabetes was evaluated by Mantel-Haenszel chi2 test. Ordinal logistic regression analysis was performed to study the effect of genotype and age on type 1 diabetes onset assessed by monthly intervals.

Results: Among the total cohort (n=1056), AA genotype was found in 436 patients (41.3%), AG genotype was observed in 484 patients (45.8%), and GG genotype was found in 136 patients (12.9%). Seasonal variation in manifestation of type 1 diabetes (highest rate in winter and lowest rate in summer period) was observed in the total cohort by the cosinor analysis. The protective GG genotype of IFIH1 polymorphism was less frequently found among the newly onset cases during summer versus winter period (9.29% vs. 12.88%, respectively). Conversely, the disease predisposing AA genotype was more frequently found among the newly onset cases in summer versus winter period (44.29% vs. 37.98%, respectively, p=0.0268). Significant effect of genotype (p=0.0266) but no effect of age (p=0.0888) was found on the seasonal variability of type 1 diabetes onset in the total cohort.

Conclusion: We confirmed the seasonal variation in the onset of type 1 diabetes in a large population of Eastern European ancestry. Importantly, we detected a significant seasonal variation in the predisposing effect of IFIH1 Ala946Thr polymorphism on type 1 diabetes susceptibility in our cohort, with a stronger prevalence of the protective GG genotype in the winter period, and lower prevalence in summer. On the other hand, the disease predisposing AA genotype was more frequent in the summer versus the winter periods. Thus, our findings suggest that this virus receptor gene may contribute to type 1 diabetes manifestation primarily in the summer period.

350

Variants in IGF-I and IGFBP-1 and their effects on circulating IGF-I and IGFBP-1 levels in type 1 diabetes

S.K. Vasan, H.F. Gu, K. Brismar;

Molecular Medicine & Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Recent genome-wide association study has shown the association of rs35767 (near IGF-I) with HOMA-IR and fasting insulin. IGF-I is an important regulator of fetal growth, type 2 diabetes and obesity. Linkage studies have shown IGF-I and binding protein polymorphisms to be also associated with T1DM. The protein products of these genes may influence antigen presentation and cellular immune response and thus have a role in T1DM pathogenesis. Genetic variations in the IGF-I and IGFBP-1 have shown to influence serum levels of IGF-I and IGFBP-1. Therefore, we aimed to study if the genetic variants of IGF-I (rs35767) and two SNPs in the IGFBP-1 gene (rs1065780 in the promoter region and rs4619 -Ile253Met) pose increased risk susceptibility to type 1 diabetes (T1DM) and influence serum concentrations of IGF-I and IGFBP-1 in subjects with T1DM and non-diabetic controls.

Materials and methods: A cohort of 250 T1DM subjects (mean age 23.11 ± 8.57 years) and 140 controls (24.77 ± 5.77) were recruited from Endocrine Clinic of Christian Medical College & Hospital, Vellore, India. Genotyping was performed using TaqMan allelic discrimination for rs35767 (IGF-I), rs2065780 and rs4619 (IGFBP-1). Fasting serum IGF-I was measured by RIA after separation of IGFs from IGFBPs by acid ethanol extraction and cryo-precipitation. IGFBP-1 were measured by in-house RIA (intra and inter-assay CV were 3% and 10%). Association of the IGF SNPs with serum IGF-I and IGFBP-1 were analysed using ANOVA. Logistic regression was used to investigate the association between the IGF SNPs in subjects with T1DM and controls.

Results: The minor allele frequencies of rs35767 (T), rs2065780 (G) and rs4619 (G) were 0.22, 0.23 and 0.20 respectively in T1DM subjects and 0.21, 0.21 and 0.18 among controls. The rs1065780 variant of IGFBP-1 was associated with increased risk of T1DM (OR 1.71, 95%CI 1.08-2.71, p=0.021). Serum IGF-I was lower in T1DM (Median 184µg/L Inter Quartile Range 137-242µg/L) compared to non-diabetic controls (325µg/L, 210-410µg/L), while serum IGFBP-1 was increased in T1DM (71.5µg/L, 34-141 µg/L) than controls (66µg/L, 44-93µg/L). Both were statistically significant (p<0.001). The risk allele (T) of rs35767 was associated with reduced serum IGF-I in controls (p=0.006). Paradoxically, the risk allele (G) of rs1065980 was associated with elevated serum IGF-I in controls (p=0.007).

Conclusions: The current study provides evidence for increased susceptibility to T1DM for rs 1065780 in the promoter region of IGFBP-1. Polymorphism in rs35767 and rs1065780 alter circulating levels of IGF-I among non-diabetic controls suggesting that variations in serum levels of IGF-I are genetically determined.

351

Progression of type 1 diabetes associated autoimmunity and the high-risk HLA class II genotype

J. Ilonen¹, J. Lempainen¹, A. Hammas¹, A.-P. Laine¹, R. Hermann¹, R. Veijola², O. Simell³, T. Härkönen⁴, M. Knip⁴;

¹Immunogenetics Laboratory, University of Turku, ²Department of Pediatrics, University of Oulu, Turku, ³Department of Pediatrics, University of Turku, ⁴Hospital for Children and Adolescents, University of Helsinki, Finland.

Background and aims: The autoimmune process leading to beta cell destruction and type 1 diabetes is of variable duration and can be staged based on the number and quality of specific disease-associated autoantibodies. HLA polymorphisms are the main genetic risk factors for type 1 diabetes. The high risk DR3-DQ2/DR4-DQ8 (DR3/DR4) genotype mainly regulates the initiation phase of the disease process but does not seem to affect progression from multiple autoantibody positivity to clinical disease. However, there are some children who despite remaining positive for a single biochemically defined autoantibody develop diabetes, and information on the role of the high-risk class II HLA genotype in such subjects might help in understanding the process.

Materials and methods: The effect of the DR3/DR4 genotype on disease progression was compared between subjects with various numbers of autoantibodies in 249 prospectively observed autoantibody-positive children.

Results: The DR3/DR4 genotype was strongly associated with disease progression among those 54 children who never developed more than one

biochemical autoantibody ($p=0.003$, Kaplan-Meier log rank test), although the genotype was unrelated to disease development among those with more advanced autoimmunity. Subsequent analysis of ZnT8 antibodies revealed that this antibody was significantly associated with development of diabetes ($p=0.047$, Fisher's Exact test) but the DR3/DR4 genotype association with progression to clinical diabetes tended to remain after exclusion of these cases.

Conclusion: These results suggest that autoimmunity spreading associated with the high-risk HLA class II genotype is taking place in subjects positive for only one biochemical autoantibody although such spreading cannot be detected by current autoantibody tests.

HLA-haplotypes, autoantibodies to beta cells: their role in the prediction of type 1 diabetes

E.V. Titovich, T.L. Kuraeva, S.A. Prokof'ev, V.A. Peterkova, I.I. Dedov;
The Institute of Pediatric Endocrinology, Endocrinology Research Center, Moscow, Russian Federation.

Background and aims: Risk of Type 1 Diabetes (T1D) development in mainly defined by susceptible haplotypes of HLA DR and DQ genes carriage and specific autoantibodies (Ab) presence. Prediction of early preclinical stage of T1DM.

Materials and methods: Predisposing and protective haplotypes (HLA-DRB1, genes DQ) together with immunological markers (ICA, GADA, IAA) have been studied in 143 discordant families, in normal siblings ($N=171$; mean age - 11.9 ± 5.8 years). Simultaneously HLA-genotyping was performed in 599 patients with Type 1 Diabetes (mean age - 7.5 ± 6.2 years). Control group included 200 individuals.

Results: During the trial the haplotypes susceptible to T1D [DRB1*4-DQA1*301-DQB1*302 (OR=4.7); DRB1*17-DQA1*501-DQB1*201 (OR=2.7); DRB1*4-DQA1*301-DQB1*304 (OR=4.0); DRB1*1-DQA1*101-DQB1*501 (OR=1.9); DRB1*16-DQA1*102-DQB1*502/4 (OR=2.4)] and protective [DRB1*15-DQA1*102-DQB1*602/8 (OR=0.08); DRB1*11-DQA1*501-DQB1*301 (OR=0.14); DRB1*13-DQA1*103-DQB1*602/8 (OR=0.16)] were defined in 599 T1D patients, belonging to Russian population. Analyzing of HLA haplotypes prevalence in patients' families and in control group it was revealed that susceptible haplotypes incidence was lower in normal siblings [DRB1*4-DQA1*301-DQB1*302, DRB1*17-DQA1*501-DQB1*201] - 45.6% and 31%, comparing with patients - 61.5% and 51.7%, respectively ($\chi^2=7.93$, $p<0.001$; $\chi^2=13.93$, $p<0.0001$); though it was higher comparing with control group - 8.5% and 10%, respectively ($\chi^2=66.7$, $p<0.0001$; $\chi^2=25.7$, $p<0.0001$). It should be noted that protective haplotypes [DRB1*15-DQA1*102-DQB1*602/8/DRB1*13-DQA1*103-DQB1*602/8] incidence was higher in normal siblings comparing with patients - 22.8% and 4.9%, respectively ($\chi^2=19.98$, $p<0.001$) and didn't differ from the incidence in control group - 22% ($\chi^2=0.03$, $p=0.85$). It is possible to suggest that protective haplotypes play their role in disease susceptibility lowering disease incidence among normal siblings. Three risk groups were selected in siblings of patients with T1D, considering that heterozygosity according to haplotypes [DQA1*0501-DQB1*0201 (DQ2) and DQA1*0301-DQB1*0302 (DQ8)] specifies the highest risk of T1D development. The high genetic risk group (DQ2/DQ8) included 13.5%, moderate risk group (DQ2/X, DQ8/X - 59.7% and low risk group (X/X) - 36.8%, where X is any haplotype, besides DQ2/DQ8. Incidence rate of two and three Ab types in high risk group was higher than in moderate and low risk groups (26.1%, 14.1%, 11.1% respectively; $p>0.05$; 8.7%, 2.4%, 0% respectively, $p<0.05$). In this case GAD was defined significantly more often in the group with DQ2/DQ8 genotype, comparing with groups of moderate and low genetic risk (65%; 37.9%; 18%, respectively; $p<0.05$). Ab to insulin were revealed in 19%; 12.9%; and 3.7% cases, respectively ($p<0.05$). T1D manifestation was observed in 11 individuals during 11 years of surveillance (6.4%). The disease was detected in 8.7% cases from high risk group, in 8.0% - from moderate risk group and in 3.3% - from low risk group. From those in whom disease developed high risk haplotypes (DQ2; DQ8) were revealed in 82% cases and only 18.2% from examined individuals didn't have susceptible haplotypes.

Conclusion: The data obtained confirmed once more once more, that DQ2, DQ8 haplotypes presence in normal siblings forecast high risk of T1D development, but even these haplotypes absence doesn't completely protect from disease development.

353

Role of the repair enzyme PIMT in type 1 diabetes: studies in patients, dogs with diabetes and PIMT knock-out mice

J.C. Wiebe¹, L. López-Ríos², Y. Brito-Casillas³, C. Melián⁴, A. Arin-Martínez^{3,5}, E. González³, A. Tugores⁶, M. Boronat^{3,7}, J. Nóvoa^{3,7}, A.M. Wäagner^{3,7};

¹Endocrinology Dept, Complejo Hospitalario Universitario Insular-Materno Infantil de Gran Canaria (CHUIMI), ²Ciencias Médicas y Quirúrgicas, Universidad de Las Palmas de Gran Canaria, ³Endocrinology Dept, CHUIMI, ⁴Hospital Clínico Universitario, Universidad de Las Palmas de Gran Canaria, ⁵Bioquímica, Biología Molecular, Fisiología, Genética e Inmunología Dept., ⁶Research Unit, CHUIMI, ⁷Ciencias Médicas y Quirúrgicas Dept, Universidad de Las Palmas de Gran Canaria, Spain.

Background and aims: Post-translational protein modifications may create new antigenic epitopes and elicit autoimmunity. The enzyme PIMT, encoded by PCMT1, repairs isomerised Asn and Asp residues (IsoAsp). We showed that a compound up-regulating PCMT1, delays diabetes onset in the BB rat. The aim of this study was to assess the role of PIMT/PCMT1 in diabetes by studying several models.

Materials and methods: Patients (with GAD65 and/or IA2 antibodies) with a short duration (<5 years) of T1D were selected. As control groups, patients with T2D (<5 years since diagnosis and no complications) and healthy subjects matched for age and gender were selected. Samples from diabetic and non-diabetic dogs were collected. The expression of PCMT1 mRNA was assessed by qPCR. Transcription levels were normalized to β -actin by comparative Ct. Red blood cells were filtered and lysed. The cytosol was separated and depleted of haemoglobin and Western Blot for PIMT was performed. Heterozygous PIMT^{+/−} mice were crossed and their offspring, genotyped. PIMT knock-out mice were compared with their littermates at 5–6 weeks of age. Oral glucose (2g/Kg) and insulin tolerance tests (0.3 U/Kg) were performed. Differences were analysed using Mann-Whitney's U test.

Results: Blood samples are available from 82 participants, though only 52 (50% women) have been analysed. Median [range] PCMT1 expression tended to be reduced in the 19 T1D (3.03 [0.49–16]; $p=0.083$) as compared to the 28 controls (6.57 [0.81–32.67]), whereas no difference was found in the small group ($N=5$) with T2D (6.73 [0.42–15.56]). When only the 15 matched control-T1D pairs were analysed, differences were non-significant ($p=0.24$). PCMT1 expression was similar in the 8 diabetic (0.95 [0.31–3.89]) and the 9 non-diabetic (0.91 [0.88–1.09]) dogs ($p>0.2$). Western Blot analysis has so far been performed in 15 human subjects (5 per group), where it showed higher PIMT expression in controls than in T1D and T2D patients. The first litter of mice analysed included one knock-out, 5 heterozygous and 3 wildtype mice. Glucose averages 15 min. after the oral glucose load, were 351 mg/dl in the knock-out, 300 mg/dl in the heterozygous and 262 mg/dl in the wildtype subjects ($p>0.2$). The glucose nadir after insulin administration was 42, 39 and 40% of baseline, respectively ($p>0.2$).

Conclusion: PCMT1 mRNA expression was normal, both in patients with T1D and in dogs with diabetes. However, preliminary results point towards possible differences in protein expression, suggesting that it might be post-transcriptionally regulated. Furthermore, although sample sizes are still small, the Pcm1 gene seems to have a dose effect on glucose tolerance in mice. Ongoing experiments and sample collection should add to these results.

Should I test this patient for maturity onset diabetes of the young?

A clinical prediction model to determine the probability of MODY

B.M. Shields¹, T.J. McDonald¹, S. Ellard², C. Hyde¹, M. Campbell³, A.T. Hattersley¹;

¹Peninsula Medical School, University of Exeter, ²Royal Devon and Exeter NHS Foundation Trust, ³SCHARR, University of Sheffield, UK.

Background and aims: Maturity-onset diabetes of the young (MODY) is often misdiagnosed as Type 1 diabetes (T1D) or Type 2 diabetes (T2D), resulting in inappropriate management. We aimed to produce a prediction model using simple clinical criteria that could be used in patients with young onset diabetes (diagnosed <35y) to assess their probability of MODY.

Materials and methods: Logistic regression was used to integrate clinical characteristics that could discriminate MODY (n=618) from T1D (n=284) and T2D (n=316). The β coefficients obtained were combined in regression equations to enable calculation of probabilities for MODY. Model performance was assessed by ROC curves and cross-validated misclassification rates.

Results: Characteristics predictive of MODY compared with T1D were lower HbA1c ($\beta=-0.54$) parent with diabetes ($\beta=3.17$), female sex ($\beta=1.32$), and older age at diagnosis ($\beta=0.1$). MODY was discriminated from T2D by lower BMI SDS ($\beta=1.01$), younger age at diagnosis ($\beta=-0.31$), female sex ($\beta=0.73$), lower HbA1c ($\beta=-0.46$), parent with diabetes ($\beta=1.68$), and not being treated with tablets or insulin ($\beta=-0.79$ and -1.16 , respectively). Both models showed excellent discrimination (ROC area under curve=0.94 and 0.98, respectively), and low rates of misclassification (9.5% and 5.6%). A 60% probability cutoff showed 93% sensitivity, 92% specificity for MODY v T2D, and 79% sensitivity, 92% specificity for MODY v T1D.

Conclusion: The clinical prediction models performed well in discriminating MODY from T1D and T2D and could be used to improve selection of patients for genetic testing. A web-based version of this model may be used by clinicians and patients, as well as the diagnostic laboratory.

Cystatin C is not a good candidate biomarker for HNF1A MODY

N. Nowak¹, M. Szopa¹, G. Thanabalasingham², T.J. McDonald³, T.J. James⁴, J. Skupien⁵, B. Kiec-Wilk¹, W. Mlynarski⁶, A.T. Hattersley⁷, K.R. Owen², M.T. Malecki¹;

¹Department of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland, ²The Oxford Centre for Diabetes, Endocrinology and Metabolism, UK, ³Institute of Biomedical and Clinical Science, Oxford, UK, ⁴Biochemistry, John Radcliffe Hospital, Oxford, UK, ⁵Harvard Medical School, Boston, USA, ⁶Medical University of Lodz, Poland, ⁷Institute of Biomedical and Clinical Science, Exeter, UK.

Background and aims: Cystatin C is an excellent marker of glomerular filtration rate (GFR). Several renal phenotypes have been described in HNF1A MODY, including tubulopathies. In addition, cystatin C expression is positively regulated by CRP the level of which is decreased in this form of monogenic diabetes. Thus, we hypothesized that serum cystatin C level might be altered in HNF1A MODY.

Materials and methods: We initially examined 51 HNF1A MODY patients, 56 subjects with type 1 diabetes mellitus (T1DM) and 39 with type 2 diabetes (T2DM), as well as 43 non-diabetic individuals (ND) from Poland. We used subjects from two UK cohorts (from Oxford and Exeter) as replication panels: 36 and 179 HNF1A MODY, 36 and 167 T2DM, respectively. In addition, 39 HNF4A, 174 GCK, 17 MODY5, 58 T1DM from Exeter were included. Cystatin C level was measured locally and all relevant clinical and biochemical variables collected. The data were analyzed with linear regression models, adjusting for sex age and estimated GFR (creatinine).

Results: In the Polish subjects, adjusted cystatin C level in HNF1A MODY was lower compared to T1DM, T2DM and ND ($p<0.05$ for all comparisons). In addition, in MODY, cystatin C-based GFR was 12.5 ml/min/1.73m² higher than the one calculated from serum creatinine level using the CKD-EPI formula (95% CI: 8.3 - 19.3, $p<0.0001$), while the two GFR estimates were similar

or cystatin C-based lowed in the other groups. However, these results were not confirmed in the UK cohorts. In the cohort from Oxford there were no significant differences in serum cystatin C levels between HNF1A MODY and T2DM ($p=0.9$). In the Exeter cohort cystatin C level did not differ significantly from any other diabetic group, except HNF1B MODY, where cystatin C-based GFR was the highest, and the difference reached borderline significance ($p=0.05$).

Conclusion: We were not able to confirm our hypothesis (supported by the initial results from the Polish study groups) that cystatin C level is altered by HNF1A mutations. Thus, this molecule cannot be considered a candidate biomarker for HNF1A MODY.

Genetic testing of MODY: results from a Mediterranean population over 13 years

J. Blanco¹, A. Amor¹, M. Mora², J. Oriola³, R. Casmitjana³, J. Ferrer², I. Conget¹;

¹Diabetes Section. Endocrinology and Nutrition Service, ²Endocrinology and Nutrition Service, ³Biochemistry and Molecular Genetics Service, Hospital Clinic, Barcelona, Spain.

Background and aims: MODY is a dominantly inherited form of diabetes that is usually diagnosed in young adults. A precise molecular diagnosis is important for prognosis and treatment, and provides important information to relatives. We aimed to describe the genetic tests requested at our hospital, one of the referral centres in Spain, for the last 13 years. Although we receive samples from all over Spain, our laboratory is the only testing centre in Catalonia. We also aimed to compare data in our region with others in Europe in which the diagnosis is largely optimized.

Materials and methods: 753 samples (607 probands and 146 relatives) were received for MODY genetic testing between October 1997 and December 2010. Minimal clinical information was available for these patients. Official Census figures (Catalonia, 2004) were used to calculate referral rates and minimum prevalence across provinces. Data were analysed using SPSS v 17.0.

Results: 510 (68%) samples were referred from adult clinics and 217 (29%) samples from paediatric centres. A mutation in glucokinase (GCK) or in hepatic nuclear factor genes (HNF1 α , HNF1 β and HNF4 α) were confirmed in 182/607 (31%) of probands. 765 genes were studied in probands (1.26 genes/patient). The frequency of mutations found was 27% in the gene sequenced firstly. 150 probands had 2 genes sequenced, of which 13% had a mutation. In 8 samples in which 3 genes were studied we did not identify mutations. GCK mutations were most frequent in both children and adults - 129 cases (70% of total; 93% and 52% in the paediatric and adult positive results, respectively). There were 47 HNF1 α mutations (25% of total and 39% of adults). Of 269 samples processed firstly for HNF1 α mutations, 14% were positive. In those cases with no detected mutation in HNF1 α , HNF4 α gene re-sequencing was performed in 14% of patients and GCK gene re-sequencing was performed in 17%. There only were 3 cases (1.6% of probands with a positive result) with HNF4 α mutations. Of the 21 samples sent to study of HNF1 β gene, 7 (4% of probands with a positive result) were positives. From 182 positive probands, we received 146 samples of relatives, of which 91 (62%) had a positive result, so we only detected an extra case in the family per 2 affected probands. 64% of samples were sent from Catalonian centres and 25 % from other Spanish hospitals. Data about referral rates and prevalence are shown in Table 1.

Conclusion: Our detection rate is similar than other countries. However, GCK mutation is the most frequent cause and we found a lower minimum prevalence. It could be due to a lower optimisation of screening of potential cases of HNF1 α mutation, a limited screening of HNF4 α and to inadequate study of relatives. The successive study of others, after a negative result in the first suspected gene, is in general only worth it for HNF4 α re-sequencing after an HNF1 α negative result.

	Population	Referrals	Referrals/ million	Pick-up rate (%)	Relatives with mutation	Cases/ million

Exome sequencing in monogenic diabetes

S. Johansson^{1,2}, H.U. Irgens¹, K.K. Chudasama¹, J. Molnes¹, P.M. Knappskog², A. Molven³, P.R. Njolstad¹;

¹Dept of clinical medicine, University of Bergen, ²Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, ³the Gade Institute, University of Bergen, Norway.

Background and aims: The emerging high-throughput sequencing technologies enable much more extensive genetic analysis of single individuals than classical Sanger sequencing. Since monogenic diabetes is characterized by extensive genetic and clinical heterogeneity we therefore wanted to examine the performance of whole-exome sequencing for diagnosis of monogenic diabetes.

Materials and methods: We performed exome sequencing in patients thought to have monogenic form of diabetes and negative for mutations in GCK, HNF1A, HNF4A, HNF1B and INS. We excluded common, non-coding and synonymous variants using extensive filtering and bio-informatic analysis. Here we report our experiences from the initial analysis of the first nine probands sequenced, focusing on ultra-rare variants in a pre-defined set of 81 genes implicated in glucose metabolism.

Results: We obtained 44X average coverage of the entire targeted exome sequence and found 416 rare coding variants per individual. Among the nine individuals, 16 non-synonymous and nonsense mutations were found in our a priori list of 81 candidate genes. All but one variant were verified by Sanger sequencing. These candidate gene mutations included an HNF4A mutation (p.R89Q), despite previous negative Sanger sequencing; a PPARG mutation (p.R357X), which was unexpected given available clinical information at investigation; an ABCC8 mutation (p.A1366T) in an individual with adult onset of diabetes (which usually are not screened for ABCC8-mutations), and two additional mutations of possible etiological importance.

Conclusion: Exome sequencing led to a genetic diagnosis in at least 3 out of 9 patients who had previously undergone conventional re-sequencing of candidate genes with negative results. Thus, exome sequencing has the potential to provide more comprehensive molecular testing than Sanger sequencing in monogenic diabetes.

Identification and functional characterisation of novel inactivating glucokinase mutations causing GCK-MODY in Slovakia

L. Valentinova^{1,2}, N.L. Beer², J. Stanik^{1,3}, N.D. Tribble², M. Huckova¹, D. Gasperikova¹, I. Klimes¹, A.L. Gloyn²;

¹DIABGENE & Diabetes Laboratory, Institute of Exp. Endocrinology, Bratislava, Slovakia, ²Oxford Centre for Diabetes Endocrinology & Metabolism, University of Oxford, UK, ³Children Diabetes Centre, First Dept. of Paediatrics, Bratislava, Slovakia.

Background and aims: Heterozygous inactivating glucokinase (GCK) mutations cause a subtype of maturity-onset diabetes of the young (GCK-MODY) characterised by mild stable fasting hyperglycaemia. Over 600 GCK mutations have been reported of which ~65% are missense. In many cases co-segregation in families has not been established and despite the importance of functional studies in ascribing pathogenicity for missense variants these have only been performed for <10% of mutations. The aim of the study was to sequence GCK in Slovakian subjects with a phenotype consistent with GCK-MODY and to explore the pathogenicity of identified variants through family and functional studies.

Materials and methods: GCK was sequenced in 128 probands. Co-segregation of identified variants was assessed where parental samples were available. Novel GCK mutations were kinetically characterised.

Results: Twenty-two mutations were identified in 36 families (including 17 missense) of which 5 (I110N, V200A, N204D, G258R, F419S) were novel. All mutations were absent from 200 normal chromosomes. Parental DNA was available for 23 probands (covering 14/22 mutations) and co-segregation established in all cases. Bioinformatic analysis predicted all missense mutations to be damaging. Eight (I110N, V200A, N204D, G258R, F419S, V244G, L315H, I436N) mutations were functionally evaluated. Basic kinetic analysis explained pathogenicity for 6 mutants which showed reduced glucokinase activity due to decreased rates of catalysis and/or affinity for glucose with relative activity indices (RAI) between 0.6–<0.001 compared to wild-type GCK (1.0). Mathematical modeling predicted thresholds for glucose stimulated insulin release (GSIR) between 5.9–7.0 mmol/L. For the remaining 2

mutants (L436N, L315H) additional molecular mechanisms were investigated including defects in regulation by glucokinase regulatory protein (GKRP) and protein stability. No differences in GCK inhibition by GKRP were observed for L315H however for I436N there was diminished inhibition compared to wild type enzyme (IC_{50} 20.3 ± 1.6mM vs. 13.8 ± 0.4mM respectively [$p < 0.02$]). Protein instability as assessed by thermal lability studies demonstrated that both L315H and I436N show marked thermal instability compared to wild-type GCK (RAI at 55°C 8.8±0.8% & 3.1±0.4% vs. 42.5±3.9% respectively [$p < 0.001$]). Mathematical modelling predicted GSIR thresholds of ~6.7mmol/L for both mutants.

Conclusion: We have identified 22 GCK mutations in 36 Slovakian families. For 25% of mutations selected for functional follow-up basic kinetic analysis was insufficient to demonstrate GCK inactivation and additional studies were required to demonstrate the molecular mechanism responsible for enzyme inactivation. Combining family, bioinformatic and functional studies can aid the interpretation of variants identified by molecular diagnostic screening.

Three ancestral mutations are responsible for a third of glucokinase diabetes in the Czech registry

O. Cinek, P. Dusatkova, S. Pruhova, K. Vesela, J. Lebl;

Department of Pediatrics, Charles University in Prague, Czech Republic.

Background and aims: The nation-wide Czech MODY registry records 135 independent families with glucokinase diabetes; of these, 21 carry the p.Glu40Lys mutation, 15 the p.315His, 13 the p.Gly318Arg and 10 p.Val33Ala. Moreover, one of these mutations is strongly geographically clustered within a single region of the country. Our aim was therefore to characterize their possible common origin, and estimate their age.

Materials and methods: Available members of the above mentioned families including the healthy relatives, as well as 94 unrelated non-diabetic subjects, were genotyped for 16 single nucleotide polymorphism markers covering a region of 14 million base pairs (Mbp) around the GCK gene (8 of these markers covering the innermost 1.5 Mbp). The assays were run in the TaqMan format assays on a 384-well LightCycler 480 platform. Haplotypes were inferred using the Haploview and Phase software, the evolutionary tree drawn using the MEGA5 program, and the age of mutations estimated using the DMLE+ program. Control data were utilized to re-check for the lack of linkage disequilibrium between the utilized markers in the general population.

Results: The p.Glu40Lys is carried on an 11-marker long conserved haplotype stretching over 9Mbp; the p.Leu315His is carried on a 7-marker conserved haplotype of 1.4 Mbp; the p.Gly318Arg is carried on a 8-marker haplotype of 4 Mbp. All these conserved haplotypes had an estimated frequency in the general population less than 0.5%. The p.Val33Ala mutation showed some indications of linkage disequilibrium to the markers, yet we could not define any significant haplotype. The mutations' age was estimated to be between 64 and 93 generations (95% confidence intervals 45–132). This indicates that the mutations may have arisen when the German tribes admixed with the Slavs.

Conclusion: Our data show that over a third of families recorded in the large Czech collection of glucokinase MODY carry one of ancestral mutations. This extent of dissemination of ancestral mutations has never been shown in other populations. Our data well demonstrate that glucokinase diabetes is unlikely to decrease the reproduction fitness, and we may even ask on the nature of a putative evolutionary advantage in times of famine and starvation, similar to the one postulated for the thrifty genotype in type 2 diabetes.

Paternal mosaicism causing recurrent transmission of a novel insulin gene mutation associated with permanent neonatal diabetes

Y.M. Bee¹, Y. Zhao², F.K.P. Yap³;

¹Department of Endocrinology, Singapore General Hospital, ²Department of Clinical Research, Singapore General Hospital, ³Department of Paediatrics, Endocrinology Service, KK Women's and Children's Hospital, Singapore.

Background and aims: We recently identified 2 siblings (one male and one female) from a Chinese family with diabetes mellitus diagnosed in the first 6 months of life. The parents and 2 other brothers do not have diabetes mellitus. We aim to perform genetic sequencing for mutation in the genes commonly

associated with neonatal diabetes mellitus (i.e. KCNJ11, ABCC8 and INS) and to investigate the possibility of somatic/germline mosaicism in the clinically unaffected parents to explain the recurrent transmission of permanent neonatal diabetes.

Materials and methods: Whole blood was collected from all members of this family and genomic DNA was extracted from peripheral leukocytes using standard procedures. Initial molecular genetic analysis for the affected daughter was performed at the molecular genetics laboratory in Exeter, United Kingdom. Subsequent analyses for the identified mutation were performed for the other family members at the genetics laboratory in Singapore General Hospital. Coding exon 3 of the insulin (INS) gene was amplified by PCR. Single-strand sequencing was carried out in both the forward and reverse directions using standard methods on an ABI 3100 (Applied Biosystems). Genomic DNA from the parents was also investigated for low-level mosaicism using an allele-specific quantitative real-time polymerase chain reaction (qPCR) assay for the identified mutation. Primers used for allele-specific amplification introduced a 2 nucleotide mismatch preventing amplification of the normal allele.

Results: We identified a novel heterozygous missense mutation in exon 3 of the insulin (INS) gene, c.326G>A, in both the affected siblings. This mutation resulted in the substitution of cysteine (C) residue by tyrosine (Y) at codon 109 of the human preproinsulin molecule, causing disruption of a critical disulphide bridge. In addition, DNA sequences of the father showed low level of the mutant allele. Quantification of the mutant allele in the lymphocyte DNA showed that he had approximately 40% of the mutant allele as his affected son, confirming somatic mosaicism.

Conclusion: We have identified the first 2 cases of permanent neonatal diabetes mellitus in Singapore due to a novel INS gene mutation, C109Y. Paternal mosaicism was responsible for the recurrent transmission of INS mutation in this family. To our knowledge, this is the second reported case of parental mosaicism for mutation of the INS gene.

R325W SLC30A8 genotype is associated in a gender specific manner with post-transplantation diabetes mellitus

E. Kang^{1,2}, F. Magkos^{2,3}, C. Kim⁴, J. Moon¹, B. Lee¹, B. Cha¹, Y. Kim⁵, H. Lee¹, C.S. Mantzoros^{2,6}

¹Internal Medicine, Yonsei University College of Medicine, Seoul, Republic of Korea, ²Division of Endocrinology, Diabetes, and Metabolism, Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, USA, ³Department of Nutrition and Dietetics, Harokopio University, Athens, Greece, ⁴Pharmacology, Yonsei University College of Medicine, Seoul, Republic of Korea, ⁵Transplantation Surgery, Yonsei University College of Medicine, Seoul, Republic of Korea, ⁶Department of Environmental Health, Harvard School of Public Health, Boston, USA.

Objective: The R325W nonsynonymous polymorphism (rs13266634) in the Zinc transporter-8 gene, SLC30A8, has been reported to be associated with posttransplantation diabetes mellitus (PTDM). Some studies reported that male gender is a risk factor of PTDM. We investigated the gender difference in PTDM development according to rs13266634 genotype.

Methods: A total of 624 unrelated renal allograft recipients (174 PTDM patients and 450 non-PTDM subjects) without previously diagnosed diabetes were enrolled. The genotyping of the SLC30A8 polymorphism was performed using real-time PCR.

Results: Among 624 patients enrolled, 403 were men and 221 were women. PTDM incidence was 28.04% (113/403) in men and 27.60% (61/221) in women. The prevalence of PTDM was 33.8% in patients carrying the R/R genotype, 26.8% in patients with the R/W genotype, and 19.8% in patients with the W/W genotype. The RW genotypes were associated with a tendency to increase PTDM risk [Hazard ratio (HR) = 1.28, P=0.214] and the RR genotypes showed increased PTDM risk [HR=2.13, P=0.014] in men. Whereas the effects of this genotype were not significant [HR=1.22, P=0.491 for R/W and HR=1.82, P=0.550 for WW] in women.

Conclusion: This study suggests that the SLC30A8 rs13266634 gene variation is associated with increased risk of development of PTDM in only men.

Are population-based carriers of a mutation associated with cystic fibrosis patients more likely to have diabetes?

A. Adler, C. Langenberg, M. Sims, N.J. Wareham;

MRC Epidemiology Unit, Institute of Metabolic Sciences, Cambridge, UK.

Background and aims: Cystic fibrosis-related diabetes (CFRD) is increasingly common and occurs in some one third of adults with cystic fibrosis (CF), an autosomal recessive disorder. $\Delta F508$, a specific mutation within the gene for the protein cystic fibrosis transmembrane conductance regulator (CFTR), is the most common mutation causing CF and is carried by approximately 3-4% of individuals in the Northern European general population. Carriers of CFTR mutations, relative to non-carriers, may be more likely to develop medical conditions that accompany CF. Therefore, we tested whether the presence of $\Delta F508$ was associated with type 2 diabetes in the adult general population in the East of England.

Materials and methods: We genotyped the $\Delta F508$ variant in three type 2 diabetes case-control studies, including a total of 4,146 cases and 4,261 controls of European descent from the Norfolk Diabetes Case-Control Study (2,767 cases, 2,216 controls), the Cambridgeshire Case-Control Study (497 cases, 483 control), and the Addition/Ely studies (882 cases, 1,562 controls). Genotyping was performed at the MRC Epidemiology Unit Research Laboratory using a custom primer pair and custom probes (call rates 94%, 92%, 98%, respectively; Hardy Weinberg equilibrium p-values >0.4). We used logistic regression analyses to test the association between $\Delta F508$ heterozygosity and diabetes risk, adjusting for age, sex and body mass index (BMI). We used random effects meta-analysis methods to combine odds ratios across studies.

Results: 2.7% to 3.6% of controls were heterozygous for the $\Delta F508$ mutation. The association between $\Delta F508$ and diabetes risk was not significant in any of the individuals studies (figure 1), with a pooled odds ratio (95% confidence interval) of 0.93 (0.73; 1.19) and no heterogeneity between studies (I-squared 0%).

Conclusion: This study has identified no association between carrying the $\Delta F508$ mutation for CFTR and the presence of diabetes mellitus. If the presence of a single $\Delta F508$ inhibits insulin production, then this effect appears insufficient to cause diabetes. In summary, despite the high rates of diabetes observed in CF, carriers of the $\Delta F508$ mutation do not have a risk of diabetes different from that of non-carriers. Figure 1. Meta-analysis of the cystic fibrosis transmembrane conductance regulator (CFTR - $\Delta F508$) and type 2 diabetes

Prevalence of diabetes and pre-diabetes in a cohort of Italian young adults affected by Williams Syndrome

B. Masserini¹, M.F. Bedeschi², V. Bianchi², M.E. Lunati¹, V. Grancini¹, P. Beck-Peccoz¹, F. Lalatta², E. Orsi¹;

¹Unit of Endocrinology and Diabetology, Department of Medical Sciences, Università degli Studi di Milano, ²Clinical Genetics Unit, Dipartimento Salute della donna, del bambino, del neonato, Fondazione IRCCS Ca' Granda - Ospedale Maggiore Policlinico, Milan, Italy.

Background and aims: Williams Syndrome (WS) is a rare, multisystemic genomic disorder. While the natural history of the disease in childhood is quite well-known, few descriptions of the adult WS medical complications have been published. Recent data showed a high prevalence of diabetes in these patients.

Materials and methods: 22 young adult patients with WS (13 females, 9 males, age: 29.2±5.4 years) were studied. A 75g oral glucose tolerance test (OGTT) was performed in all but one who had known diabetes mellitus (DM). β -cell function was estimated with HOMA-B% and with insulinogenic index at 30 minutes ($\Delta I/\Delta G_{30}$). The insulin sensitivity was assessed with HOMA-IR, QUICKI and composite insulin sensitivity Matsuda index (ISI).

Results: Impaired glucose tolerance (IGT) was diagnosed in 12 subjects and DM in one, thus showing that 59% of this population had impaired glucose metabolism. ICA and GAD antibodies were absent. Logistic regression showed that the presence of impaired glucose metabolism was not associated with BMI ($P=0.267$, $B=0.118$), age ($P=0.977$, $B=0.004$), family history of diabetes ($P=0.653$, $B=0.747$), which are known risk factors for DM. WS subjects with IGT were more insulin-resistant than WS with normal glucose metabolism (HOMA-IR 2.3±0.9 vs 1.0±0.6, $P=0.008$; QUICKI 0.34±0.02 vs 0.39±0.04, $P=0.002$, ISI 3.2±1.4 vs 7.4±2.8, $P=0.006$). WS subjects with normal glucose tolerance compared to healthy adults matched for gender, age and BMI did not show any difference in β -cell function, insulin sensitivity, insulin levels during OGTT, but showed higher glucose levels at 120' after glucose load.

Conclusion: Given the high prevalence of impaired glucose regulation, adults with WS should be screened for diabetes or IGT. The reasons of this high prevalence of impaired glucose metabolism are not known. We excluded autoimmunity and usual risk factors for DM. However insulin resistance is likely to have a role in impaired glucose metabolism in WS subjects as it does in general population and lifestyle diabetogenic risk factors can have a role too. In fact these patients have limited physical activity due to mental deficiency or orthopaedic problems. However hemizygosity for a gene mapping to the WS chromosome region could be the factor responsible for the high frequency of diabetes and IGT in WS.

Glycotoxin and autoantibodies are additive environmentally-determined predictors of type 1 diabetes: a twin and population study

H. Beyan¹, H. Riese^{2,3}, M.I. Hawa¹, G. Beretta¹, H.W. Davidson⁴, J.C. Hutton⁴, H. Burger^{3,5}, M. Schlosser^{6,7}, H. Snieder², B. Boehm⁷, R.D. Leslie¹;

¹Centre for Diabetes, Blizard Institute of Cell and Molecular Science, London, UK, ²Department of Epidemiology, Unit of Genetic Epidemiology & Bioinformatics, Groningen, Netherlands, ³Department of Psychiatry, Interdisciplinary Center for Psychiatric Epidemiology, Groningen, Netherlands, ⁴Barbara Davis Center, Aurora, USA, ⁵Department of Epidemiology, Groningen, Netherlands, ⁶University of Greifswald, Institute of Pathophysiology, Germany, ⁷Division of Endocrinology and Diabetes, University Medical Center Ulm, Germany.

Background and aims: Type 1 diabetes mellitus is caused by destructive innate and adaptive immune responses. Serum diabetes-associated autoantibodies, to islet cell autoantibodies (ICA), glutamic acid decarboxylase (GADA), insulinoma-associated antigen-2 (IA-2A) and zinc transporter-8 (ZnT8A), reflect adaptive immunity, while carboxy-methyl-lysine (CML), an advanced glycation end-product, is associated with proinflammation. We assessed in a twin study whether serum CML levels and autoantibodies in type 1 diabetes were genetically determined, and whether they predicted diabetes in a population-based cohort.

Materials and methods: Serum CML and autoantibodies were determined prospectively in: a classical study of twins discordant for type 1 diabetes (32 monozygotic (MZ), 32 dizygotic (DZ) pairs); and, a population study of 7,287 normal subjects. In the latter, ICA positive subjects were followed for diabetes development. CML levels were determined by ELISA, autoantibodies by radio-immunoprecipitation and indirect immunofluorescence, HLA class II genotyping by sequence-specific oligonucleotides.

Results: CML levels were increased in diabetic and non-diabetic twins, population-based autoantibody positive and pre-diabetic subjects (all $p<0.001$). Twin CML correlations (r) were strong, irrespective of zygosity: model-fitting showed familial environmental factors explained 75% of variance. Autoantibodies were more frequent in diabetic than non-diabetic twins ($p<0.001$); but twin correlations were weak, irrespective of zygosity; non-shared environment explained all variance. Elevated CML in ICA positive subjects was a persistent and additive predictive marker of progression to diabetes.

Conclusion: Familial and non-shared environmental factors were strong determinants of serum CML and diabetes-associated autoantibodies, respectively. CML, a glycotoxin, is an additional diabetes-risk determinant with autoimmunity, and deserves consideration as a potential therapeutic target.

Does the present incidence of type 1 diabetes in Poland in children fit the primary prediction for 2009?

J. Polanska¹, A. Szadkowska², M. Mysliwiec³, G. Deja⁴, A. Brandt³, A. Chobot⁵, P. Jarosz-Chobot⁴;

¹Silesian University of Technology, Gliwice, ²Medical University of Lodz, ³Medical University of Gdansk, ⁴Medical University of Silesia, Katowice, ⁵Clinical Hospital No 1, Zabrze, Poland.

Background and aims: Based on the rapid incidence increase of type 1 diabetes (T1DM) in Polish children (1989 - 2004) an incidence estimation for 2005 - 2025 was performed. The aim was to assess whether the temporal changes in incidence of T1DM in Polish children fit the primary predictive model.

Materials and methods: Children under 15yrs with newly diagnosed T1DM are ascertained prospectively (EURODIAB criteria) in several regional Polish registers. The prediction was constructed (GAM - general additive model) using incidence data collected 1989-2004 from 7 regions, covering ~35% population of Poland. The model was validated using Wielkopolska (Poznan) region data (1970-1989). The updated age- and sex- standardized incidence data (2005-2009) was derived from ~25% population (3 regions: Lodz, Pomorze, Silesia).

Results: During the last five years the age- and sex- standardized IR increased significantly from 16.1 [per 100,000] in 2005 to 21.0 in 2009 ($p=0.02$), which

is consistent with the GAM predicted dynamics (1.19 per year per 100,000) and it is higher than in the previous five-year period 2000–2004 (see figure). There were no significant differences between boys and girls. The most significant raise, consistent with the GAM prediction, was noticed among children aged 10–14 (from 16.0 per 100,000 to 23.4; annual increase 2.07 per year per 100,000 $p=0.02$). The significant increase of IR among children aged 0–4 and 5–9 was not observed (from 11.8 to 14.3; $p=0.24$ and from 20.1 to 24.4 per 100,000; $p=0.08$ respectively), which is disagreeing with GAM prediction. **Conclusion:** The present incidence of type 1 diabetes in Poland in children fits the primary prediction. The intuitively expected indicators of incidence saturation have not been observed yet. We confirm that the dramatic increase could cause real downstream effects on the national health care system in Poland.

Pattern as well as pre-diabetic absence or presence of antibodies reveals phenotypic difference among LADA patients: results from the HUNT study

E. Pettersen¹, K. Midtthjell², V. Grill¹

¹Norwegian University of Science and Technology, Institute of cancer research and molecular medicine, Trondheim, ²Norwegian University of Science and Technology, Institute of public health and general practice, HUNT, Levanger, Norway.

Background and aims: Latent autoimmune Diabetes in the Adult (LADA) comprises a large part of all diabetes. Yet, the etiology of LADA is not completely clarified, nor distinctions from “classical” type 1 diabetes (T1D). Here we investigated cross sectionally the pattern, and prospectively also the pre-diabetic appearance of autoantibodies in LADA and adult onset T1D (age at onset >25) in a geographically defined and all-population-inclusive cohort of individuals >=20 years of age.

Methods: Patients with known diabetes were identified from the second (1995–1997) and third (2006–2008) population health survey in Nord-Trøndelag County, Norway (HUNT2 and HUNT3). Patients were classified by measurements of antibodies against glutamic acid decarboxylase (GADA) and by C-peptide. Patients classified as LADA were GADA positive and not treated with insulin within 12 months of diagnosis. Patients were classified as “classic” T1D if starting insulin treatment within 12 months of diagnosis and being either GADA positive, or GADA negative with fasting C-peptide levels <150 pmol/l. Measurements of antibodies against IA2 and ZnT8 were then carried out by means of RIA.

Results: Prevalent cases: Eighteen out of 162 LADA patients tested positive for other antibodies than GADA. Doubly and triply positive LADA patients vs. singly positive has had their diabetes diagnosis for a shorter time ($p=0.026$), had lower systolic blood pressure ($p=0.011$) and higher birth order ($p=0.020$), tended to have lower hip circumference ($p=0.057$) and higher non-fasting blood glucose ($p=0.058$). Age at onset was not associated with numbers of antibodies. Comparing LADA with adult onset T1D ($n=103$), LADA patients less frequently had more than one antibody (2 antibodies

$p=0.031$ and 3 antibodies $p=0.042$) but had higher GADA and IA2A-titers ($p=0.0002$ and $p=0.002$ respectively). Incident cases: Twenty-two out of 34 (65%) incident cases of LADA at HUNT3 were already antibody-positive 11 years earlier at HUNT2. Patients who were antibody positive at HUNT2 were diagnosed at younger age (54.4 ± 11.0 vs. 66.3 ± 8.63 , $p=0.002$), had lower blood pressure at HUNT2 ($p=0.048$) and were associated with higher GADA-titer at HUNT3 ($p=0.006$) than antibody negative patients. Thirteen out of 24 incident T1D cases (54%) were antibody positive already at HUNT2. There were no distinctive differences between antibody positive and antibody negative T1D patients either at pre-diabetes (HUNT2) or at overt diabetes (HUNT3). Antibody negative LADA at HUNT2 (pre-diabetes) were diagnosed at an older age than negative T1D ($p=0.004$).

Conclusion: Pattern, as well as pre-diabetic absence or presence of antibodies, reveals phenotypic differences among LADA patients. Differences were also found in comparison to adult-onset T1D. The differences observed could have therapeutic implications.

Frequency of diabetic ketoacidosis in children with newly diagnosed type 1 diabetes in Serbia

I. Rakocevic¹, D. Miljus¹, T. Knezevic¹, D. Zdravkovic², J. Vlaski³, S. Sajic⁴, L. Kitaresku⁵, S. Kanacki Stankovic⁶, M. Ljubojevic⁷

¹Institute of Public Health of Serbia, ²Institute for Mother and Child Health Care of Serbia, ³Institute for child and youth health care of Vojvodina, Novi Sad, ⁴University children's hospital, Belgrade, ⁵General Hospital Zrenjanin, ⁶General Hospital Pancevo, Pancevo, Serbia, ⁷General Hospital Uzice, Serbia.

Background and aims: Diabetic ketoacidosis (DKA) is a frequent acute complication at onset of type 1 diabetes and is inversely related to incidence of type 1 diabetes. Compare to other European countries, incidence of type 1 diabetes in children aged 0–14 years in Serbia (13.1 per 100,000) indicates a moderate risk for this disease. Aim of this study was to determine the prevalence of DKA among children with newly diagnosed type 1 diabetes in Serbia in 2009.

Materials and methods: We conducted a cross-sectional study of newly diagnosed type 1 diabetes patients aged 0–14 years, from 10 regions in Serbia, identified through Serbian Diabetes Registry in year 2009. All comparisons were age and sex standardized to the national population. To compare the prevalence between the two groups, χ^2 -test was performed.

Results: DKA was observed in 39 (41.5%) of 94 newly diagnosed type 1 diabetes patients. There was no difference in the frequency of DKA between boys and girls (46.9 vs. 35.6%; $P=0.284$). The mean \pm SD age of the patients initially presenting with DKA was 8.2 ± 3.7 years. Boys were older than girls (9.6 vs. 6.3 years; $P=0.006$), and the proportion of boys increased by age. In agreement with previous studies, we observed that DKA was the most common among children aged <5 years (58.3%). Prevalence decreased significantly with age, and was the lowest in those aged 10 to 14 years (58.3% vs. 36.7%; $P=0.002$). Prevalence of DKA at onset of diabetes in summer was 33.3%, and in winter 46.2%. The difference was not statistically significant ($P=0.098$). The proportion of ketoacidosis increase concurrently with the proportion of newly diagnosed diabetes patients in winter.

Conclusion: The overall frequency of DKA in children with newly diagnosed type 1 diabetes in Serbia is high. Children less than 5 years of age have the highest risk of DKA at onset of diabetes. Increased public awareness about symptoms and signs of diabetes in childhood may reduce DKA rate at diabetes onset. In order to decrease frequency of diabetic ketoacidosis at diagnosis of type 1 diabetes there is an urgent need for prevention programmes to be designed.

Pancreatic atrophy is apparent at the onset of type 1 diabetes in adults
A.J.K. Williams¹, S.J. Thrower², I.M. Sequeiros³, A. Ward⁴, A.S. Bickerton⁵, J.M. Triay⁶, M.P. Callaway³, C.M. Dayan⁷;

¹School of Clinical Sciences, University of Bristol, ²Diabetes & Endocrinology, University Hospitals Bristol NHS Trust, ³Radiology, University Hospitals Bristol NHS Trust, ⁴Diabetes & Endocrinology, Royal United Hospital, Bath, ⁵Diabetes, Endocrinology & General Medicine, Yeovil District Hospital, ⁶Diabetes & Endocrinology, Weston General Hospital, ⁷Centre for Endocrine & Diabetes Science, University of Cardiff, UK.

Background and aims: Pancreatic atrophy is a characteristic finding in long-standing type 1 diabetes; pancreas size is reduced by 50% in adult patients who have had clinical disease for more than 10 years. Our aim was to determine whether pancreatic size was already reduced at disease onset and discover whether pancreatic volume in patients could be related to measures of metabolic and immune function.

Materials and methods: Pancreatic volume was measured in 21 male adult patients (median age 30 years, range 18 to 42 years) and 24 male healthy controls (median age 27 years, 19 to 44 years) by magnetic resonance imaging using a validated 3-D volumetric interpolated breathhold examination (VIBE) sequence; a T1 volume gradient echo sequence with fat saturation. Planar image slices throughout the pancreas were acquired at 2.5-mm intervals. Coded scans were analysed by an experienced radiologist who was ignorant of diabetes status. The patients had been diagnosed for a median of 3.6 months (range 1 to 7.9 months). Fasting blood samples were taken for measurement of glucose, C-peptide, HbA1c and the islet autoantibodies GADA, IA-2A and ZnT8A. Stimulated C-peptide was also measured in patient samples following injection of 1mg glucagon.

Results: Median pancreatic volume of the patients was 95 ml (range 37 to 141 ml) compared to 115 ml (range 67 to 195 ml) in the controls ($p=0.012$). Pancreatic volume correlated with body weight in patients and controls ($y=1.21x+15.7$, $p=0.012$). Following adjustment for body weight, median pancreatic volume index was found to be 20% less in patients (1.22 ml/Kg, range 0.56 to 1.74 ml/Kg) than in controls (1.53 ml/Kg, range 0.95 to 2.75 ml/Kg, $p=0.001$). No significant correlation was seen between pancreatic volume index in patients and diabetes duration, fasting glucose, HbA1c and stimulated C-peptide. Sixteen patients were positive for at least one islet antibody but there was no relationship between pancreatic volume index and the number of islet autoantibodies.

Conclusion: Pancreatic volume is reduced by 20% in patients with type 1 diabetes within months of diagnosis, suggesting that atrophy may begin years before the onset of clinical disease. Pancreatic atrophy within individuals is therefore a potential clinical marker of disease progression. The interaction between the exocrine and endocrine compartments within the pre-diabetic pancreas needs to be explained.

Guangdong type 1 diabetes mellitus translational medicine study (1): clinical characteristics of 3,159 type 1 diabetic patients

J. Li¹, D. Cai², G. Luo³, G. Wu⁴, S. Lin⁵, L. Yuan⁶, M. Xu⁷, L. Zeng¹, S. Li⁸, D. Chen⁹, J. Wu¹⁰, Y. Fang¹¹, J. Lin¹², J. Weng¹;

¹The Third Affiliated Hospital of Sun Yat-Sen University, Guangzhou, ²Zhujiang Hospital, Southern Medical University, Guangzhou, ³Shenzhen Second People's Hospital, ⁴Affiliated hospital of Guangdong medical college, Zhanjiang, ⁵The first Affiliated Hospital of Shantou University Medical College, ⁶Zhuhai People's hospital, ⁷Huizhou Municipal Central Hospital, ⁸Qingyuan People's hospital, ⁹Guangzhou First Municipal People's Hospital, ¹⁰Yue Bei people's Hospital, Shaoguan, ¹¹Jieyang People's Hospital, ¹²Jiangmen Central Hospital, China.

Background and aims: There are limited data on epidemiology and management of T1DM among Cantonese population. Given that, we initiated a series of province-wide studies to find out the current situation and to explore an appropriate management model for T1DM in Guangdong Province, China. First, we conducted this survey to provide the clinical characteristics of T1DM in Guangdong Province, China.

Materials and methods: A web-based registry database was established in August 2010. Data of established T1DM and newly diagnosed T1DM patients in 89 tertiary and secondary hospitals from all of the 21 cities in Guangdong Province were registered in the database from January 2000 to March 2011. Their medical records were collected and analyzed. The protocol and informed consent document were approved by the research ethics board of the 3rd affiliated hospital of Sun Yat-Sen University. All patients gave written informed consent.

Results: A total of 3,159 T1DM patients (1,698 males and 1,461 females) were enrolled in this study. The peak time of onset occurred at 20–29 years (mean age (SD) 28.8 (15.0) years) with about 26.93% of all patients, whereas the percentage of patients with the onset age <15 years was only 19.27%. The average disease duration was 5.7 (5.2) years. The mean BMI was 19.86 (3.45) kg/m² (data available in 1,886 patients). Family histories with diabetes in first-degree relatives were positive in 278 (8.80%) patients. Frequency of diabetic ketoacidosis (DKA) at onset of the disease was as high as 47.33% (data available in 2,846 patients). Among 1,428 patients with records on accompanying diseases, 42 (2.94%) had hypothyroidism, 51 (3.57%) had hyperthyroidism and another 5 (0.35%) patients had subclinical hyperthyroidism. Among patients with records on chronic diabetic complications, 17.48% (301/1,722) had diabetic nephropathy, 13.18% (221/1,677) had diabetic retinopathy, and 16.37% (281/1,717) had diabetic neuropathy. The morbidity of chronic complications increased with the duration of diabetes. For those with duration < 5 years, only 12.48 % (126/1,010) had nephropathy, while among patients with disease duration 5–15 and > 15 years, the percentage increased to 16.73% (94/562) and 54.74% (75/137), respectively. In terms of insulin regimens, 3.2% (101/3,159) were treated with insulin pumps. Among 1,376 patients with valid data of insulin categories, 49 (3.56%) were on animal insulin, 692 (50.29%) were on human insulin, and 635 (46.15%) were on human insulin analogues.

Conclusion: Our survey showed unique clinical characteristics of T1DM patients in Guangdong Province, China as compared with those in high or intermediate incidence regions: older age, higher morbidity of DKA at onset and lower BMI.

Causes of death after initiation of dialysis among patients with childhood-onset type 1 diabetes in Japan: DERI mortality study

A. Morimoto¹, R. Nishimura¹, H. Sano¹, K. Utsunomiya¹, N. Tajima²;
¹Division of Diabetes, Metabolism and Endocrinology, Department of Internal Medicine, Jikei University School of Medicine, Tokyo, ²Jikei University School of Medicine, Tokyo, Japan.

Aim: To investigate causes of death after initiation of dialysis among patients with type 1 diabetes in Japan.

Methods: Subjects were 92 patients (37 males and 55 females) who died after initiation of dialysis, from 223 deceased cases taken from a total of 1,387 patients with childhood-onset type 1 diabetes. They were registered from two nationwide type 1 diabetes surveys in Japan and had been diagnosed with type 1 diabetes at less than 18 years of age between 1965 and 1979. All patients

were tracked for survival status until January 1, 2005 (follow-up period: 35 years), with status determined based on questionnaires sent to their attending physicians or the residents' records. Dialysis status and causes of death were identified through questionnaires or death certificates. The causes of death were divided into 9 groups (1. diabetic renal disease (RD); 2. acute diabetic complications; 3. accident/suicide; 4. cardiovascular disease (CVD); 5. infections; 6. malignant neoplasms; 7. other non-diabetic causes; 8. other diabetic causes; 9. unknown) and were also compared by follow-up period divided into quartiles (<14.8, 14.8–20.7, 20.8–26.0, >= 26.1 years). Statistical analyses were performed using SAS 9.1.

Results: The mean age at diagnosis of the 92 subjects was 11.1 ± 3.8 (SD) years, with a duration of diabetes of 23.9 ± 6.9 years. The mean follow-up period was 20.5 ± 7.6 years, and the mean age of death was 35.0 ± 7.3 years. The causes of death identified were RD: 35 cases, CVD: 25 cases, infections: 20 cases, other non-diabetic causes: 4 cases, unknown cause: 3 cases, acute diabetic complications: 2 cases, other diabetic causes: 2 cases, accidents and suicides: 1 case, and malignant neoplasms: 0 case. Among 25 patients who died from CVD, cerebral hemorrhage was the most frequent (10 cases, 40%), and myocardial infarction was the second most common cause of death (6 cases, 24%). The percentage of death from RD decreased as the follow-up period increased (<14.8 years: 56.5%, 14.8–20.7 years: 47.8%, 20.8–26.0 years: 34.8%, >=26.1 years: 13.0%). The percentage of death from CVD tended to increase as the follow-up period increased (<14.8 years: 21.7%, 14.8–20.7 years: 13.0%, 20.8–26.0 years: 26.1%, >=26.1 years: 47.8%). There was no trend identified in the percentage of death from infections according to the follow-up period (<14.8 years: 8.7%, 14.8–20.7 years: 34.8%, 20.8–26.0 years: 17.4%, >=26.1 years: 26.1%).

Conclusion: RD, CVD and infections were found to be the leading causes of death after initiation of dialysis among patients with childhood-onset type 1 diabetes in Japan. The percentage of death from RD was high in the earlier follow-up period although they had already initiated dialysis. Reasons for this might include the initiation of dialysis at a much later stage compared to recent patients with renal failure, because it was not until the early 1980s that dialysis became available for health insurance coverage in Japan, and that the technology for dialysis had not been as advanced. However, the percentage of death from RD decreased as the follow-up period increased while the percentage of death from CVD tended to increase as the follow-up period lengthened. Cerebral hemorrhage was the most frequent, and myocardial infarction the second most common cause of death among patients who died from CVD.

PS 013 Which treatments are we using?

371

Prevalence of antidiabetic medication use prior to and during pregnancy, 2001–2008

J.M. Lawrence¹, V.Y. Chiu¹, J.Q. Wang¹, T.C. Cheetham²;

¹Research & Evaluation, Kaiser Permanente, Pasadena, USA, ²Pharmacy Analytic Services, Kaiser Permanente, Downey, USA.

Background and aims: With the increasing incidence of type 1 diabetes, the declining age at diagnosis for type 2 diabetes, and increasing prevalence of risk factors for gestational diabetes mellitus, more girls and women will be at elevated risk for DM or develop DM before or during their reproductive years. We examined trends in use of antidiabetic medications prior to and during pregnancy to explore how the use of drugs to treat diabetes is changing over time among pregnant women.

Materials and methods: We examined antidiabetic medication use in the 120 days before the last menstrual period (prepregnancy) and during the 2nd/3rd trimester of pregnancy among 135,111 women privately-insured and low income women (mean age 29.5 ± 6.0 years; 50% Hispanic, 26% White 12% Asian, 10% Black, 2% Other) with 161,217 births in a US managed care plan's hospitals from 2001–2008 using pharmacy records and infant birth certificates. Multivariate analysis was used to examine trends in antidiabetic medication use over the 8-year period after adjustment for repeated pregnancies, maternal age, race/ethnicity, and education using the SAS GENMOD procedure.

Results: Of the 161,217 births, 1.2% was to women using one or more antidiabetic drug prepregnancy while 4.5% was to women using antidiabetic medications during the 2nd/3rd trimester. Prior to pregnancy, 0.75% used metformin, 0.35% used insulin, and 0.23% used a sulfonylurea. Use of any antidiabetic medication pre-pregnancy \approx tripled from 2001 to 2008 (0.58% to 1.72%) with a 16% annual increase (95% CI 1.14–1.18) after adjusting for demographics and repeated pregnancies. Most of the increase was among women using metformin only (0.14% to 1.02%) versus other oral medications (0.20% to 0.26%) or insulin (0.24% to 0.40%). The use of antidiabetic medications increased by 7% per one year increase in maternal age (95% CI 1.06–1.08). During the 2nd/3rd trimester, 3.80% used insulin, 0.77% sulfonylurea, and 0.22% metformin. Use of antidiabetic medications increased by 17% from 2001 to 2008 (4.06% to 4.77%), with a 1.3% annual increase (95% CI 1.003–1.024) after adjusting for demographics and repeated pregnancies. The use of insulin declined (3.95% to 3.47%) while sulfonylureas (0.11% to 0.71%) and metformin (0.01% to 0.51%) use increased during pregnancy. Pregnant women who were older, had less than a high school education, and who were not non-Hispanic white were more likely to use these medications during pregnancy than their other pregnant counterparts (all p 's < 0.001). Overall, 0.4% births were to women who only used antidiabetic medications pre-pregnancy, 3.7% to women who only used them during pregnancy, 0.8% to women who used them both pre-pregnancy and during pregnancy, and 95.1% to women who did not use them. The majority of women who discontinued using antidiabetic medication after they become pregnant without starting another antidiabetic medication were using metformin; 60% of women using metformin pre-pregnancy did not use antidiabetic medications during pregnancy.

Conclusions: The increasing prevalence of antidiabetic medication use in the preconception period indicates a rise in DM and/or insulin resistance among childbearing women. However, the use of antidiabetic medications during pregnancy increased minimally over this same period in this diverse cohort. This study will continue to explore the association between risk factors and diabetes treatment on maternal and infant health outcomes.

Sulphonylurea use in a woman with TNDM due to KCNJ11 mutation during pregnancy

Z. Gaal¹, I. Kantor², A. Bodnar¹, Z. Papp¹, L. Albert³, G. Karaszi³, K. Papp³, I. Balogh⁴;

¹4th Department of Medicine, Josa Andras Teaching Hospital, Nyiregyhaza,

²Department of Pediatrics, Josa Andras Teaching Hospital, Nyiregyhaza,

³Department of Obstetrics and Gynecology, Josa Andras Teaching Hospital,

Nyiregyhaza, ⁴Department of Clinical Biochemistry and Molecular Pathology, University of Debrecen, Hungary.

Background and aims: Children diagnosed with diabetes within the first 6 months of their life (referred to as neonatal diabetes) are likely to have monogenic diabetes. Approximately 25% of Transient Neonatal Diabetes Mellitus (TNDM) cases are caused by KCNJ11 and ABCC8 gene mutations. Sulphonylureas (SU) are effective in most KCNJ11 gene (encoding Kir6.2) related TNDM patients. There are few data on SU use in pregnancy in a KCNJ11 mutation carrier. We report SU use in a woman with TNDM due to the KCNJ11 mutation during pregnancy.

Materials and methods: A woman with the c.685G>A (p.E229K) Kir6.2 mutation became pregnant at the age of 16. The index patient in her family was her father. Her father and her brother have the same mutation and all of them were successfully transferred to sulphonylurea from insulin. The patient had been treated on 60 mg gliclazide daily for 4 years. She was not adherent to therapy, she used the tablets only every other day. Her HbA1c level was 8.2 % when she was referred to our clinic at the 11th week of her pregnancy. Despite of medical advice she made the decision to keep the baby by all means. She had no chronic diabetes complications. As her diabetes was very unstable during the years of insulin treatment and SU treatment had been optimal for years we decided to continue SU treatment. Her blood glucose was tested 3-4 times a day, Guardian Real Time Continuous Monitoring was performed in the second and in the third trimester.

Results: From the second day of directly observed gliclazide treatment she was normoglycemic during the whole pregnancy. This was supported by 2 CGMS, SMBG (3-4 times a day) and 3 consecutive HbA1c levels (5.8-5.2 -5.2%). There was no need to increase the dose of the SU. Cesarean delivery was carried out in the 38th week. The Apgar score of the newborn girl (weight 3010g) was 10 at 1 minute. The same mutation was identified from the umbilical cord blood. The baby has had no diabetes so far and her development is normal. Her blood glucose was checked regularly in the last 7 month. Our patient, the mother gained 10 kg during the pregnancy and her present BMI is 31kg/m². Since her labour she is not adherent to the therapy again, directly observed therapy is not possible. Her present SMBG range is 5-12 mmol/l, and the last 2 HbA1c was 9.1-9.3%.

Conclusion: The optimal dose of gliclazide was safe and effective for the patient and for the baby. In KCNJ11 gene caused mutation cases of TNDM the SU can maintain normoglycemia during pregnancy. This is the first case report of gliclazide use during pregnancy in TNDM caused by KCNJ11 mutation and the first identification of KCNJ11 mutation in a newborn. In some cases directly observed SU treatment is necessary in TNDM patients.

373

Change of management status in newly diagnosed Korean type 2 diabetic patients: 3-year follow-up of Korean type 2 diabetes prospective cohort study

M. Choi, S. Chin, S. Rhee, S. Chon, Y. Hwang, I.-K. Jeong, S. Oh, K. Ahn, H. Chung, J.-T. Woo, S.-W. Kim, J.-W. Kim, Y. Kim, Korea National Diabetes Program (KNDP) Group;

Department of Endocrinology and Metabolism, Kyung Hee University School of Medicine, Seoul, Republic of Korea.

Background and aims: Population based studies described that the prevalence of diabetic complication at time of diagnosis varies between 10% and 20%. About 50% of the subjects of UKPDS had substantial macro- or micro-vascular abnormalities at the time of T2DM diagnosis. The aims of this study were to describe the prevalence of diabetic complications among newly diagnosed diabetic patients who were enrolled to Korea national diabetes program (KNDP) constructing the type 2 diabetes cohort consisting of 12 university hospitals.

Materials and methods: Of 4,256 patients enrolled to the cohort, 712 newly diagnosed drug naïve patients were participated in this study. Metabolic profiles and diabetic complication status at diagnosis were investigated. And, data

of all 198 newly diagnosed type 2 diabetics who reached 3-year follow-up periods were compared with the baseline data including metabolic profiles and complication status.

Results: Mean age and HbA1c at the time of diagnosis were 51.3 ± 10.0 years and 8.2 ± 2.4% in 712 newly diagnosed drug naïve patients. The prevalence of metabolic syndrome at diagnosis was 88.8%. The prevalence of diabetic nephropathy, retinopathy, and neuropathy at the time of diagnosis were 21.4%, 8.4%, and 38.6% of 712 newly diagnosed drug naïve patients, respectively. During 3-year follow-up, lipid profile including total cholesterol, HDL-cholesterol, and LDL-cholesterol improved significantly compared with the baseline (P<0.001) in 198 subjects who reached 3-year follow-up. The glycemic control was improved in all glycemic parameter; fasting plasma glucose (FPG), postprandial plasma glucose (PPG), and HbA1c (FPG; 150.8 ± 54.6 vs. 128.9 ± 36.8 mg/dL, P<0.001, PPG; 266.7 ± 89.8 vs. 163.3 ± 65.4 mg/dL, P<0.001, and HbA1c; 8.0 ± 2.3 vs. 6.8 ± 0.9, P<0.001). Insulin secretory function measured by insulinogenic index was improved from 0.15 ± 0.16 to 0.38 ± 0.60 (P=0.013). At 3-year follow-up period, diabetic nephropathy assessed by urine albumin excretion was 20.8% of 198 subjects who reached 3-year follow-up, as compared with 25.5% at the baseline. Prevalence of diabetic retinopathy assessed by funduscopy was 15.2%, as compared with 9.8% at the baseline. Prevalence of diabetic polyneuropathy assessed by neuropathic symptom questionnaire was 17.7%, as compared with 34.1% at the baseline. There was significant improved carotid intima medial thickness after 3-year follow-up (P<0.001).

Conclusion: In conclusion, there had been an improvement in the management of glycemic control and cardiovascular risk factors while management status to prevent chronic complication was not enough. The introduction of intensive and systematic care into clinical practice should be necessary to prevent diabetes related chronic complication.

374

Time to insulin initiation, glucose control and occurrence of diabetes related complications in France, Germany and UK from 2005 to 2010

K. Kostev, U. Mergenthaler;

CES LifeLink - Patient Data, IMS Health GmbH & Co OHG, Frankfurt, Germany.

Background and aims: The market entrance of innovative oral anti-diabetics (OAD) like glitazones and DDP-4 inhibitors over the past years has enabled the time to insulin treatment for patients with diabetes mellitus type 2 (T2D). The study aimed to evaluate firstly whether the time to insulin has increased from 2005 to 2010 and to examine secondly the status of patients regarding diabetes-related events and glucose control before start of insulin therapy.

Material and methods: This retrospective cohort study analysed data collected by general practitioners in France, Germany and the UK using three longitudinal databases of the IMS® Disease Analyzer. The databases were searched for diabetes patients > 40 years (ICD-10 code E11; first diagnosis = index date) initiated on insulin therapy (ATC: A10C) between 1/2005 and 12/2010. Endpoints were (i) time from index date to initiation of insulin therapy (ii) the last HbA1c value within 6 months before start of insulin therapy (iii) percentage of patients with at least one macrovascular event (myocardial infarction, stroke, heart failure, coronary heart disease) between index date and first insulin prescription (iiii) mean number of different diabetes complications (myocardial infarction, stroke, heart failure, coronary heart disease, peripheral arterial occlusive disease, retinopathy, polyneuropathy, nephropathy) per patient from index date to first insulin prescription. Differences were tested by using Wilcoxon Rank Sum Test and Chi Square Test.

Results: Overall, 6,368 patients in Germany (mean age: 68.0 years [SD: 11.7], 51.7% male), 3,047 patients in France (mean age: 65.7 years [SD: 12.7], 53.7% male), and 1,998 patients in UK (mean age: 64.4 years [SD: 11.9], 55.3% male), had started with insulin therapy between 2005 and 2010. From 2005 to 2010, median duration until insulin initiation increased from 2.6 years to 4.2 years (p<0.001) in Germany, from 1.4 years to 3.2 years (p<0.001) in France and from 4.7 years to 5.6 years (p<0.001) in UK. In all three countries the percentage of patients with at least one macrovascular event before insulin initiation was higher in 2010 compared to 2005: in Germany 50.5% vs 45.3%, in France 26.3% vs. 18.5%, in UK 31.7% vs. 27.4%. In Germany, the difference was statistically significant (p<0.001). Mean number of different diabetes related complications per patient was slightly higher in 2010 compared to 2005: in Germany 1.31 (SD 1.29) vs. 1.17 (SD 1.20), in France 0.50 (SD 1.01) vs. 0.42 (SD 0.83), in UK 0.74 (SD 0.86) vs. 0.46 (SD 0.78). In UK, the difference was statistically significant (p<0.001). Median HbA1c values increased

from 7.80% in 2005 to 8.10% in 2010 in German patients ($p=0.0278$), from 8.55% to 8.60% ($p=0.0801$) in France and from 9.40% to 9.55% in the UK ($p=0.1344$).

Conclusion: This real-world data analysis show that time to insulin has significantly increased in Germany, France and UK from 2005 to 2010. HbA1c values of insulin naïve patients increased in all three countries. Concurrently, a clear trend indicating an increased morbidity regarding diabetes-related complications at insulin initiation can be observed in all three countries. Further research is needed to evaluate the underlying factors in Germany, France and UK more in detail.

Probability of the insulin initiation in type 2 diabetes patients depending on diabetes related complications

J. Rex, K. Kostev, U. Mergenthaler;

CES LifeLink - Patient Data, IMS Health GmbH & Co OHG, Frankfurt, Germany.

Background and aims: Type 2 diabetic patients failing oral anti-diabetes medications need insulin. Not only inadequate glucose control but also other factors may have an influence on the duration until insulin therapy is initiated. The study aimed to evaluate whether chances for insulin initiation in patients with diabetes mellitus type 2 depend on diabetes-related events before start of insulin therapy.

Material and methods: This retrospective cohort study analysed data collected by general practitioners in France, Germany and the UK using three longitudinal databases of the IMS® Disease Analyzer. The analyzed database period was January 1995 to December 2010. The first diabetes diagnosis (ICD: E11) was defined as the index date. Age at index date was above 40 years. Main outcome measure was the initiation of insulin therapy depending on micro- and macrovascular complications recorded in the database after index date. A multivariate Cox regression model was fitted with the duration until insulin treatment initiation as dependent variable (up to 10 years after index date) and indicator variables for specific micro- or macrovascular diagnoses. Demographic and clinical data were also analyzed and included as confounders.

Results: Overall, 44,440 patients in Germany (mean age: 63.9 years [SD: 11.0], 51.2% male), 10,148 patients in France (mean age: 62.3 years [SD: 10.8], 58.8% male), and 25,499 patients in the UK (mean age: 63.4 years [SD: 11.4], 55.0% male), were diagnosed with type 2 diabetes in 1995–2009. Of them 9,747 (21.9%) in Germany, 702 (6.9%) in France and 3,936 (14.4%) in the UK began treatment with insulin within 10 years after index date. In all three countries patients with diabetes related complications in the time of oral treatment have significant higher chances to get the insulin therapy. In Germany, hazard ratios were 1.64 ($p<0.001$) for polyneuropathy, 1.45 ($p<0.001$) for cardiac insufficiency, 1.42 ($p<0.001$) for renal insufficiency, 1.41 ($p<0.001$) for retinopathy, 1.29 ($p<0.001$) for peripheral arterial disease, 1.21 ($p<0.001$) for stroke, 1.20 ($p<0.001$) for chd and 1.15 ($p=0.008$) for myocard infarction. In France, hazard ratios were 2.06 ($p=0.025$) for polyneuropathy, 2.54 ($p<0.001$) for cardiac insufficiency, 2.72 ($p=0.002$) for renal insufficiency, 3.23 ($p=0.103$) for retinopathy, 1.85 ($p=0.022$) for peripheral arterial disease, 1.54 ($p=0.003$) for chd. In the UK, hazard ratios were 1.54 ($p<0.001$) for polyneuropathy, 1.72 ($p<0.001$) for cardiac insufficiency, 1.20 ($p<0.001$) for renal insufficiency, 1.38 ($p<0.001$) for retinopathy, 1.61 ($p=0.086$) for peripheral arterial disease, 1.47 ($p<0.001$) for chd and 1.97 ($p<0.001$) for myocard infarction.

Conclusion: This real-world data analysis shows that patients affected from diabetes-related complications, are more frequently subject to a premature initiation of insulin therapy than patients having no complications. In this respect microvascular complications show higher impact than macrovascular complications. In routine care Insulin seems to be used to protect from recurrence or aggravation of complications.

Supported by: Sanofi-Aventis Diabetes Division

376

Glycaemic control in 163 121 patients with type 2 diabetes on different glucose-lowering treatments: nationwide cross-sectional survey

S. Gudbjornsdottir¹, M. Miftaraj², A.-M. Svensson², J. Cederholm³, N. Ekstrom¹, B. Zethelius³, B. Eliasson¹;

¹Department of Medicine, Gothenburg, ²National Diabetes Register, Gothenburg, ³Department of Public Health and Caring Sciences, Uppsala, Sweden.

Background and aims: Current treatment guidelines advocate strict glycaemic control in type 2 diabetes. The clinical results, however, are likely to vary between treatments and groups of patients. The aim of this survey was to present HbA1c results among patients on the most common glucose-lowering regimens in clinical practice.

Materials and methods: Cross-sectional study in 163 121 patients reported to the Swedish National Diabetes Register (NDR). Patients on continuous pharmacological treatment were defined as patients who had been dispensed glucose-lowering agents at least two times, corresponding to six months use, during 2009. Patients using the 12 most common treatment regimens, each group representing >1% of all patients on glucose-lowering treatment, and patients on non-pharmacologic treatment were included. Clinical characteristics and results were compared using general linear modelling.

Results: Of the 108 618 patients treated with the most common pharmacological treatments, a total of 38,5% were treated with metformin, 6,4% sulfonylurea (SU), 15,5% metformin + SU, 3,4% metformin + meglitinide, 5,9% metformin + insulin NPH, 7,0% metformin + premixed insulin (direct-acting), 2,1% premixed insulin (direct-acting) + SU, 2,2% metformin + SU + insulin NPH, 3,2% metformin + direct acting insulin + insulin NPH, 4,7% direct acting insulin + insulin glargine, 6,3% premixed insulin (direct-acting). In addition, 54 503 patients underwent non-pharmacological treatment. There were statistically significant differences in mean (\pm SD) HbA1c between the groups, varying between $6.8\pm0.9\%$ in metformin (lowest) and $7.9\pm1.2\%$ in premixed with direct-acting insulin + SU (highest). The proportion of patients reaching HbA1c $\leq 7\%$ varied between 68,2% in metformin, and 24,5% in premixed with direct acting insulin + SU. The proportion of patients with HbA1c $\geq 9\%$ varied between 17.4% in premixed with direct acting + SU, and 2.3% in SU. In a subgroup of newly diagnosed patients (<3 years duration) mean HbA1c varied between $6.8\pm0.9\%$ in metformin monotherapy or in SU monotherapy, and $7.9\pm1.4\%$ in premixed with direct acting + SU. The patients with non-pharmacological treatment presented a mean HbA1c of $6.4\pm0.9\%$. The proportion of patients reaching HbA1c $\leq 7\%$ was 81,3% and 2,0% had HbA1c $\geq 9\%$. In a subgroup of newly diagnosed patients with non-pharmacological treatment mean HbA1c was $6.4\pm0.8\%$. Comparisons between genders showed higher proportions of men reaching HbA1c $\leq 7\%$, on all treatments; however, these differences were not statistically significant after adjustment for age.

Conclusion: There are profound differences in glycaemic control between different treatment groups, indicating a major challenge for diabetes care to optimize and develop treatments. Patients treated with metformin presented the best glycaemic control, apart from the non-pharmacologically treated. In most groups, including newly diagnosed patients or patients with non-pharmacological treatment, treatment targets are difficult to reach.

Study of Once-Daily Levemir (SOLVE™) 1: clinical inertia in the initiation of insulin therapy in people with poorly controlled type 2 diabetes in real-life clinical practice

K. Khunti¹, J.-F. Yale², L. Meneghini³, SOLVE Study Group;

¹Department of Health Sciences, University of Leicester, UK, ²McGill Nutrition and Food Science Centre, Royal Victoria Hospital, Canada,

³University of Miami Miller School of Medicine, USA.

Background and aims: Initiation of insulin therapy is considerably delayed, despite recently published guidelines from numerous countries encouraging the earlier and appropriate use of insulin and continued targeting of HbA1c values <7.0%. The aim of this analysis of SOLVE baseline data is to provide insights into the timing of insulin initiation in real-life clinical practice in relation to recommended glycaemic goals.

Materials and methods: SOLVE is a 24-week international observational study involving 10 countries evaluating the safety and effectiveness of once-daily insulin detemir in insulin naïve people with type 2 diabetes mellitus (T2DM) treated with one or more oral anti-diabetic drugs (OADs).

Results: A total of 14,785 participants have been enrolled in the study (mean age 61 ± 11 years, 53% male, and T2DM duration 10 ± 7 years). Prior to the initiation of once-daily insulin detemir, mean HbA1c was $9.0 \pm 1.7\%$, with 45% having HbA1c values $\geq 9.0\%$, and 25% having HbA1c values $\geq 10.0\%$. Only 7% of participants initiating insulin therapy had HbA1c levels of $<7.0\%$. Mean pre-insulin HbA1c (see figure) was highest in UK ($9.8 \pm 1.7\%$), Turkey ($9.8 \pm 1.8\%$), Israel ($9.5 \pm 1.6\%$), Italy ($9.2 \pm 1.5\%$) and Portugal ($9.1 \pm 1.7\%$); and lowest in Poland ($8.3 \pm 1.2\%$), China ($8.3 \pm 1.7\%$), Germany ($8.7 \pm 1.3\%$), Spain ($9.0 \pm 1.4\%$), and Canada ($9.0 \pm 1.7\%$). The proportion of patients with HbA1c $\geq 9.0\%$ ranged from 66% (UK) to 22% (Poland). The mean pre-insulin FBG of the total cohort was 10.6 ± 3.3 mmol/L; with substantial differences between countries ranging from 13.3 ± 4.2 mmol/L (Turkey) to 8.9 ± 2.0 mmol/L (Poland). Prior to insulin initiation, patients had received OAD therapy for mean 9 ± 7 years. Biguanides and sulphonylureas were the most commonly prescribed oral agents in all participating countries. Mean starting dose of insulin detemir for the total cohort was 0.16 ± 0.09 IU/kg, with a range of 0.12 IU/kg (Canada and UK) to 0.21 IU/kg (Turkey).

Conclusion: Despite documented benefits of timely blood glucose control and consensus guidelines encouraging earlier use of insulin replacement, there continues to exist considerable clinical inertia with respect to initiating appropriate insulin therapy, with nearly 50% of patients having HbA1c $\geq 9.0\%$. SOLVE highlights the importance of identifying and understanding regional and global practice habits and barriers to care, providing the basis for discussion and implementation of appropriate intensification of therapy in order to achieve glycaemic control earlier in the course of T2DM.

Study of once-daily levemir (SOLVE™) 2: global baseline data and patterns of oral-antidiabetic drug (OAD) use before and after basal insulin initiation

L. Meneghini¹, K. Khunti², J.-F. Yale³, SOLVE Study Group;

¹Division of Endocrinology, Diabetes & Metabolism, University of Miami Miller School of Medicine, USA, ²Department of Health Sciences, University of Leicester, UK, ³McGill Nutrition and Food Science Centre, Royal Victoria Hospital, Montreal, Canada.

Background and aims: Considerable variations exist across countries in the approach to glycaemic management and therapy intensification for people with type 2 diabetes mellitus (T2DM). The aim of this cross-sectional baseline analysis is to provide insight into the timing of insulin initiation in real-life clinical practice in relation to glycaemic control and complexity of oral antidiabetic drug (OAD) use.

Materials and methods: SOLVE is a 24-week international observational study in 10 countries evaluating the safety and effectiveness of once-daily insulin detemir in insulin naive people with T2DM treated with one or more OADs.

Results: A total of 14,785 participants have been enrolled in the study: age 61 ± 11 years, 53% male, T2DM duration 9.9 ± 7.1 years, BMI 29.3 ± 5.3 . Pre-insulin HbA1c was $9.0 \pm 1.7\%$, with 45% of participants having HbA1c values $\geq 9.0\%$. Prior to insulin initiation, participants had received OAD therapy for 8.7 ± 6.7 years, with most patients on combination of 2xOAD (55%), 27% on monotherapy, and 17% on >2 xOAD. The most frequent OAD treatment regimen was a biguanide + sulphonylurea (38%). Overall, 82% were treated with a biguanide prior to initiating insulin therapy. Other OAD treatments included sulphonylureas (63%), glinides (16%), thiazolidinediones (TZD)

(13%), α -glucosidase inhibitors (13%) and DPP4 inhibitors (5%). Differences in OAD use were evident among participating countries. Pre-insulin duration of OAD use by country ranged from 11.4 ± 7.5 years (Italy) to 6.4 ± 5.1 years (China). DPP4 inhibitors were most commonly used in Portugal (46%), Israel (19%), Germany (19%), Spain (16%) and Canada (11%); whereas TZD were most often prescribed in Canada (26%), Turkey (23%) and the UK (21%). At the time of insulin initiation, the proportion of participants using glinides increased by 19%, whereas biguanides, sulphonylureas, TZD and DPP4 inhibitors were withdrawn in 3%, 18%, 32% and 37% of users, respectively. The proportion of participants on 2 and >2 xOAD agents also fell from 55% to 53% and from 17% to 11%, respectively.

Conclusion: There is substantial delay with respect to appropriate initiation of insulin replacement in real-life clinical practice, as reflected by the elevated baseline HbA1c in SOLVE. Considerable regional differences exist in the timing of insulin initiation and in the use of oral agents. Despite guideline recommendations to pursue target HbA1c $<7.0\%$, many patients have poor glycaemic control despite prolonged treatment with multiple oral agents. SOLVE provides an opportunity to better define and understand global and regional trends in diabetes treatment intensification and devise targeted treatment strategies to address glycaemic goal attainment in real world settings.

Influence of type 2 associated polymorphisms on weight development in offspring of mothers with gestational diabetes

M. Roßbauer¹, K. Adler¹, C. Winkler², H. Grallert³, T. Illig³, A.-G. Ziegler^{1,2}, S. Hummel^{1,2},

¹Forschergruppe Diabetes, Klinikum Rechts der Isar, University of Technology, Munich, ²Institute of Diabetes Research, Helmholtz Center Munich, Neuherberg, ³Institute of Epidemiology, Helmholtz Center Munich, Neuherberg, Germany.

Background and aims: Offspring of mothers with gestational diabetes (OGDM) are at increased risk to develop obesity and type 2 diabetes (T2D). Maternal pregravid obesity and large for gestational age (LGA) status of the child are predictors of obesity in OGDM. T2D risk alleles at the HHEX-IDE, CDKAL1 and PPAR γ 2 loci are associated with birth weight or weight development during childhood. The aim of this study was to determine whether these alleles are associated with fetal growth and growth during infancy in offspring of mothers with gestational diabetes.

Materials and methods: A total of 192 OGDM (76 female, median birth weight 3620g, 53 with LGA) who were enrolled in the prospective German GDM offspring study between 1989–2000 were studied. Data on birth weight (adjusted for gestational age and sex), BMI at the age of 2 years (expressed as age- and sex corrected standard deviation scores, SDS) and single-nucleotide polymorphism (SNP) genotyping of CDKAL1, HHEX-IDE, PPAR γ 2 and WFS1 were analysed. Statistical analysis was performed by linear regression.

Results: Birth weight percentiles were increased by 12.8 (95% CI:2.2–23.3, $p=0.02$) in OGDM with the homozygote T2D risk genotype (Pro/Pro) of the SNP rs1801282 on the PPAR γ gene region compared to OGDM with only one risk allele (none had no risk allele). BMI at the age of 2 years was associated with the PPAR γ rs1801282, WFS1 rs1801214 and HHEX-IDE rs10882102 gene loci. In the univariate analysis BMI-SDS was increased by 0.61 SDS (95% CI:0.2–1.1, $p=0.009$) in OGDM with two T2D risk alleles on the PPAR γ gene region compared to OGDM with one risk allele and by 0.31 SDS (95% CI:0.02–0.61, $p=0.039$) per T2D risk allele on the WFS1 gene region. In contrast, BMI-SDS was lower in OGDM with T2D risk alleles on the HHEX-IDE locus by -0.42 SDS (95% CI:0.7–0.1, $p=0.002$) per risk allele. This effect on BMI corresponded to a weight difference of 1.0 kg between offspring with two vs. no risk alleles ($p=0.02$). These effects remained significant after adjustment for LGA and maternal obesity in early pregnancy. Analysis of gene-gene interaction showed that the combination of two risk alleles from both, the PPAR γ and WFS1 gene region, is associated with the highest BMI-SDS at age 2 years (BMI-SDS 0.50 vs. -0.16 in offspring with 4 vs. 1 risk allele, $p=0.002$). However when adding the HHEX-IDE genotype to the model, the effect of the PPAR γ and WFS1 risk genotypes on BMI were no longer significant. In OGDM with 4 T2D risk alleles on the PPAR γ and WFS1 loci BMI-SDS was lower by 0.52 SDS per T2D risk allele on the HHEX-IDE locus (95% CI:1.18–0.27, $p=0.008$). The CDKAL1 polymorphism had no effect on weight development in OGDM. **Conclusion:** The recently reported association of the PPAR γ Pro/Pro genotype with increased BMI has been confirmed in our study on OGDM. The BMI increasing effect was highest in offspring with the simultaneous presence of WFS1 risk alleles. However, this effect is abolished by the BMI decreasing effect of HHEX-IDE risk alleles what is consistent with recent reports on the association of T2D susceptibility genotype at the HHEX-IDE locus with reduced BMI in offspring of parents with T1D.

A gene expression signature for insulin resistance in hepatocytes caused by excess lipid

B. Hayward¹, N. Konstantopoulos¹, J. Molero¹, J. Jowett², K.R. Walder¹,

¹Metabolic Research Unit, Deakin University, Geelong, Australia, ²Baker IDI Heart and Diabetes Institute, Melbourne, Australia.

Background and aims: Multiple pathways are implicated in insulin resistance, such as hyperlipidemia, elevated levels of pro-inflammatory cytokines and/or induction of oxidative or ER stress. The complexity of insulin resistance hinders effective characterisation and personalised treatment of type 2 diabetes. We propose that small sets of genes known as gene expression

signatures (GES) that reflect different insulin resistant states can be identified. The GES provides an unbiased transcriptional snapshot of the integrated cellular response to an insult.

Materials and methods: Hyperlipidemia-induced insulin resistance was modelled in FAO liver cells using palmitate (PA), and this phenotype was reversed using metformin and sodium salicylate. Global gene expression profiling was performed using microarrays. This was followed by bioinformatics analyses to identify the GES whose expression levels most significantly discriminated between the insulin resistant and insulin sensitive states. Insulin sensitivity was assessed by glucose production as the functional endpoint.

Results: In vehicle-treated FAO cells, insulin (0.1nM, 24h) decreased glucose production by 34 \pm 1% ($P < 0.0001$, $n=8$) indicating an insulin sensitive state. PA treatment (75 μ M, 48h) impaired the ability of insulin to decrease glucose production by ~80% ($P = 0.0035$, $n=8$) indicating a state of insulin resistance. The inhibitory effect of PA on glucose production was reversed by the addition of metformin (0.25mM) and sodium salicylate (2mM) in the final 24h of the PA treatment, returning glucose production to levels not significantly different to vehicle treated cells ($P = 0.078$, $n=8$). This study identified a set of five genes whose expression profile best defines the difference between insulin sensitivity and PA-induced insulin resistance in FAO liver cells. This complements our previous work identifying an inflammation based GES developed using TNF α to induce insulin resistance in 3T3-L1 adipocytes, and reversed by acetylsalicylic acid and troglitazone. We will next assess the ability of this GES to subgroup patients in human cohorts such as the San Antonio Family Heart Study.

Conclusion: This study has identified a set of genes whose expression profile best defines the difference between insulin sensitivity and PA-induced insulin resistance in FAO liver cells. The GES gives us the power to profile patients with type 2 diabetes, and then develop specific therapies targeted against each profile. The GES approach therefore opens the door for the development of personalised medicine for the treatment of type 2 diabetes.

Long-chain polyunsaturated fatty acids modify the association between genetic variants in FADS and low density lipoprotein cholesterol

S. Hellstrand, E. Sonestedt, U.C. Ericson, B. Gullberg, E. Wirfält, B. Hedblad, M. Svensson, M. Orho-Melander;

Lund university, Clinical Sciences, Malmö, Sweden.

Background and aim: Variants in the fatty acid desaturase (FADS) gene cluster have been associated with LDL, HDL and triglyceride concentrations in genome-wide association studies. FADS converts the α -linolenic acid (ω -3) and linolenic acid (ω -6) into long-chain polyunsaturated fatty acids. A high plasma concentration of long-chain ω -3 polyunsaturated fatty acids has been associated with decreased risk for metabolic syndrome and cardiovascular disease. We investigated the interaction between different intake levels of polyunsaturated fatty acids (PUFA) and the FADS polymorphism rs174547 (T/C) on LDL, HDL and triglyceride concentrations.

Materials and methods: We included 4,635 (45–68 years, 60% females) participants from the Malmö Diet and Cancer cardiovascular sub-cohort. Diet was assessed by combining a 168-item dietary questionnaire, 7-day menu book and a 1-h diet history interview. The percentages contributed by the specific PUFAs to total energy intake (E%) were divided in tertiles; low, medium and high. The General Linear Model was used to examine interactions, adjusted for several confounders.

Results: The minor C-allele (allele frequency 34%) of rs174547 was significantly associated with lower LDL ($p=0.03$). We observed a significant interaction between the FADS genotype and long-chain ω -3 PUFAs intakes on LDL plasma concentrations (p -interaction=0.01). The C-allele was significantly associated with lower LDL among individuals with low intakes of long-chain ω -3 PUFA (≤ 0.14 E%, $p<0.001$), but not among those with medium (0.14–0.28 E%) or high (>0.28 E%) intakes ($p=0.98$ and $p=0.86$, respectively). Significant interaction was observed between the FADS genotype and the ratio of α -linolenic and linolenic fatty acid intakes on the HDL cholesterol concentration (p -interaction=0.03). Across tertiles of the α -linolenic-linolenic fatty acid ratio there was no significant association between the C-allele and HDL concentration.

Conclusion: Our findings suggest that the dietary intakes of different PUFAs may modify the associated effect of the genetic variation in FADS on LDL and HDL concentration.

The glucokinase regulatory protein rs1260326 polymorphism interacts with omega-3 PUFA to influence insulin resistance and inflammation in metabolic syndrome

P. Perez-Martinez¹, J. Delgado-Lista¹, A. Garcia-Rios¹, J.M. Ordovas², E.E. Blaak³, A. Malczewska-Malec⁴, C. Defoort⁵, U. Risérus⁶, J.A. Lovegrove⁷, C.A. Drevon⁸, H.M. Roche⁹, J. Lopez-Miranda¹,
¹Lipid and Atherosclerosis Unit, IMIBIC/Reina Sofia University Hospital/ University of Cordoba, and CIBER Fisiopatología Obesidad y Nutrición, Instituto de Salud Carlos III, Cordoba, Spain, ²JM-USDA Human Nutrition Research Center on Aging at Tufts University, Boston, USA and the Department of Epidemiology and Population Genetics Centro Nacional Investigación Cardiovasculares, Madrid, Spain, ³Department of Human Biology, NUTRIM, School for Nutrition, Toxicology and Metabolism, Maastricht, Netherlands, ⁴Department of Clinical Biochemistry, and Department of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland, ⁵INSERM 476, Lipid nutrients and prevention of metabolic diseases, INRA, 1260, Université de la Méditerranée, Marseille, France, ⁶Clinical Nutrition and Metabolism, Department of Public Health and Caring Sciences, Uppsala University, Sweden, ⁷Department of Food and Nutritional Sciences and the Institute for Cardiovascular and Metabolic Research, University of Reading, UK, ⁸Department of Nutrition, Institute of Basic Medical Sciences, Faculty of Medicine, University of Oslo, Norway, ⁹Nutrigenomics Research Group, UCD School of Public Health and Population Science, UCD Conway Institute, University College Dublin, Ireland.

Background and aims: Glucokinase Regulatory Protein (GCKR) plays a central role regulating both hepatic triglyceride and glucose metabolism. Fatty acids are key metabolic regulators, which interact with genetic factors and influence glucose metabolism and other metabolic traits. Omega-3 polyunsaturated fatty acids (n-3 PUFA) have been of considerable interest, due to their potential to reduce metabolic syndrome (MetS) risk. We examined whether genetic variability at the GCKR gene locus was associated with the degree of insulin resistance, plasma concentrations of C-reactive protein (CRP) and n-3 PUFA in MetS subjects.

Materials and methods: Homeostasis model assessment of insulin resistance (HOMA-IR), HOMA-B, plasma concentrations of C-peptide, CRP, fatty acid composition and the GCKR rs1260326-P446L polymorphism, were determined in a cross-sectional analysis of 379 subjects with MetS participating in the LIPGENE dietary cohort.

Results: Among subjects with n-3 PUFA levels below the population median, carriers of the common C/C genotype had higher plasma concentrations of fasting insulin ($P=0.019$), C-peptide ($P=0.004$), HOMA-IR ($P=0.008$) and CRP ($P=0.032$) as compared with subjects carrying the minor T-allele (Leu446). In contrast, homozygous C/C carriers with n-3 PUFA levels above the median showed lower plasma concentrations of fasting insulin, peptide C, HOMA-IR and CRP, as compared with individuals with the T-allele.

Conclusion: We have demonstrated a significant interaction between the GCKR rs1260326-P446L polymorphism and plasma n-3 PUFA levels modulating insulin resistance and inflammatory markers in MetS subjects. Further studies are needed to confirm this gene-diet interaction in the general population and whether targeted dietary recommendations can prevent MetS in genetically susceptible individuals.

Fat depot specific differences in mRNA expression of novel loci associated with waist-hip ratio

D. Schleinitz¹, N. Klötting^{2,3}, J. Breitfeld¹, M.R. Schön⁴, J. Jenkner⁴, T. Lohmann⁵, M. Dreßler⁵, M. Stumvoll², M.I. McCarthy⁶, C. Lindgren⁶, P. Kovacs¹, M. Blüher²;

¹Interdisciplinary Centre for Clinical Research, University of Leipzig, Germany, ²Department of Medicine, University of Leipzig, Germany, ³IFB Adiposity Diseases, University of Leipzig, Germany, ⁴Municipal Clinic Karlsruhe, Clinic of Visceral Surgery, Germany, ⁵Municipal Clinic Dresden-Neustadt, Dresden, Germany, ⁶WTCHG, University of Oxford, UK.

Background and aims: Body fat distribution is one of the main predictors of obesity-associated complications. It might be hypothesised that changes in the gene expression or in gene function caused by genetic variants may

result in metabolic alterations related to obesity. We therefore investigated the adipose tissue expression profiles of 6 loci (TBX15, WARS, PIGC, STAB1, GRB14, ZNRF3), identified in a recent genome-wide association study (GWAS) for WHR, as their exact role in fat distribution remains largely unknown. Effects of genetic variants within these loci (rs984222 TBX15/WARS; rs6784615 STAB1; rs1011731 PIGC; rs4823006 ZNRF3; rs10195252 GRB14) on gene expression, WHR, and obesity related traits were examined.

Materials and methods: Paired samples of visceral (vis) and subcutaneous (sc) adipose tissue were obtained from 297 Caucasian men and women who underwent open abdominal surgery. Abdominal vis and sc fat area was calculated using CT scans and percentage body fat was measured by dual-energy X-ray absorptiometry. Gene expression was measured by quantitative real-time PCR by using TaqMan methodology. SNP genotyping was done using the TaqMan SNP Genotyping assay. Differences in mRNA expression between vis and sc adipose tissue were assessed using the paired t-test. Correlation analyses were carried out and multivariate linear relationships were assessed by generalized linear regression models. Two-sided P-values <0.05 were considered to provide nominal evidence for association (adj. age, gender).

Results: Differential expression between vis and sc adipose tissue could be observed for all tested genes. Except for STAB1 with higher mRNA expression in sc adipose tissue of males vs. females, there were no gender differences in gene expression in either tissue. Surprisingly, no correlation between WHR and fat mRNA expression of any of the genes was observed except for WARS whose expression in vis fat correlated positively with WHR in men. However, mRNA expression of several genes (e.g. WARS, PIGC, STAB1) correlated with BMI. Further, STAB1 expression in sc adipose tissue correlated with fat mass, and ZNRF3 expression in sc tissue correlated negatively with vis fat area. In addition, vis as well as sc expression of WARS and PIGC correlated negatively with both vis and sc fat area. Nominal associations were detected for rs984222 and TBX15 mRNA expression, rs4823006 and ZNRF3 mRNA expression, and rs10195252 and GRB14 mRNA expression, whereat rs984222 was also associated with BMI, sc and vis fat area as well as the GRB14 SNP with waist and waist-hip ratio in men (adj. age, BMI).

Conclusion: Besides rather moderate correlations of the expression levels with BMI or WHR, the most striking feature of expression of the 6 examined genes is the inter-depot variability as well as correlations with the vis and sc fat area. Our data further support the role of genes from recent GWAS in the regulation of fat distribution.

The presence of methylation quantitative trait loci indicate a direct genetic influence on the level of methylation in adipose tissue

A. Drong¹, G. Nicholson², M. Schuster³, MolPAGE Consortia, F. Karpe⁴, M.I. McCarthy⁴, C.C. Holmes², M. Rantalainen², C.M. Lindgren¹;

¹Wellcome Trust Centre for Human Genetics, University of Oxford, UK, ²Department of Statistics, University of Oxford, UK, ³Epigenomics AG, Berlin, Germany, ⁴Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK.

Background and aims: Obesity is a condition of excess body fat that increases the risk for many diseases, including type 2 diabetes. Interestingly, studies have shown that upper body fat increases this risk, whereas lower body fat is related to reduced risk. It is of interest to understand if differences in disease risk are associated with expression and repression of certain genes and CpG methylation. As the measure of DNA methylation within tissue samples is quantitative in nature, methylation quantitative trait loci (meQTL) studies can be carried out. This project aimed to identify meQTL with the attempt find loci related to obesity as well as highlighting differences between these two types of fat depot.

Materials and methods: We analysed 294,025 genetic markers in 52 individuals and quantile-normalised differential methylation hybridization (DMH), which covers 51,430 methylation variable probes (40 for abdominal and 12 for gluteal adipose tissue) for association. A linear model was applied with an additive genetic effect and including the following covariates: gender, age, batch and case/control status for metabolic syndrome where appropriate. The meQTL analysis was limited to cis regions of 1 Megabase (MB). A false-discovery rate (FDR) threshold set to 5% was used to adjust for multiple testing.

Results: The distribution for the CpG methylation data of this study showed bimodality as found in previous studies, with a “hypomethylated mode” at 30% methylation and a “hypermethylated mode” at 70%. We did not detect any significant differences in methylation of CpG sites between the gluteal and the matching abdominal tissue samples. While we found no significant

meQTL hits in gluteal tissue (likely due to lower number of samples (N=12) in gluteal tissue), there were 701 in abdominal tissue after FDR correction ($p < 0.05$). These meQTL loci show a mean SNP-CpG distance of 182 Kilo-base (range 1 Base pairs - 1 MB). The top five meQTL hits were rs936266 ($p = 1.29 \times 10^{-15}$, closest gene MYH15), rs6456548 ($p = 4.34 \times 10^{-14}$, closest gene NRSN1), rs10233199 ($p = 4.34 \times 10^{-14}$, closest gene ZNF680), rs2293859 ($p = 2.05 \times 10^{-13}$, closest gene TDH) and rs3448 ($p = 4.45 \times 10^{-13}$, closest gene RHOA).

Conclusion: The presence of the meQTLs in abdominal adipose tissue indicates a direct genetic influence and consequently also an indirect influence on the general molecular phenotype of adipose tissue. Defining the genetic influence on both gene expression and CpG methylation in abdominal and gluteal adipose tissue can help towards characterizing these types of tissue and finding molecular pathways associated with obesity.

Genome-wide gene expression in peripheral blood of type 2 diabetes patients and subjects with normal glucose tolerance: the population-based KORA Survey F4

M. Carstensen¹, C. Herder¹, S. Landwehr², W. Rathmann², B. Thorand³, C. Meisinger³, K. Heim⁴, T. Meitinger⁴, H.-E. Wichmann⁵, S. Martin⁶, W. Koenig⁷, K. Straßburger², M. Roden^{1,8}, H. Prokisch⁴, T. Illig⁹; ¹Institute for Clinical Diabetology, ²Institute of Biometrics and Epidemiology, German Diabetes Center, Düsseldorf, ³Institute of Epidemiology II, Helmholtz Zentrum München, Neuherberg, ⁴Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, ⁵Institute of Epidemiology I, Helmholtz Zentrum München, Neuherberg, ⁶Verbund der Katholischen Kliniken, Düsseldorf, ⁷University of Ulm Medical Center, Ulm, ⁸Department of Metabolic Diseases, University Hospital Düsseldorf, Düsseldorf, ⁹Institute of Molecular Epidemiology, Helmholtz Zentrum München, Neuherberg, Germany.

Background and aims: Genetics and lifestyle factors are both responsible for the manifestation of type 2 diabetes (T2D). Although genomics research has become more important over the last years, there are still wide gaps in our knowledge about the impact of genes on the development of T2D. A better understanding of the genetic effects may allow individualised prevention measures in the future. Therefore, we used peripheral blood to assess which genes are differentially expressed in T2D patients compared to subjects who had normal glucose tolerance (NGT).

Materials and methods: In the population-based KORA Survey F4 (Augsburg/Germany), whole-blood samples from fasting study participants were collected in PAXgene tubes between 8 and 11 a.m. After the isolation of total RNA, the whole-genome gene expression analysis was performed using the Illumina HumanHT-12 v3 Expression BeadChip. This BeadChip targets 48,804 transcripts, which represent more than 25,000 annotated genes. The transcripts were designed using the RefSeq and UniGene databases. For our analyses, we used RefSeq annotated 32,067 transcripts which are well-characterised. The association between gene expression and T2D were analysed by linear regression models using normalised gene expression levels as dependent variables. Multiple testing was corrected via multiple testing procedure based on Storey critical values which controls the false discovery rate (FDR) at a level of 0.05.

Results: This analysis is based on expression data from 515 individuals with NGT (47.2% men) and a BMI of 30.5 ± 3.7 kg/m² (mean \pm standard deviation [SD]) and 59 subjects with newly diagnosed T2D (54.2% men, BMI 27.8 ± 4.2 kg/m²). Subjects in both groups were aged between 62 and 81 years. In the age and sex-adjusted analysis, 311 transcripts were differentially expressed in T2D patients in comparison with subjects with NGT. After additional adjustment for BMI 9 transcripts remained significantly associated with T2D. The mean difference in gene expression for these 9 transcripts (8 up-regulated, 1 down-regulated in T2D patients) was $0.73 \times \text{SD}$ based on the SD calculated for the NGT subjects. Database searches indicated that the proteins encoded by these 9 transcripts are involved in the regulation of transcription and other pathways.

Conclusion: In our analysis, 311 transcripts were differentially regulated in peripheral blood of T2D patients in comparison with individuals with NGT. However, most of these associations were confounded by BMI. These findings will allow further analyses to characterise the involved genes in detail and to investigate their contribution to the manifestation of T2D.

Reduced expression of cytochrome c oxidase and its copper chaperons leads to blunted glucose stimulated insulin secretion

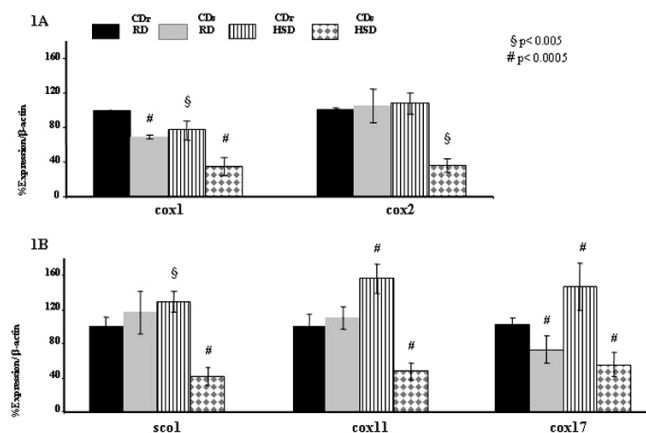

C. Mantzur¹, G. Aharon-Hananel¹, F. Vernea², A. Jörns³, S. Lenzen⁴, I. Raz¹, S. Weksler-Zangen¹;

¹Diabetes Unit, Hadassah University Hospital, Jerusalem, Israel, ²Department of Pathology, Hadassah University Hospital, Jerusalem, Israel, ³Centre of Anatomy, ⁴Institute of Clinical Biochemistry, Hannover Medical School, Germany.

Background and aims: Pancreatic β -cells couple mitochondrial oxidation of glucose to insulin secretion via cytochrome C oxidase (COX). Assembly and catalytic activity of COX depends on copper (Cu) ions distributed to COX by the Cu-chaperons Cox17, sco1/sco2 and cox11. Cohen diabetic sensitive (CDs) rats exhibit hyperglycemia due to reduced glucose stimulated insulin secretion (GSIS) when fed a high-sucrose-low-copper-diet (HSD) but remain normoglycemic on regular diet (RD). Resistant (CDr) rats remain normoglycemic on either diet. Feeding CDs rats with Cu-enriched HSD prevented β -cell dysfunction. We observed decreased protein levels of COX in CDsHSD islets in association with low COX activity. We examined the role of differential gene expression of COX and its Cu-chaperones in the regulation of GSIS.

Materials and method: Expression of COX subunit 1(cox1) and 2 (cox2) and of the Cu-chaperons Cox17, sco1/sco2 and cox11 was assessed in RNA extracted from the pancreases of CDs and CDr rats fed RD (CDsRD, CDrRD) or HSD (CDsHSD, CDrHSD) by qRT-PCR. **Results:** Expression of Cox1 and Cox17 were initially reduced in pancreases of normoglycemic-CDsRD rats compared CDrRD (figs 1A & 1B). Cox1 expression was further reduced in pancreases of hyperglycemic-CDsHSD rats [figure1A]. Expression of the Cu-chaperons increased in CDrHSD (sco1 +30%, cox11 +50%, cox17 +40%) and decreased in CDsHSD (sco1 -60%, cox11 -50%, cox17 -45%).

Conclusion: The CDs rats carry an initial inborn deficit in COX expression which is further augmented by lack of Cu. CDrHSD increased Cu-chaperones expression to compensate for low Cu concentration while CDsHSD lack this ability. Low expression of pancreatic Cu-chaperons in CDsHSD pancreases could lead to lower Cu concentration in the mitochondria minimizing Cu ions transfer to COX, thereby diminishing Cox 1 & Cox2 expression, protein levels and activity leading to diminished GSIS

Genetic variation at the STAMP2 locus interacts with promoter variants of TNF α and IL-6 pro-inflammatory cytokines on the risk of type 2 diabetes and the metabolic syndrome

F. Fumeron^{1,2}, A. Miot³, A. Lamri^{1,2}, N. Emery¹, N. Munoz-Bellili¹, G. Velho¹, O. Lantieri⁴, P. Froguel⁵, B. Balkau⁶, M. Marre^{1,7}, the D.E.S.I.R. study group;

¹UFR de Medecine, INSERM U695, Paris, ²Université Paris Diderot-Paris 7, ³Department of Internal Medicine, CHU Poitiers, ⁴IRSA, La Riche,

⁵Institut Pasteur, Lille, ⁶CESP, INSERM U1018, Villejuif, ⁷Department of Endocrinology, Diabetology, Nutrition, and Metabolic Diseases, AP-HP, Paris, France.

Background and aims: STAMP2 (six transmembrane protein of prostate 2), initially discovered in the prostate, is mainly expressed in adipose tissue. In mice, STAMP2 is up-regulated by TNF α and IL6 in adipocytes. Conversely, STAMP2 expression seems to down regulate the pro-inflammatory cytokine expression and/or the insulin resistant response to them. In the D.E.S.I.R. prospective study, the IL6 promoter polymorphism (SNP) -174G/C was associated with type 2 diabetes (T2D) but not with the metabolic syndrome (MetS), and no association with T2D or MetS was found with TNF α -308G/A and STAMP2 SNPs. We now assessed the interactions between STAMP2 SNPs, and TNF α and IL6 promoter variants, on the risk of T2D and the MetS in the D.E.S.I.R. cohort.

Materials and methods: Over 4000 men and women could be analyzed for the prevalence and the 9 year incidence of T2D and the MetS. The interactions between SNPs were tested by logistic regression. The odds ratios to develop T2D and the MetS were assessed separately, by logistic regression, adjusting for age, sex, and BMI. Nine SNPs of STAMP2, the TNF α -308 G/A and the IL6 -174 G/C were investigated.

Results: The STAMP2 rs12386756 G>A and IL6 -174 G/C interacted for the susceptibility to T2D (p interaction =0.03 and 0.05 for prevalence and incidence respectively). The IL6 -174 G/C was significantly associated with T2D only for carriers of the A allele (for prevalence: OR, 0.67; 95%CI, 0.49-0.91; for incidence: OR, 0.59; 95%CI 0.40-0.88). The STAMP2 rs8122 C/T SNP interacted with TNF α -308 G/A for susceptibility to MetS (p=0.04 and 0.01 for prevalence and incidence respectively). The -308 A allele was associated with MetS in CC genotype only (for prevalence: OR, 0.70; 95%CI 0.53-0.93; for incidence: OR, 0.61 95%CI, 0.43-0.86). Weaker interactions between TNF α -308G/A and STAMP2 rs1026311 G/C and rs1981529 T/C were found.

Conclusion: The allelic variation at the STAMP2 locus modulates the effects of the promoter variants of IL6 and TNF α genes on T2D and the MetS in a prospective cohort. This could be indicative in humans of a cross talk between STAMP2 and pro-inflammatory cytokines, such as that found in mice.

Genome-wide sequencing and gene expression QTL mapping in the Goto-Kakizaki rat identify Ascl3 as a regulator of adipocyte function

S. Dubois¹, P.J. Kaisaki², G.W. Otto², C. Domingues¹, A. Rimmer², K. Argoud², G. Lunter², D. Gauguier¹;

¹Centre de Recherche des Cordeliers, Paris, France, ²Wellcome Trust Centre for Human Genetics, Oxford, UK.

Background and aims: Genetic studies in humans and animal models have identified numerous diabetes and obesity susceptibility loci that remain to be functionally characterized. We aim to identify candidate genes accounting for a quantitative trait locus (QTL) linked to adiposity and glucose tolerance mapped to chromosome 1q33 in a F2 cross and in congenic strains derived from the Goto-Kakizaki (GK) rat model of spontaneous diabetes mellitus and Brown Norway (BN) controls.

Materials and methods: Illumina gene expression bead chips were used to quantify the expression of 20,000 transcripts in adipose tissue from F2 (GKxBN) hybrids (n=138) and a congenic strain containing GK alleles at the adiposity/glucose tolerance QTL introgressed onto a BN genetic background. Gene expression QTLs (eQTLs) were mapped in the F2 cross using the R statistical package and validated in the congenics by qRT-PCR. We used next-generation sequencing technologies to sequence the GK rat genome and identify genetic variants in QTLs. Fibroblasts were isolated from adipose tissue of BN, GK and congenic rats to measure cell proliferation (Hoechst, ³H incorporation and Brdu) and differentiation (Oil-Red-O). The effect of promoter variants in candidate genes was assayed by luciferase assay.

Results: We identified 585 statistically significant eQTLs (LOD>9). Among the 172 positional candidate genes mapped to 1q33, 44 correspond to eQTLs

and 27 showed evidence of differential expression between congenics and BN controls. Following analysis of polymorphisms in the GK genome sequence, we were able to identify false positive eQTLs and to carry out functional analysis of polymorphisms in positional candidate genes. We selected Ascl3 (eQTL LOD=43 in the F2) which was found strongly down regulated in the congenics (-84%; p=6.10⁻⁴) when compared to BN. We identified an 8bp deletion in Ascl3 promoter in the GK, which causes a 38% decrease in transcriptional activity. Furthermore, we found a 70% significant decrease in cell proliferation and a 22% decrease in cell differentiation (p=0.02) in congenic and GK strains when compared to BN.

Conclusion: Combined analysis of genome sequence and gene expression data in an experimental F2 cross and in congenic strains allowed the identification of Ascl3 as a transcription regulator accounting for a QTL linked to adiposity and glucose tolerance in the GK rat. These results provide new insights into the transcriptional regulation of adipocyte function.

PS 015 Molecular machinery of insulin secretion

Sorting nexin 19 regulates the number of dense core vesicles in pancreatic beta cells

S. Harashima, Y. Wang, Y. Seino, N. Inagaki;

Diabetes and Clinical Nutrition, Kyoto University, Japan.

Background and aims: The sorting nexins (SNX) belong to a large family that is involved in protein sorting and intracellular trafficking. SNX19 is a 992 long amino acid member of this family which has a phox (PX) domain (a binding motif to phosphatidylinositol) at the COOH-terminus and a PX-associated (PXA) domain at the NH2-terminus. The function of SNX19 is not known but it binds to the dense core vesicle (DCV) transmembrane protein IA-2. IA-2 is a major autoantigen in type 1 diabetes. This molecule is present in neuroendocrine cells throughout the body and the knockout of IA-2 in mice results in the impairment of the secretion of hormones and neurotransmitters resulting in a variety of phenotypes characterized by impaired insulin secretion, glucose intolerance, female infertility, abnormalities in learning and behavior and loss of circadian rhythm. Overexpression of IA-2 in MIN6 cells and a rat pheochromocytoma cell line PC12 cells increased insulin secretion and dopamine release, respectively. Because SNX19 binds to IA-2, the present experiments were initiated to study the effect of the knockdown and reconstitution of SNX19 in MIN6 cells on the biology and physiology of DCV including the half-life and number of DCV and the cellular content and secretion of insulin.

Materials and methods: Stable SNX19 knockdown (SNX19KD) MIN6, a mouse pancreatic beta-cell line, and stable SNX19-reintroduced SNX19KD MIN6 were established. Quantification of DCV, lysosomes and autophagy were performed by electron micrographs. The half-life of DCV was detected by pulse-chase experiment. Insulin content and insulin secretion were measured by ELISA. Lysosomal activity was determined by cathepsin D activity kit.

Results: Insulin secretion and content were decreased in stable SNX19KD MIN6 cells compared to those in control MIN6 cells. Electron micrographs showed that the number of DCV in SNX19KD MIN6 cells was decreased about 75% and that the size of DCV was about 40% less, respectively, compared to those in control cells. Moreover, when SNX19 was reintroduced in SNX19KD MIN6 cells, insulin content, insulin secretion, and the number of DCV were increased. The half-life of DCV was decreased in SNX19KD cells but was prolonged in SNX19KD cells in which SNX19 was reintroduced. The number of lysosomes, activity of lysosome enzyme cathepsin D and LC3-II, an autophagic marker, were increased about 3-fold in SNX19KD MIN6 cells compared to those in control cells. On the other hand, they were decreased to about half to one third in SNX19-reintroduced SNX19KD MIN6 cells.

Conclusion: SNX19 regulates the number of DCV and insulin content by stabilizing DCV in beta-cells.

Involvement of heparan sulphate 3-O-sulfotransferase isoform-1 for insulin secretion pathway

I. Takahashi, K. Ohashi, N.J. Shervani, K. Nata;

Department of Medical Biochemistry, Iwate Medical University, Yahaba, Japan.

Background and aims: Heparan sulfate (HS) is linear polysaccharides consisting of repeating disaccharide unit backbone onto which is superimposed a complex pattern of modifications, most notably addition of sulfate groups. The produced polymorphic sulfated sequence motifs are responsible for binding to a variety of signaling molecules and modulating their biological functions. Recently, we found HS is localized exclusively around beta cells in islets of adult mice and required for islet morphogenesis, beta cell proliferation and insulin secretion. Depletion of HS in beta cells using the technique of knockout mouse or enzymatic removal of HS decreased glucose-induced insulin secretion (GIIS). However the contribution of sulfate fine structure in HS to β -cell function is still unclear. The aim of this study is to clarify how sulfate group(s) in HS surrounding beta cells affects insulin secretion and cell growth.

Materials and methods: Subclone of MIN6, insulin-secreting mouse insulinoma cell line, was isolated based on effective GIIS and high expression of

HS. GIIS was examined in islets, MIN6 and isolated subclone MIN6T3 after removal of sulfate groups by sodium chlorate (a competitive inhibitor of glycosaminoglycan sulfation). Quantitative RT-PCR was used for analyzing mRNA expression of HS modification enzymes and components of signaling pathway. Expression of 3-O-sulfotransferase isoform-1 was silenced and GIIS was examined.

Results: GIIS in the sodium chlorate-treated mouse pancreatic islets, MIN6 and its subclone MIN6T3 showed about 62.4%, 52.4% and 62.5% decrease compared to the controls ($p < 0.01$). Addition of exogenous soluble HS in culture recovered GIIS of the MIN6 and MIN6T3 treated with sodium chlorate. The HS modification enzymes, including N-deacetylase/N-sulfotransferases, C5-epimerase and 6-, 3-O-sulfotransferases were detected in MIN6T3. Among these genes, mRNAs of several N-, O-sulfotransferase enzymes were induced by sodium chlorate-treatment. Silencing of a 3-O-sulfotransferase isoform-1, one of these upregulated enzymes, by RNA interference reduced GIIS to less than 70% of control treatment ($p < 0.01$). Insulin secretion induced by KCl was, however, unaffected in MIN6T3 with RNA interference. To determine the expression pattern of the components of signaling pathway downstream of HS especially affected by 3-O-sulfate modification, we used quantitative RT-PCR to evaluate the expression of genes encoding of Fgf, Notch, Hedgehog, Wnt and Tgf β . In 3-O-sulfotransferase isoform-1 silenced MIN6T3, the mRNA levels of Jagged2 and Delta-like4, the Notch ligands, were increased when compared to the non-treatment control (1.2- and 3.3-fold, respectively).

Conclusion: Our data indicate that 3-O-sulfate groups modified by 3-O-sulfotransferase isoform-1 plays important role(s) in the insulin secretory pathway, selectively through upstream of membrane depolarization in beta cells. Our result also suggests Notch signaling pathway including Jagged2 and Delta-like4 may be involved in the signaling pathway in beta cells downstream of HS.

Attenuation of glucose-induced insulin secretion from pancreatic beta cells by intermittent hypoxia via down-regulation of CD38

H. Ota^{1,2}, S. Tamaki¹, A. Itaya-Hironaka², A. Yamauchi², S. Sakuramoto-Tsuchida², T. Morioka¹, S. Takasawa², H. Kimura¹;

¹Second Department of Internal Medicine ²Biochemistry, Nara Medical University, Kashihara, Japan.

Background and aims: Sleep apnea syndrome (SAS) is characterized by recurrent episodes of oxygen desaturation during sleep, the development of daytime sleepiness, and deterioration in the quality of life. Up to 30% of the adult population in Western countries are thought to be affected by asymptomatic SAS and approximately 2-4% by symptomatic SAS. Accumulating evidence suggests the association of intermittent hypoxia (IH), a hallmark of SAS, and type2 diabetes independently on body mass index and waist circumference. In addition to the development of glucose intolerance and insulin resistance, the progression to type 2 diabetes is dependent on the impairment of glucose-induced insulin secretion (GIS) from pancreatic beta cells. However, the direct effects of IH on GIS are elusive.

Materials and methods: Hamster insulinoma HIT-T15 cells and isolated rat islets were exposed either to 64 cycles/24 h of IH (5 min hypoxia (1% O₂)/10 min normoxia (21% O₂)), or normoxia for 24 h. After the treatment, the medium was discarded, and islets and HIT-T15 cells were incubated either in RPMI1640 medium containing 5.5 mM or 22 mM glucose in normoxia for 30-60 min. After glucose stimulation for 30 min (60 min in HIT-T15), the medium was recovered. Insulin concentration in the islet medium was determined by a rat insulin ELISA kit. Real-time RT-PCR of insulin, CD38, glucose transporter 2 (Glut2), glucokinase (GK), sulfonylurea receptor1 (SUR1), and L-type Ca channel1.2 (Cav1.2) was performed using normoxia- or IH-treated islet RNA as template. To evaluate the effect of IH on CD38 promoter activity, HIT-T15 cells were transiently transfected with the reporter plasmid consisting of a luciferase reporter gene under the control of human CD38 promoter, and luciferase activities were measured after the exposure to IH or normoxia. GIS from HIT-T15 cells transfected with either control vector or CD38 expression vector was also assayed by ELISA.

Results: GIS from IH-treated HIT-T15 beta cells was significantly attenuated ($P < 0.05$), whereas that from the cells treated with normoxia was increased by high glucose. GIS from rat islets was also abolished by the treatment of IH ($P < 0.05$). The levels of insulin mRNAs in HIT-T15 cells and rat islets were unchanged. The mRNA levels of Glut2, GK, SUR1, and Cav1.2 in IH-treated islets were unchanged between IH-treated and normoxia-treated islets. We

then analyzed genes involved in Ca^{2+} mobilization from intracellular pools such as CD38, and found that the mRNA level of CD38 was significantly lower in IH-treated islets than in normoxia-treated islets (39% of the control). The reporter gene assay revealed that the transcription of CD38 was significantly attenuated by IH ($P < 0.01$), and the transfection of CD38 expression vector recovered the attenuation of GIS by IH ($P < 0.05$).

Conclusion: It is quite possible that the cyclic change of hypoxia-reoxygenation, which occurs in SAS patients, attenuates glucose-induced insulin secretion from pancreatic beta cells via CD38 down-regulation, resulting in glucose intolerance and type 2 diabetes.

392

Involvement of the interaction between neuronal NO synthase and its protein inhibitor PIN in the control of insulin secretion

K. Mezghenna^{1,2}, J. Leroy^{1,2}, F. Castex^{1,2}, P. Petit^{1,2}, R. Gross^{1,2}, A.-D. Lajoix^{1,2}; ¹FRE 3400, CNRS, ²University of Montpellier I, France.

Background and aims: We have previously shown that rat pancreatic β -cells express an isoform of neuronal NO synthase (nNOS) that controls insulin secretion through metabolic and non-metabolic activities. This latter activity is related to the interaction of nNOS with its protein inhibitor PIN at the level of insulin secretory granules. PIN is also the light chain of cytoskeletal motors like myosin V. Our aim is therefore to investigate the possible involvement of nNOS and PIN interaction in the control of glucose-induced insulin secretion.

Materials and methods: nNOS, PIN, and myosin V interaction was evidenced by immunoprecipitation and Western blotting in INS-1 cell extracts. nNOS-PIN interaction was analyzed using the Spot method consisting in the multiple synthesis of overlapping peptides on cellulose membranes. Insulin secretion was studied on INS-1 cells at low and stimulating glucose concentrations.

Results: In the INS-1 β -cell line, we could bring evidence for a direct interaction between nNOS, PIN, and myosin V by immunoprecipitation, confirming our previous immunofluorescence study. Moreover, PIN appeared to recruit myosin V as overexpression of PIN led to higher levels of immunoprecipitated myosin V. In order to set up tools to dissociate nNOS-PIN interaction, we analyzed the nNOS regions involved in this interaction, by performing the synthesis of peptides covering the nNOS sequence. We were able to identify two interacting zones: a strong affinity zone from amino acid 225 to 241 of nNOS and a zone of low affinity from residue 195 to 211. Mutational analysis performed on the high affinity zone allowed us to make out a peptide with three punctual mutations according to the native sequence, IDVGIQVDWD, that inhibits nNOS-PIN interaction with a K_i of 0.4 μM . This peptide, conjugated to the HIV sequence TAT to render it cell-permeant, was, at a 20 μM concentration, able to dissociate nNOS-PIN interaction by 47% as compared to a control peptide after a 7-hour pre-incubation period with INS-1 cells. At a more functional level, the peptide decreased insulin secretion induced by 5.6 mM glucose by 20% ($p < 0.05$), but did not modify insulin response in the presence of 2.8 mM glucose.

Conclusion: Our data strongly suggest that the nNOS-PIN interaction is involved in the modulation of insulin response to glucose, possibly at the level of the exocytotic machinery.

393

The transcription factor ZBED6 is expressed in βTC6 and MIN6 cells and affects insulin production

X. Wang¹, L. Jiang², L. Andersson^{2,3}, N. Welsh¹;

¹Medical Cell Biology, Uppsala University, ²Department of Medical Biochemistry and Microbiology, Uppsala University, ³Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Uppsala, Sweden.

Background and aims: ZBED6 is a novel transcription factor derived from a domesticated DNA transposon. ZBED6 is exclusive to placental mammals and highly conserved among species. Silencing of ZBED6 in mouse C2C12 myoblasts affected IGF2 expression, cell proliferation, wound healing and myotube formation. Chromatin immunoprecipitation (ChIP) sequencing using C2C12 cells identified about 2,500 ZBED6 binding sites in the genome. Among these putative ZBED6 regulated genes, we found several genes that control pancreatic beta cell differentiation and function. The aim of the present study is to investigate the role of ZBED6 in beta cell function using the mouse βTC6 and MIN6 cell lines.

Materials and methods: Two stable ZBED6-shRNA βTC6 cell lines with different shRNA sequences (sh1 and sh2) were generated using lentivirus. The expression of ZBED6, Hif1- α , Pdx-1, Glucokinase, MafA and Insulin was examined by real-time PCR and/or immunoblotting. The subcellular localization of Pdx-1 was studied by immunofluorescence and confocal microscopy. For insulin content analysis, stable ZBED6-shRNA MIN6 cell lines were generated. Insulin release and content from MIN6 cells were measured by Meso Scale Discovery Insulin Assay Kit.

Results: ZBED6 expression was significantly knocked down at the protein level in both sh1 and sh2 βTC6 cell lines (sh1, 40 \pm 5%; sh2, 56 \pm 8%). As control an shMock lentiviral vector lacking ZBED6 shRNA sequencing was used. Morphological changes were observed in both sh1 and sh2 cell lines and it could be observed that the ZBED6 deficient cells formed islets-like clusters to a higher degree than control cells. Hif1- α expression was significantly down-regulated in sh1/2-cells while Pdx-1 was significantly up-regulated. Up-regulation of Pdx-1 was also confirmed by immunoblotting, and immunofluorescence staining showed nuclear localization of Pdx-1 in all βTC6 cell lines. Effects of ZBED6 knock down on Glucokinase, MafA and Insulin expression are listed in Table 1. Due to low insulin content of βTC6 cells, a stable ZBED6-sh1 MIN6 cell line was generated (49 \pm 7% ZBED6 mRNA vs shMock, $p < 0.05$). Similar morphological changes were observed in sh1 MIN6 cells as those observed in βTC6 cells. In addition, the insulin content of sh1 MIN6 cells was increased with 55% ($p < 0.05$) as compared to shMock MIN6 cells.

Conclusion: The transcription factor ZBED6 is expressed in beta cell lines and lowering of ZBED6 levels results in increased expression of beta-cell specific genes and augmented insulin contents.

	shMock βTC6	ZBED6-sh1 βTC6	ZBED6-sh2 βTC6
Zbed6	100%	25 \pm 3% *	41 \pm 5% *

Expression and function of CCL5 and GPR75 in islets of Langerhans

B. Liu¹, Z. Hassan¹, S. Amisten², D. Stubbart¹, A. King¹, P.M. Jones¹, S.J. Persaud¹;

¹Diabetes Research Group, Division of Diabetes & Nutritional Sciences, King's College London, UK, ²Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford University, UK.

Background and aims: G protein-coupled receptor 75 (GPR75) is a novel human GPCR that encodes a 540 amino-acid protein. Kidney cells transfected with a GPR75 plasmid show Gq-dependent elevations in intracellular Ca^{2+} ($[\text{Ca}^{2+}]_i$) in response to chemokine (C-C motif) ligand 5 (CCL5), a 68 amino-acid chemokine. GPR75 does not share sequence homology nor ligand homogeneity with the chemokine receptor family, thus distinguishing it as an atypical chemokine receptor. We have recently amplified GPR75 mRNA in human and mouse islets, and found that GPR75 mRNA expression is significantly higher than that of other CCL5 receptors. This study was therefore aimed at investigating the expression and function of CCL5 and GPR75 in islets of Langerhans.

Materials and methods: CCL5 and GPR75 expression and cellular localisation were examined by Western blotting and immunohistochemistry. Changes in $[\text{Ca}^{2+}]_i$ were measured in mouse MIN6 β -cells by single cell Ca^{2+} microfluorimetry. Dynamic insulin secretion was quantified by radioimmunoassay after perfusion of isolated mouse and human islets. In *in vivo* experiments, mice were subjected to intraperitoneal glucose tolerance tests (IPGTTs) following a single administration of glucose (2g/kg body weight) in the absence or presence of 65pmol recombinant mouse CCL5.

Results: Immunohistochemistry demonstrated extensive GPR75 immunostaining of islet β -cells in mouse and human pancreas sections and this was confirmed by detection of a 59 kDa immunoreactive protein by Western blotting of islet proteins. CCL5 was also expressed by both mouse and human islets, although it was localised to insulin-expressing β -cells in human pancreas and to non- β -cells in mouse pancreas. Administration of recombinant mouse CCL5 induced rapid, reversible increases in $[\text{Ca}^{2+}]_i$ in Fura 2-loaded MIN6 cells (87 \pm 2%, 88 \pm 2% and 92 \pm 1% of the peak tolbutamide response at 0.25, 2.5 and 25nM CCL5 respectively, n=37). In addition, CCL5 significantly potentiated glucose-induced insulin secretion from mouse islets (20mM glu-

cose: $619 \pm 153\%$ basal; 20mM glucose+20nM mouse CCL5: $1559 \pm 456\%$ basal; $n=4$, $P<0.01$) and human CCL5 had similar stimulatory effects on insulin secretion from human islets. IPGTTs in lean mice showed that CCL5 reduced average blood glucose concentrations (CCL5 at 0, 15', 30', 60', 90' and 120 minutes after i.p. injection: 4.3 ± 0.2 , 16.5 ± 1.7 , 20.0 ± 2.4 , 14.5 ± 1.7 , 9.8 ± 0.9 and 7.4 ± 0.2 mM; $n=6$; control: 3.7 ± 0.2 , 21.6 ± 1.8 , 24.2 ± 1.4 , 18.3 ± 1.7 , 11.9 ± 0.7 and 7.6 ± 0.4 mM; $n=4$, $P<0.05$). Improvements in glucose tolerance in response to exogenous CCL5 were also observed in insulin-resistant ob/ob mice ($P<0.05$ vs controls at $t=15$ and 30min).

Conclusion: Both CCL5 and GPR75 are expressed by pancreatic islet cells with GPR75 predominantly expressed by insulin-secreting β -cells. Our results also indicate that exogenous CCL5 increases β -cell $[Ca^{2+}]_i$, stimulates insulin secretion from isolated mouse and human islets and improves glucose tolerance in vivo. These data suggest that CCL5 and/or GPR75 may be novel targets for the treatment of type 2 diabetes.

The complement inhibitor protectin influences insulin secretion and is correlated to glucose intolerance in humans

U. Krus¹, V. Nagaraj¹, B. King², A. Blom², E. Renström¹;

¹Lund University Diabetes Center, Clinical sciences, Malmö, ²Medical Protein Chemistry, Laboratory Medicine, Malmö, Sweden.

Background and aims: Complement activation is known to be involved in the pathology of type 1 diabetes but little is known about the role of complement in type 2 diabetes even though complement genes are expressed in the pancreatic islets. Gene expression data showed that of all complement-related genes, the complement inhibitor protectin (CD59) was most highly expressed in human and rodent islets. Protectin is a cell surface GPI linked protein, which main function is to prevent complement-mediated cell lysis. In this study we aimed to investigate the role of protectin in terms of insulin secretion and expression in healthy and diabetic human islets, as well as in rat islets and clonal beta-cells.

Materials and methods: Gene expression in Wistar and Goto-Kakizaki (GK) rat islets and INS1 832/13 cells: cDNA from isolated rat islets and INS1-832/13 cells was analyzed for gene expression using Q-PCR. Gene expression in human islets: Total RNA was isolated from pancreatic islets from 80 donors using the AllPrep DNA/RNA Mini Kit (Qiagen) and analyzed using Gene 1.0 ST whole transcript based assays (Affymetrix). Knockdown of protectin: INS-1 832/13 cells were transfected with 30 nM siRNA directed against rat protectin (Ambion) using Dharmafect (Dharmacon). Knockdown was verified with Q-PCR after 48h. Reduction in surface protectin after siRNA treatment was confirmed by flow cytometry. Insulin secretion assay in clonal beta-cells: 72h after siRNA transfection, INS1-832/13 cells were preincubated for 2 hours in 2.8 mM glucose and then stimulated with 2.8 or 16.7 mM glucose for one hour. Insulin secretion in human islets: Islets were preincubated for 30 min in KRB with 1 mM glucose in presence or absence of protectin antibody and then stimulated with 1 or 16.7 mM glucose for one hour.

Results: Gene expression of protectin in the diabetic GK rat was significantly lower than in the healthy Wistar rat, 0.52 relative HPRT compared to 1.4 ($p<0.05$). To mimic this effect, we used siRNA to silence protectin in clonal beta-cells. Treatment with siRNA reduced mRNA expression with 85% ($p=0.001$). Protein levels were decreased with approximately 50% as verified by flow cytometry. Silencing of protectin caused a 50% reduction in glucose-stimulated insulin secretion ($p<0.05$). In human islets gene expression of protectin was significantly increased in individuals with high HbA1c ≥ 6.0 ($n=23$) compared to healthy individuals with HbA1c ≤ 5.5 ($n=27$) ($p=0.01$). Blocking the complement-inhibitory site on protectin with a monoclonal antibody led to a tendency of an increase in insulin secretion in healthy human islets, whereas it caused a tendency to a decrease of insulin secretion in diabetic islets.

Conclusion: We have found that the complement inhibitor protectin is important for insulin secretion, and is regulated in response to high HbA1c. We believe that the decreased expression in GK rat is caused by genetic factors, whereas the increased expression in diabetic humans is a compensatory response to maintain functional insulin secretion. The stimulatory effect on insulin secretion seen in human islets when the known functional site is blocked indicates that protectin has other yet unknown signalling properties. *Supported by: NN foundation, Swedish Research Council, NNCIT*

Serotonin (5-HT) receptor expression in human islets of Langerhans

M. Fex¹, H. Bennet¹, M. Dekker Nitert², Å. Lernmark¹;

¹Diabetes and Celiac Disease, Clinical Science, ²Diabetes and endocrinology unit, Clinical Science, Malmö, Sweden.

Background and aims: Regulation of insulin secretion is pivotal to maintain overall glucose homeostasis. When insulin secretion fails due to a complex interaction between genes and environment, type 2 diabetes prevails. Serotonin (5-HT) and its receptors have been suggested to play an active role in β -cell expansion during pregnancy in rodents. 5-HT is produced in β -cells, stored in insulin granules and thus co-released with insulin upon stimulation. 5-HT receptors belong to a diverse group of G-protein coupled receptors and ligand gated ion channels causing transient or persistent intracellular changes depending on the type of receptor activated. The presence of 5-HT receptors in the human endocrine pancreas remains a largely unexplored area. Therefore, in this study, this issue is further investigated.

Materials and methods: Human islets from 64 islet donors were provided in collaboration with the Nordic Network for Clinical Transplantation, Sweden. mRNA was isolated from untreated islets and microarray with the Affymetrix TM Gene 1.0 ST Whole Transcript Assay was performed and normalized by RMA normalization. Logistic regression was used to correlate between gene expression, metabolic parameters, gender and purity.

Results: Human islets of Langerhans express low levels of mRNA for 17 different serotonin receptors. Twelve of these receptors belong to the G-protein coupled receptor family, but expression for all members of the voltage-gated ion channel 5-HTR3 receptor family was also observed. 5-HTR2A mRNA levels were significantly correlated to HbA1c ($\beta=0.2888$, $P=0.038$). Donor body mass index (BMI) was significantly negatively correlated to 5-HTR3E ($\beta=-0.252$, $P=0.044$) and 5-HTR4 ($\beta=-0.314$, $P=0.011$). Furthermore, male donors had significantly higher expression levels of 5-HTR3C ($P=0.01$) and 6 (78.8 ± 10.7 vs 69.4 ± 9.4 , $P<0.000$) receptors than female donors. Islet purity was positively correlated to expression of 5-HTR1F ($\beta=0.373$, $P=0.009$) and negatively to 5-HTR5A ($\beta=-0.250$, $P=0.046$).

Conclusion: Seventeen different 5-HT receptors are expressed in human islets of Langerhans. As serotonin is expressed and co-released with insulin, serotonin and its receptors could modulate hormone secretion from various cell types within the human islet of Langerhans.

Knockdown of 5-HT2b receptor decreases glucose stimulated insulin secretion in a clonal (INS (832/13) beta cell line

H. Bennet¹, C.L.F. Nagorny², N. Wierup³, M. Dekker-Nitert⁴, Å. Lernmark¹, M. Fex¹;

¹The unit of diabetes and celiac disease, ²Molecular metabolism

³Neuroendocrine cell biology, ⁴Diabetes and endocrinology, Clinical Science, Malmö, Sweden.

Background and aims: 5-Hydroxytryptamine (5-HT), also known as serotonin activates a large family of receptors. 5-HT1a, 5-HT2b and 5-HT1d have all previously been shown to be expressed in islets of Langerhans from rodents. All three receptors are G-protein coupled receptors but activation result in different cellular events due to activation of different G-proteins. The amine 5-HT has been shown to be present and co-secreted with insulin from pancreatic beta-cells. As both receptors and amines are present within the islets, serotonin may potentially regulate hormone secretion from islets of Langerhans. We have previously investigated activation of 5-HT2b using a selective 5-HT2b agonist (alpha-Methyl serotonin) which potentiates glucose stimulated insulin secretion in the clonal beta-cell line, INS-1 (832/13). These experiments have also been performed in primary cells; mouse and human islets of Langerhans, with the same result. In this study we investigate the effect on insulin secretion in INS-1 (832/13) cells by performing specific knock down of the receptor.

Materials and methods: We used RT PCR and sequence specific primers to detected expression of the receptors in the beta-cell line (INS 832/13) and in islets of Langerhans. Immuno-histochemical analysis was used to detect the receptors at the protein level in rodent islet and human islets. We used Q (Quantitative) PCR and sequence specific primers to detect expression of the receptor in the INS-1 (832/13) cell line. Transfection was performed with RNA interference and Lipofectamine 2000. The knock down was verified by QPCR using specific primers and western blot.

Results: 5-HT2b mRNA was found in the 832/13 cells. We also found both 5-HT1a and 5-HT2b to be expressed in rodent and human islets, at both mRNA and protein level. Interestingly, 5-HT receptors in islets were localized in two different cell types in the islets. In rodent islets, 5-HT2b was predominantly expressed in beta-cells while 5-HT1a was more abundant in the alpha-cells. In human, islets the situation was reversed. The expression of the receptor was determined by QPCR and showed a robust expression in the INS-1 (832/13) cells. Specific knock down of the 5-HT receptor was achieved with -50% and verified by q-PCR and western blot. When cells treated cells were stimulated with high glucose, a significant decrease in insulin secretion at stimulatory concentrations of glucose (16.7 mM) was observed as compared to controls.

Conclusion: Our previous experiments show that an activation of 5-HT2b receptor using alpha-methyl serotonin potentiates glucose stimulated insulin secretion. Conversely, in knock down experiments, cells with a decreased expression of the 5-HT2b receptors display a perturbation of glucose stimulated insulin secretion. Therefore, our results strongly suggest that the 5-HT2b receptor plays a pivotal role in regulation of glucose stimulated insulin secretion.

High GADA titre: a marker of insulin dependence in adult onset autoimmune diabetes

S. Zampetti¹, M. Capizzi¹, M. Spoletini¹, C. Tiberti¹, E. Bosi², R. Buzzetti¹, NIRAD Study Group;

¹Clinical Sciences Department, Sapienza, University of Rome, ²Diabetes and Endocrinology, San Raffaele Vita-Salute University, Milan, Italy.

Background and aims: In latent autoimmune diabetes of adults (LADA), the progression to insulin-dependent diabetes is usually faster than in type 2 diabetes but the factors influencing this progression are not completely understood. The aim of the present study was to determine whether GADA titre could define the risk of progression to insulin therapy in LADA patients. We also evaluated other parameters (gender, BMI, TPO and IA-2 antibodies) associated with early development of insulin dependence. Adult onset GADA positive autoimmune diabetes subjects (n=191) were selected from the Non Insulin Requiring Autoimmune Diabetes (NIRAD) study cohort of 4,250 type 2 diabetes subjects. The analysis of GADA titre showed a bimodal distribution which identified two subgroups of patients with high (>32 GADA U) and low GADA titre (≤32 GADA U).

Materials and methods: One hundred ninety GADA positive patients were followed for 6 years from diagnosis to evaluate the progression of patients started insulin therapy. Kaplan-Meier curves were plotted and log-rank test was performed to identify possible markers capable to influence the progression into insulin dependence. During the follow up, 6 patients out of 191 GADA positive dropped out from the study.

Results: The number of GADA positive autoimmune diabetes patients who required insulin therapy was 93/191 (48.7%). We observed that a significant higher number of high GADA titre patients 61/93 (65.6%) progressed to insulin dependence within 6 years of diagnosis compared to low GADA titre patients 32/93 (34.4%) (p=0.003). Furthermore, GADA positive autoimmune diabetes patients with BMI<25 kg/m² had a faster progression, although not statistically significant, towards insulin therapy compared to patients with BMI ≥ 25 kg/m² (p = 0.07). Finally, we observed that gender, TPO and IA-2 Ab titre were not predictive markers of progression into insulin dependence.

Conclusion: High GADA titre is a marker of progression towards insulin dependence in LADA patients.

Influence of HLA genes on antibody reactivity to the juxtamembrane and central region epitopes of the autoantigen IA-2

K. Gulati, K.A. McLaughlin, C.C. Richardson, M.R. Christie;

Division of Diabetes and Nutritional Sciences, King's College London, UK.

Background and aims: The HLA locus is the major genetic determinant of susceptibility to Type 1 diabetes, with 95% of Caucasian Type 1 diabetic patients expressing HLA-DR3, HLA-DR4 or linked HLA-DQ alleles. Knowledge of the relationships between HLA gene expression and immune responses to islet antigens in Type 1 diabetes is important for the development of individualised, targeted immune intervention. IA-2 is a major autoantigen in Type 1 diabetes, and antibody responses to the molecule have been shown to be weakly associated with HLA-DR4. Several specific regions of antibody reactivity to the IA-2 protein have been identified, including two linear epitopes within the juxtamembrane domain (JM1 and JM2) and a major conformational epitope within the 831-860 region that is represented by a central region IA-2 construct (643-937). The aim of this study was to further define the relationship of HLA gene expression to the presence of antibodies to these specific epitopes on the IA-2 autoantigen.

Materials and methods: Serum samples were obtained from 110 Type 1 diabetic patients within 6 months of diagnosis and studied for the presence of autoantibodies to IA-2 constructs representing the cytoplasmic region of IA-2 (IA2ic; 604 - 979), and to the central region (643 - 937) and juxtamembrane (605 - 693) domains of IA-2 by radioligand binding assays. Antibodies to specific JM1 (601 - 620) and JM2 (621 - 640) epitopes within the juxtamembrane domain were detected by determining blocking effects of peptides

corresponding to the amino acid sequences of these linear epitopes. HLA genotyping for DR and DQ alleles was performed by PCR with sequence-specific primers.

Results: Antibodies to the cytoplasmic domain of IA-2 were detected in 75% of HLA-DR3/4 heterozygous patients, in 67% of HLA-DR4/non-DR3 patients and in 63% of those negative for HLA-DR4. Antibodies to JM domain epitopes were detected in 37% of HLA-DR4-positive patients, but in only 7% of those lacking HLA-DR4 ($p < 0.01$). There was a similar association of HLA-DR4 expression with antibodies to central region epitopes (HLA-DR4-positive 44%; non-DR4 20%; $p < 0.05$). In HLA-DR4 subjects, juxtamembrane domain antibody reactivity was predominantly to the JM2 epitope. The frequencies of antibodies to JM and central region epitopes were similar in HLA-DR4-DQ8 and HLA-DR4-DQ7 patients, indicating that the HLA association is with primarily with the DR rather than DQ locus.

Conclusion: Analysis of antibodies to specific epitopes on the IA-2 molecule identifies immune reactivity more strongly associated with HLA-DR4 expression than antibody reactivity to the whole molecule. Furthermore, the low frequency of antibodies to JM and central region epitopes in HLA-DR4-negative subjects (27%), despite a high prevalence of antibodies to IA-2ic (63%), is indicative of an unidentified epitope linked to a non-HLA-DR4 allele. Hence, studies of immune reactivity to specific epitopes on autoantigens will help determine the role of HLA genes in regulating autoimmune responses in type 1 diabetes.

Investigation of the HLA-B39 epitopes for preproinsulin, GAD65/67, IA-2 and IA-2B (phogrin)

G.P. Bondinas¹, A.K. Moustakas², M.-L. Mikk³, M. Kiviniemi³, J. Ilonen³, G.K. Papadopoulos¹;

¹Laboratory of Biochemistry and Biophysics, Epirus Institute of Technology, Arta, ²Organic Farming, Technological Educational Institute of Ionian Islands, Argostoli, Cephalonia, Greece, ³Immunogenetics Laboratory, University of Turku, Finland.

Background and aims: It has been shown that the highest-risk allelic combination of type 1 diabetes, (HLA-DR3/4), in the presence of HLA-B39 exhibits marked acceleration of disease onset, from the point of detection of the first biochemically-defined diabetes-related autoantibody. We wished to investigate the bases for this property, by scanning the major type 1 diabetes autoantigens for possible peptides that could be recognized by cytotoxic T cells restricted to HLA-B39.

Materials and methods: The aminoacid sequences of four diabetes-related autoantigens (preproinsulin, GAD65, IA-2 and IA-2b (phogrin), the last two in their antigenic regions) were scanned for the presence of motifs for HLA-B39. We limited ourselves to alleles B3901 and 3906, already known to be present within the studied population in proportion of 83.3 % to 16.7 % respectively. The motif for HLA-B3901 was obtained from the data base www.syfpeithi.de while that for -B3906 was deduced by molecular simulation based on the crystal structure of HLA-B3501 to have identical B, F anchors. We recorded both strong epitopes, and weak ones (strong anchors at pocket B, weak ones at pocket F). We considered lysine at pocket B as rendering a strong motif, in contrast to the prediction of the data base. Upon scanning we performed molecular simulation studies of several epitopes from the above autoantigens bound to B3901. We included GAD67 in the scan in order to determine if there were specificities of the one isoform versus the other regarding the HLA-B3901 allele.

Results: The four autoantigens are replete with epitopes to HLA-B3901/3906, both strong as well as weak ones, from octamers to endecamers. The epitopes, both strong and weak, cover the entire autoantigen sequences indicating that there seems to be no selectivity. The following summary of results indicates the extent of reactivities:

autoantigen	Weak epitopes	strong epitopes	total aminoacid sequence scanned
Preproinsulin	5	9	110
GAD65	15	23	585
GAD67	9	19	594
IA-2	31	39	379
IA-2b	18	33	376

There are a number of cases where a given aminoacid stretch contains overlapping octamers to endecamers, with identical pocket B anchor. Of special interest are the cases where strong and weak epitopes are present in regions reactive with specific autoantibodies, as in the regions 250-295 and 521-575 of GAD65, and the region of B4-C10 of proinsulin. The molecular simulation results of a number of these interesting epitopes in complex with HLA-B3901 demonstrate very good fit into the groove of B3901.

Conclusion: One intriguing hypothesis, which must be tested experimentally, for the HLA-B39 acceleration, concerns the possibility of autoantibody-mediated antigen presentation via the class I MHC pathway, to explain the several epitopes in regions recognised by the autoantibodies.

Decreased levels of memory T cells and increased levels of plasmacytoid dendritic cells in type 1 diabetes patients with short disease duration

B. Prietl, G. Bock, E. Hoeller, J. Mader, M. Wolf, W.B. Graninger, B.M. Obermayer-Pietsch, T.R. Pieber;

Department of Internal Medicine, Medical University of Graz, Austria.

Background and aims: In type 1 diabetes (T1D), a T cell mediated autoimmune disease, both, the adaptive as well as the innate immune system are involved in destruction of β -cells. The aim of this study was to elucidate the frequency of peripheral innate and adaptive immune cells as well as regulatory cells in the blood of T1D patients with short disease duration in comparison to healthy individuals.

Materials and methods: Peripheral blood from 38 T1D patients with disease duration < 5 years with a median age 21 years (interquartile range: 15-39) and 38 healthy individuals with a median age of 26 years (23-29) was stained with fluorochrome conjugated antibodies and a multi-parameter FACS analysis was performed to quantify the following immune cells: CD4⁺CD25^{high}FoxP3⁺CD127^{dim} Tregs, memory and naïve subpopulations of CD4⁺ and CD8⁺ T cells, NK, NKT, myeloid dendritic cells (mDC) and plasmacytoid dendritic cells (pDC). The total number of neutrophil, basophil and eosinophil granulocytes as well as monocytes was measured by the use of a haematological cell counter.

Results: The percentage of CD4⁺ memory T cells within leukocytes was significantly decreased in patients compared to controls [median+interquartile range: 6.5 (5.3-7.3)% vs. 7.5 (6.8-8.8)%, $p < 0.001$]. CD8⁺ memory T cells were also decreased in patients [1.9 (1.4-2.7)%] compared to controls [2.6 (2.0-3.4)%, $p = 0.003$]. Furthermore pDC were increased in the Lin CD45⁺DR⁺ population in the T1D group compared to healthy subjects [36.4 (32.5-43.7)% vs. 31.1 (25.7-36.3)%] whereas mDC were equally distributed in both groups. The frequency of peripheral Tregs, whole population of CD4⁺ and CD8⁺ T cells, NK, NKT, mDC and all subtypes of granulocytes and monocytes were similar between T1D patients and healthy controls. Levels of C-reactive protein were within the normal range in both investigated groups.

Conclusion: The results of this study show clear differences in important subtypes of peripheral T cells and pDC but no alteration in the frequency of regulatory T cells in T1D patients with short disease duration. Further studies are needed to elucidate the impact of the observed changes in the frequency of memory T cells and pDC in the pathogenesis of T1D.

High risk vs low risk nondiabetic first degree relatives of type 1 diabetics: differences in CXCR3+, CCR4+ and CD25hi T memory cells

A. Jotic¹, N. Lalic¹, T. Milicic¹, I. Markovic², M. Zamaklar¹, K. Lalic¹, L. Lukic¹, N. Rajkovic¹, M. Macesic¹, J. Seferovic¹, S. Aleksic¹;

¹Department for Metabolic disturbances, intensified insulin treatment and cell therapy in diabetes, Clinic for Endocrinology Clinical Centre of Serbia,

²Institute for Biochemistry Medical Faculty University of Belgrade, Serbia.

Background and aims: It has been previously suggested that changes in T memory lymphocyte subsets might be associated with the onset of Type 1 diabetes (T1D). Simultaneously, the expression of Th1 and Th2 associated chemokine receptors determine the recruitment of CD4⁺T cells into sites of inflammation, and the disturbance in T regulatory (T reg) subsets, contribute together to the onset of T1D. However, the relevance of the changes in expression of chemokine receptors CXCR3, CCR4, and CD25hi on T memory cells, for the development of T1D has not yet been elucidated. Therefore, the aim of this study was to compare the changes in percentage of (a) CXCR3+

(Th1-associated) (b) CCR4+ (Th2 associated) and (c) CD25hi (T reg associated) subsets of T memory cells, between two groups, the high-risk and the low-risk group, of nondiabetic first-degree relatives (FDRs) of patients with T1D as well as in the group of healthy controls. The difference between the two groups of FDRs was based on presence or absence of glutamic acid decarboxylase (GADA) and tyrosine phosphatase insulinoma antigen-2 (IA-2) antibodies. Thus, in the study we included 12 high-risk nondiabetic FDRs (GADA+, IA-2+) (group A) and 37 low-risk nondiabetic FDRs (GADA-, IA-2-) (group B) and 20 healthy unrelated control subjects.

Materials and methods: T1D and glucose intolerance were excluded in the study by using WHO criteria. GADA and IA-2 levels were determined by ELISA. The percentages of CXCR3+, CCR4+ and CD25hi T memory cell subsets were analyzed in peripheral blood by using four-color immunofluorescence staining and flowcytometry.

Results: When the percentage of CXCR3+ T memory cells was analyzed, it was found to be higher in group A vs groups B and C (A: 63.25 ± 6.52 vs B: 51.83 ± 6.77 ; C: 52.89 ± 6.25 %, $p < 0.05$). In contrast, the percentage of CCR4+ T memory cells was significantly lower in group A vs groups B and C (A: 30.02 ± 3.20 vs B: 41.48 ± 8.54 ; C: 40.65 ± 7.20 %, $p < 0.05$). Simultaneously, the percentage of CD25hi T memory cells was significantly lower in group A vs groups B and C (A: 0.16 ± 0.03 vs B: 0.26 ± 0.01 ; C: 0.26 ± 0.06 %, $p < 0.05$).

Conclusion: Our results have demonstrated that high risk FDRs showed higher levels of CXCR3+ T memory cells associated with increased Th1 response, together with lower levels of CCR4+ Th2 and CD25hi T reg cells subsets. The results imply that in FDRs the risk for developing T1D might be associated with enhanced activity of Th1 and diminished activity of Th2 and T regulatory immune response.

403

HLA- and autoantibody-associated T-cell responses to IA-2 determinants in type 1 diabetes

K.A. McLaughlin¹, K. Gulati¹, C.C. Richardson¹, D. Morgan², H.J. Bodansky², P.A. McKinney², R.G. Feltbower², M.R. Christie¹;

¹Division of Diabetes and Nutritional Sciences, King's College London,

²Paediatric Epidemiology Group, University of Leeds, UK.

Background and aims: Type 1 diabetes is associated with expression of HLA-DR3, DR4, DQ2 and DQ8, but the manner by which these gene products influence autoimmune responses to pancreatic islet antigens is poorly understood. HLA-DR4 associations have been observed for antibodies to IA-2, but this is likely to reflect a primary association with T-cell responses. The aim of this study is to identify T-cell responses to specific IA-2 peptides that are associated with HLA-DR4 and linked to antibody responses to specific regions of IA-2.

Materials and methods: Peripheral blood lymphocytes were obtained from 26 Type 1 diabetic patients aged 12–29 years within 6 months of disease onset. Frequencies of T-cells secreting the cytokines IFN- γ , IL-10 and IL-17 in response to 7 peptides previously shown to represent major T-cell determinants in diabetes were determined by ELISPOT and expressed as a stimulation index (SI) relative to numbers of cytokine-secreting cells in medium alone. Responses with SI > 3 were considered positive. Patients were typed for HLA-DR and DQ alleles by PCR using sequence-specific primers. Sera from the same patients were analysed for autoantibodies to constructs representing the cytoplasmic (605–979), juxtamembrane (605–693), tyrosine phosphatase (643–979) and central region (643–937) domains of IA-2 by radioligand binding assay.

Results: Positive IL-10 responses were detected to all 7 peptides tested, but strongest SIs (4–19) were observed to peptides representing 831–850, 841–860, 853–872 and 955–976 regions of IA-2. Positive responses to at least one of these peptides were observed in 11/17 (65%) patients expressing HLA-DR4, but were absent in non-DR4 patients ($p < 0.05$). IL-17 responses to the peptides tested were rare, but were also detected exclusively in DR4-positive patients, and 5/9 of responses detected were accompanied by an IL-10 response to the same peptide. Co-incubation of cells with IL-1 β , that is known to promote differentiation of Th17 cells, specifically increased peptide-stimulated IL-17 responses. The proportion of patients showing IFN- γ responses to the selected peptides were low (23%), and these were detected at similar frequencies in HLA-DR4-positive and negative individuals. Significantly higher IL-10 responses to peptides 841–860 and 853–872 were observed in patients positive for antibodies to the central region construct ($p < 0.05$) that harbours an epitope overlapping the 841–872 region. IFN- γ responses were not associated with autoantibodies.

Conclusion: T-cells responding to IA-2 determinants in HLA-DR4-positive diabetic patients are characterised by secretion of the regulatory cytokine IL-

10, but also include cells secreting IL-17, supporting a role for Th17 cells in disease pathogenesis. The balance may be shifted towards secretion of the pro-inflammatory cytokine by the presence of IL-1 β , as may occur in an insulinitis. The association of T-cell responses to specific determinants with presence of antibodies to an overlapping epitope supports a role for T-B collaboration in autoimmunity in Type 1 diabetes.

Membrane and intracellular expression of CTLA-4 in T regulatory lymphocytes (Tregs) and monocytes of healthy subjects and patients with type 1 diabetes: similarities, differences and correlations

S.A. Paschou¹, G. Vartholomatos², A. Petsiou², N. Kolaitis², E. Giotaki³, A. Tsatsoulis¹, G.K. Papadopoulos⁴;

¹Department of Endocrinology, Medical School, University of Ioannina, Ioannina, Greece, ²Unit of Molecular Biology, Laboratory of Haematology, University Hospital of Ioannina, ³Department of Nursing, Epirus Institute of Technology, Ioannina, ⁴Laboratory of Biochemistry and Biophysics, Faculty of Agricultural Technology, Epirus Institute of Technology, Arta, Greece.

Background and aims: CTLA-4 (Cytotoxic T Lymphocyte Antigen-4, ITIM12) is genetically linked to type 1 diabetes and is thought to be one of the major suppressive molecules of Tregs, acting as a negative regulator at the immune synapse between antigen-presenting cells and T effector cells. The aim of our study was to investigate the membrane and intracellular expression of CTLA-4 in Tregs and monocytes of type 1 diabetes patients and healthy controls.

Materials and methods: Peripheral blood from 13 newly-diagnosed (nd) type 1 diabetics (9M/4F, ages 12.5 ± 9.4 years), 26 long standing (ls) patients (12 M/14F, ages 26.7 ± 9.2 years) with mean disease duration of 11.6 ± 7.4 years and 32 healthy controls (c) with no first or second degree relatives suffering from any autoimmune disease (13M/19F, ages 25.3 ± 11 years) was analysed by triple colour flow cytometry for the mCTLA-4 (membrane) and icCTLA-4 (intracellular) expression in Tregs and monocytes.

Results: There is a very significant deficiency in the amount of Tregs at the disease onset, which is only partly corrected in long standing patients. CTLA-4 is clearly expressed both in the membrane and the cytoplasm of Tregs without differences between type 1 diabetes patients and controls (nd: mCTLA-4 % 26.20 ± 28.33 MFI (Mean Fluorescence Intensity - number of molecules per cell) 129.18 ± 151.48 , icCTLA-4 % 44.86 ± 37.70 MFI 449.89 ± 282.60 , ls: mCTLA-4 % 14.97 ± 18.84 MFI 172.33 ± 158.68 , icCTLA-4 % 44.02 ± 44.51 MFI 350.81 ± 280.78 , c: mCTLA-4 % 19.23 ± 26.02 MFI 178.73 ± 140.94 , icCTLA-4 % 37.93 ± 46.79 MFI 450.18 ± 598.00) (in all comparisons $p > 0.05$). CTLA-4 is also clearly expressed both in the membrane and the cytoplasm of monocytes with significantly lower percent of membrane expression in long standing diabetics compared to controls ($p = 0.007$). (nd: mCTLA-4 % 25.31 ± 28.89 MFI 154.36 ± 110.20 , icCTLA-4 % 47.64 ± 44.30 MFI 848.75 ± 709.48 , ls: mCTLA-4 % 8.90 ± 6.49 MFI 274.36 ± 295.60 , icCTLA-4 % 56.18 ± 45.56 MFI 885.08 ± 707.15 , c: mCTLA-4 % 23.67 ± 27.17 MFI 238.21 ± 242.69 , icCTLA-4 % 40.27 ± 47.79 MFI 902.28 ± 660.02) (in all other comparisons $p > 0.05$). There are highly statistically significant positive correlations of the frequency and intensity of CTLA-4 expression between Tregs and monocytes both in newly-diagnosed type 1 diabetics (mCTLA-4 % $r = 0.553$, $p = 0.05$ MFI $r = 0.803$, $p = 0.001$, icCTLA-4 % $r = 0.935$, $p < 0.001$ MFI $r = 0.746$, $p = 0.005$) and controls (mCTLA-4 % $r = 0.396$, $p = 0.03$, icCTLA-4 % $r = 0.95$, $p < 0.001$ MFI $r = 0.558$, $p = 0.003$), which partially change in long standing patients (mCTLA-4 % $r = 0.215$, $p = 0.302$ MFI $r = 0.328$ $p = 0.110$, icCTLA-4 % $r = 0.732$, $p < 0.001$ MFI $r = -0.537$, $p = 0.012$).

Conclusion: The significant membrane and intracellular expression of CTLA-4 in Tregs and monocytes confirms the importance of this molecule in the mechanisms of peripheral tolerance. The highly correlated expression of CTLA-4 between Tregs and monocytes of healthy controls and newly-diagnosed type 1 diabetes patients, which partially change in long standing patients, should be further investigated.

Low frequency of T regulatory lymphocytes in children under 5 years old with newly recognised type 1 diabetesA. Szypowska¹, A. Stelmaszyk-Emmel¹, U. Demkow¹, D. Witkowski², W. Feleszko¹, W. Łuczyński³;¹Medical University of Warsaw, ²The Children's Memorial Health Institute, Warsaw, ³Medical University of Białystok, Poland.

Background and aims: The incidence of type 1 diabetes (T1D) in children has been increasing worldwide, with the greatest increase in children <5 years old. Previous observations pointed to critical role for T regulatory cells (Tregs) in the maintenance of self tolerance and the pathogenesis of diabetes. The suppressive capacity of Tregs is mainly contact-dependent but also based on immunosuppressive cytokines production: interleukin-10 (IL-10) and transforming growth factor-beta (TGF-beta). There are no studies focused on Tregs in children <5 yrs with T1D. The aim of the study was to analyze different subpopulations of Tregs in children with newly recognized T1D.

Materials and methods: 80 children <18 yrs. old were enrolled to the study, 40 subjects with newly recognized T1D and 40 healthy controls. Children with T1D were divided into two groups: 20 children <5 yrs (mean age: 2.8±1.1 yrs) and 20 children >5 yrs (mean age: 12.9±3.4 yrs). The control group consisted of 20 healthy children <5 yrs (mean age: 2.6±1.0 yrs) and 20 children >5 yrs (mean age 10.7±3.7 yrs). Flow cytometric analysis of Tregs was performed in blood samples from all children. The intra- and extracellular proteins were evaluated using monoclonal antibodies to the following markers: CD4, CD25, CD127, Foxp3, IL-10, and TGF-β. The following data were collected: morphology, fasting C-peptide, ICA, GADA, IA-2A.

Results: There was significantly lower percentage of CD4+CD25highCD127lowFoxp3+ cells in children <5 yrs with T1D compared to children >5 yrs with T1D (median 0.865% vs. 1.555%, respectively, $p=0.017$). There was the lower frequency of CD4+CD25highCD127lowFoxp3+ cells in children >5 yrs with T1D compared to healthy controls (median 1.555% vs. 3.44%, respectively, $p=0.0009$). The percentages of the following subpopulation of lymphocytes was lower in children <5 yrs with T1D compared to age matched healthy controls: CD4+CD25highCD127lowFoxp3+ (median 0.865% vs. 4.53%, $p<0.0001$); CD4+CD25highTGF-β (median 0.93% vs. 1.74%, $p=0.049$); CD4+CD25highIL-10 (mean 1.15 ± 1.16% vs. 1.96 ± 1.38%, $p=0.036$). There was no significant difference in the following populations of Tregs between children >5 yrs with T1D and age matched healthy controls CD4+CD25highTGF-β (median 1.46% vs. 1.05%, $p=0.616$); CD4+CD25highIL-10 (median 1.39% vs. 0.96, $p=0.620$). There was no significant difference in the following populations of Tregs between children <5 yrs and >5 yrs with T1D: CD4+CD25highTGF-β (1.74% vs. 1.46%, $p=0.104$), CD4+CD25highIL-10 (median 0.87% vs. 1.29%, $p=0.328$). Children <5 yrs with T1D had the lower C-peptide level compared to children >5 yrs with T1D (median 0.32 ng/ml vs. 0.80 ng/ml, $p=0.0005$).

Conclusion: Children <5 yrs. with newly recognized T1D showed more significant changes in different subpopulations of Tregs compared to children >5 yrs with T1D that might reflect the influence of more aggressive beta cells destruction and T1D onset at a younger age. Further clinical studies investigating the regulatory T cells in the large cohort of children with type 1 diabetes are needed.

PS 017 Stem cell and islet cell proliferation: expanding knowledge and new developments

Role of ductal cell dedifferentiation on new beta cell formation in the post-natal rat pancreas undergoing regeneration after partial pancreatectomyN. Tellez^{1,2}, M. Vilaseca^{1,2}, J. Escoriza^{1,2}, E. Montanya Mias^{1,2};¹Lab. Diabetes and Experimental Endocrinology, IDIBELL-University of Barcelona, L'Hospitalet de Llobregat, ²CIBERDEM, Barcelona, Spain.

Background and aim: Partial pancreatectomy (Px), a well defined model of pancreatic regeneration, induces profound changes in tissue composition and cell phenotype. Specifically, areas composed of metaplastic ducts that have been proposed to harbour progenitor cells appear immediately after surgery. In a recent study, we found that beta cell neogenesis was stimulated in Px rats treated with gastrin (Px+G). The aim of the study was to investigate whether key aspects of beta cell neogenesis could be identified by comparing the endocrine regeneration events that take place in Px and Px+G rat pancreases.

Material and methods: Sprague-Dawley rats underwent 90%-Px and were treated with [15leu] gastrin-17 (Px+G, n=19) or with vehicle (Px+V; n=20). Pancreatic remnants were harvested on days 1 and 3 after Px and processed for total RNA extraction or paraffin embedding. Gene expression was determined by quantitative real time PCR and protein identification by immunofluorescence.

Results: Blood glucose levels were similar between both Px groups (Px+V: 126±10 mg/dl; Px+G: 110±8 mg/dl). Beta cell mass was significantly increased in Px+G rats 72h following Px (Px+V: 0.28±0.076 mg, Px+G: 0.57±0.11 mg; $p<0.05$), but beta cell replication and apoptosis were similar in both Px groups (Px+V: 3.92±0.44%, Px+G: 3.20±0.31%; $p=ns$ for beta cell replication and Px+V: 0.59±0.23%, Px+G: 0.37±0.20%; $p=ns$ for beta cell apoptosis). The number of small beta cell clusters (< 5 insulin-positive cells), an indirect marker of beta cell neogenesis, was increased in Px+G remnants, suggesting that the higher beta cell mass in Px+G group was attributable to increased beta cell neogenesis. Gene expression of pro-endocrine transcription factors: neurog3, neuroD1, pdx-1 and nkx6.1 was upregulated, and ductal cell markers ck20, ca2, hnf1β, hnf6 and prominin1 downregulated in Px+G remnants compared with Px+V ($p<0.05$). Initially after pancreatectomy regions of metaplastic ducts surrounded by mesenchymal cells are formed. The relative volume of these areas of regeneration was similar in both groups (Px+V: 38±7.05% and Px+G: 35.1±5.68%). Metaplastic ducts had lower immunoreactivity for CK20 and 41.7±0.7% of these cells exhibited low nuclear expression of the key endocrine differentiation marker NKX6.1 which is beta cell specific in the post-natal pancreas. In Px+G remnants 57.6±3.9% of metaplastic ductal cells expressed low levels of NKX6.1 ($p<0.05$ vs Px+V).

Conclusion: This study supports the concept that after 90% Px, new beta cells are formed by neogenesis that contribute to the regeneration of the beta cell mass. The enhanced ductal cell plasticity in Px rats treated with gastrin, illustrated by downregulation of ductal cell markers and higher percentage of ductal cells expressing the endocrine differentiation marker NKX6.1, suggests that cell dedifferentiation / redifferentiation processes play a role on new beta cell formation in the post-natal rat pancreas after partial pancreatectomy.

TCF7L2 plays a role in beta cell regenerationK. Maedler¹, J. Kerr-Conte², L. Shu¹;¹Centre for Biomolecular Interactions, University of Bremen, Germany,²Centre for Biomolecular Interactions, Thérapie Cellulaire du Diabète, INSERM / Université de Lille, France.

Background and aims: Both type 1 and type 2 diabetes are characterized by a loss and dysfunction of the β-cell. A major goal of diabetes therapy is to promote the formation of new β-cells. Polymorphisms of TCF7L2, a transcription factor of the Wnt signaling pathway, have been reported to be associated with T2DM, regulating β-cell survival and function. Pancreatic duct cells are considered a potential source of β-cell regeneration. Here we provide a possible role for TCF7L2 in β-cell regeneration from pancreatic ductal epithelial cells.

Materials and methods: Pancreatic sections from three mouse models (high fat/high sucrose fed mice: HFD, Exendin-4: Ex-4 10nmol/kg and streptozotocin: STZ, 90 mg/kg -treated mice) and from healthy individuals and patients with T2DM were used to investigate the association of β -cell regeneration and TCF7L2 expression by immunostaining of insulin, CK19, TCF7L2, Ki67 and Pdx-1. TCF7L2 was overexpressed in isolated human pancreatic exocrine cells and immunostaining and RT-PCR analysis for insulin, CK19, Ki67, Pdx-1 and ngn3 were performed to investigate the effect of TCF7L2 on duct cell to β -cell conversion.

Results: We found increased intra-islet TCF7L2 expression in STZ- and Ex-4 treated mice, compared to controls (49.65% in STZ- and 40.9% in Ex-4-treated compared to 24.7% TCF7L2 positive β -cells in control mice, $p < 0.05$). Increased TCF7L2 expression was also observed in HFD treated mice, but only after 4 and 8 weeks of feeding (26.3% TCF7L2 positive β -cells in ND control mice, 42.8% positive β -cells after 4 weeks and 36.25% positive β -cells after 8 weeks HFD feeding, $p < 0.05$), in contrast, intra-islet TCF7L2 expression decreased after 12 weeks of HFD feeding (18.8% TCF7L2 positive β -cells after 12 weeks and 9.8% after 16 weeks HFD, $p < 0.05$), which occurred in parallel with the development of β -cell failure, suggesting that expression levels of TCF7L2 correlate with β -cell de-compensation and the progression of diabetes. Increased TCF7L2 expression in ductal epithelial cells was observed in STZ- and Ex-4 treated mice (68.3% TCF7L2 positive ductal cells in STZ- and 56% in Ex-4-treated mice, compared to 32.21% in control mice, $p < 0.005$). An increased number in Pdx-1 positive ductal cells were found in these mice; 5.3% Pdx-1 positive CK19 positive cells were found in STZ-treated mice and 3.3% in Ex-4 treated mice, compared to 0.7% in the control mice ($p < 0.005$). Together with the appearance Pdx-1 positive ductal epithelial cells in STZ- and Ex-4 treated mice, small islet-like cell clusters (ICCs) which all expressed TCF7L2 originated in the vicinity of the ductal epithelium. In isolated human exocrine cells *in vitro*, TCF7L2 overexpression increased proliferation of pancreatic ductal cells (3.69% Ki67 positive ductal cells in TCF7L2 overexpressing ductal cells, vs. 0.9% in GFP control, $p < 0.005$), together with induction of Pdx-1 and ngn3 expression by 4.2-fold and 5.1-fold respectively, compared to GFP-transfected ductal cells. In accordance what was seen in mouse models, ICCs next to ductal cells and insulin positive ductal cells were also present in patients with T2DM, but were rarely found in non-diabetic individuals.

Conclusion: Our finding implies a correlation of TCF7L2 expression and β -cell regeneration. TCF7L2 could trigger differentiation from ductal epithelial cells into β -cells *in vitro*. Our data support TCF7L2 as a new target for diabetes treatment to promote new β -cell formation.

Liganded-thyroid hormone receptor and activin convert pancreatic AR42J-B13 cells into insulin-producing cells

F. Furuya, K. Asami, M. Aoyagi, H. Shimura, T. Kobayashi;

Third department of internal medicine, University of Yamanashi, Japan.

Background and aims: One goal of diabetic regenerative medicine is to instructively convert mature pancreatic exocrine cells into insulin-producing cells. It is still unclear which factors regulate pancreatic regeneration and β -cell neogenesis and which precursor cells are involved. Neurogenin 3 (ngn3) is a transcription factor that is essential for the differentiation of pancreatic endocrine cells. The expression of ngn3 is restricted to immature endocrine cells and is considered to be a marker of endocrine progenitor cells during development of the pancreas. Recently, we reported overexpression of liganded thyroid hormone receptor α (TR α) used by adenovirus vector (AdTR α) enhanced proliferation of pancreatic β -cells *in vivo*. In the present study, we investigated the influence of TR α on transdifferentiation of pancreatic exocrine cells to endocrine cells.

Materials and methods: Rat pancreatic AR42J-B13 cells possess exocrine and neuroendocrine properties. Previous reports indicated that in the presence of betacellulin or hepatocyte growth factor, activin-treated AR42J-B13 cells convert to insulin-producing cells. To identify the role of TR α in the process of differentiation of pancreatic β -cells, AR42J-B13 cells were infected with AdTR α with or without activin treatment. The expression of ngn3 or insulin mRNA were analyzed by quantitative RT-PCR. AdTR α -associated protein expression of ngn3 or insulin was analyzed by Western blot or immunocytochemistry, respectively. To explore whether liganded-TR α -induced transdifferentiation is direct or indirect effect, AdTR α -infected AR42J-B13 cells were concomitantly transfected with small interfering RNA (siRNA) against ngn3.

Results: Infection with AdTR α to activin-pretreated AR42J-B13 cells with T3-treatment enhanced the expression levels of ngn3 mRNA (2.6-fold) and protein (3.4-fold), compared without T3-treatment. No insululin-staining was observed in activin-pretreated AR42J-B13 cells. Overexpression of liganded-TR α induced the insulin protein expression in activin-treated AR42J-B13 cells. The siRNA-associated inhibition of reexpressed ngn3 significantly prevents AdTR α -induced transdifferentiation of AR42J-B13 cells into insulin-producing cells.

Conclusion: AR42J-B13 cells have the potential to differentiate into both exocrine and neuroendocrine cells. We have postulated that AR42J-B13 cells would provide a good *in vitro* model with which to study the differentiation of exocrine or neuroendocrine cells in islets. Present study supports the hypothesis that liganded-TR and activin induce ngn3 expression and endocrine differentiation of AR42J-B13 cells to insulin-producing cells. Liganded-TR α may be a target for therapeutic strategies that can induce the expansion and regeneration of pancreatic β -cells.

Understanding the role of the transcription factor Math6 during endocrine cell development

M. Ejarque^{1,2}, G. Pujadas^{1,2}, J. Altirriba², R. Gomis^{1,2}, R. Gasa^{1,2};

¹Laboratori de Diabetis i Obesitat, Centro Esther Koplowitz (CEK), Institut d'investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), ²Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Barcelona, Spain.

Background and aims: The bHLH transcription factor Neurogenin3 (Neurog3) initiates the endocrine differentiation program in the embryonic pancreas. We previously identified the bHLH factor Math6 as a component of the pancreatic transcriptional cascade downstream of Neurog3. Math6 is found in Neurog3+ endocrine progenitors and, mirroring Neurog3, is down-regulated in mature islet cells. While Math6 is essential for early embryonic development, the function of this factor during endocrine differentiation remains elusive. This work aims to gain insight into the molecular function of Math6 during the endocrine differentiation program initiated by Neurog3 in the pancreas.

Materials and methods: We have generated a recombinant adenovirus encoding a Math6-specific shRNA (shMath6) and used it to down-regulate expression of this factor in Neurog3-expressing pancreatic duct cells (mPAC). We have analyzed global changes in gene expression profiles in response to shMath6 using Affymetrix microarrays. To study cell cycle regulation, we have used cell count measurements, brdU incorporation, DNA content (propidium iodide), FACS sorting and phospho-histone3 staining.

Results: Math6 silencing affects significantly the expression of 293 genes in mPAC cells. Gene Ontology analysis has revealed cell cycle as the biological function most significantly represented among the modified genes. To establish the potential role of Math6 on cell cycle regulation, we have assessed the functional effects of shMath6 on cell proliferation and found that shMath6 decreases both cell number (-30%) and brdU incorporation (-47%). We have also analyzed cell cycle phase distribution and found that shMath6-treated cells accumulate at G2/M phases (+70%). This accumulation most likely occurs at the transition from G2 to M because phospho-histone3, a mitotic marker, is decreased in shMath6-expressing cells. We are currently determining the cell cycle genes that mediate these effects by validating potential candidates identified in the microarray analysis.

Conclusion: These results uncover a potential role of Math6 in the control of cell cycle progression and provide novel insights into the link between Neurog3 and the cell cycle, a poorly understood but important aspect of endocrine cell differentiation. These data may be useful for the development of *in vivo* protocols for the generation of replacement β cells for the treatment of diabetes.

Pancreatic islet plasticity induced by sodium tungstate in IRS2-deficient mice modelJ. Oliveira^{1,2}, S. Rebuffat^{1,2}, A. García^{1,2}, A. Novials^{1,2}, R. Gomis^{1,2};¹IDIBAPS- Hospital Clinic/ Universitat de Barcelona, ²Ciberdem, Barcelona, Spain.

Background and aims: Insulin receptor substrate (IRS) 2 is one of the two major substrates for the insulin and insulin like growth factor signalling receptors and is required for various biological processes, such as nutrient metabolism, cell-cycle control, apoptosis and differentiation. Interestingly, IRS-2 is involved in the regulation of beta cell proliferation, as has been demonstrated using total IRS-2 knockout (IRS-2^{-/-}) mice. These animals develop type 2 diabetes associated with hepatic insulin resistance and a lack of compensatory beta cell hyperplasia. In this study we used sodium tungstate treatment as a tool to investigate the regulation of pancreatic islet plasticity in IRS-2^{-/-} mice. **Materials and methods:** 10 weeks wild type and knockout IRS2 C57Bl/6 mice were divided into two groups and given a solution of 2mg/ml of sodium tungstate in distilled water (treated group) or only distilled water (control group) for 21 days. During this period, physical status and blood glucose levels were recorded and glucose tolerance accessed before and after the treatment. Morphometric analysis of the pancreas was performed after the treatment. To determine differential gene expression between the four experimental groups we performed microarrays analysis (n=12) with isolated pancreatic islets.

Results: The administration of sodium tungstate significantly decreased glycemia in IRS-2^{-/-} mice while no changes were observed in the healthy animals (values day 0: 221±26 mg/dl versus values day 21: 134±23 mg/dl, n=9). By contrast, IRS-2^{-/-} control group developed hyperglycemia and diabetes during the experiment. Similarly, the administration of tungstate to IRS-2^{-/-} mice also improved glucose tolerance. Immunohistochemical analysis of insulin expression revealed, as expected, a reduced total beta cell area relative to total pancreas area in IRS-2^{-/-} control group (0.24%±0.2 versus 0.66%±0.2 in wild type animals, n=9). However, treated IRS-2^{-/-} mice showed an increment/preservation of pancreatic beta cell, reaching the levels found in the healthy treated animals (0.65%±0.3 versus 0.66%±0.2, n=7-9). In agreement with previous reports, tungstate treatment did not induce any significant modification in the healthy animals. IRS-2^{-/-} control animals had a higher number of apoptotic cells detected by cleaved caspase 3 immunostaining relative to total islet cell number than the healthy animals (24.7%±25 versus 0.37%±0.62). The treatment significantly decreased the rate of beta cell apoptosis in IRS-2^{-/-} mice (3.8%±2.4). Analysis of beta cell replication determined by the frequency of Ki67- positive beta cell nuclei revealed an increment of proliferation in treated IRS-2^{-/-} mice when compared to healthy animals (0.2%±0.2 versus 0.05±0.1). No Ki67- positive beta cells were found in IRS-2^{-/-} control animals. The analysis of the arrays from treated IRS-2^{-/-} animals identified 148 genes downregulated compared to IRS-2^{-/-} control group. Interestingly, 30% of these genes are the same genes that were upregulated in IRS-2^{-/-} control group and whose expression was restored by the tungstate treatment. Among these genes are the ones involved in inflammatory response and regulation of cell death.

Conclusion: Our results demonstrate that tungstate treatment reverses the diabetic phenotype of IRS-2 knockout mice and modifies the expression of a set of genes that seems to be participating in the recovery of endocrine function.

The homeoprotein Alx3 interacts with Pax6 to regulate glucagon gene expression in pancreatic islet cells

M. Vallejo, M. Mirasierra;

Instituto de Investigaciones Biomedicas Alberto Sols, Madrid, Spain.

Background and aims: In previous studies we determined that Alx3, an aristaless-type homeodomain transcription factor, is expressed in pancreatic islets and participates in the regulation of insulin and somatostatin gene expression. In addition, we demonstrated that lack of Alx3 in mice leads to alterations in glucose homeostasis, including increased fasting blood glucose levels and impaired glucose tolerance tests. Insulin resistance associated to defective Akt-dependent signaling in liver and muscle develops with age and is evident in mice older than 36 weeks, whereas young Alx3-deficient mice exhibit mild hyperglycemia and normoinsulinemia accompanied by unal-

tered peripheral insulin sensitivity, thus suggesting a defect in glucose sensing mechanisms in islets. Gene expression studies carried out by quantitative RT-PCR revealed that islets from Alx3-deficient mice contain lower levels of glucagon mRNA that those obtained from control animals, suggesting that the glucagon gene is under regulation by Alx3. In the present study we aimed to determine the participation of Alx3 in the transcriptional regulation of the glucagon gene.

Materials and methods: Luciferase reporter genes were constructed by standard recombinant DNA techniques. Transfection studies were carried out in pancreatic islet-derived alfaTC1 cells, as well as in non-islet cells. Binding of Alx3 to promoter elements was investigated by chromatin immunoprecipitation and electrophoretic mobility shift assays.

Results: Chromatin immunoprecipitation from DNA extracted from isolated mouse islets and alfaTC1 cells confirmed that Alx3 occupies the glucagon gene promoter in vivo. The region of the glucagon promoter that recognizes Alx3 corresponds to the proximal segment spanning nucleotides -370 to +16, relative to the transcription initiation site. Transfections with an Alx3 expression vector and a luciferase reporter plasmid incorporating this region in Hela cells demonstrated that Alx3 transactivates the glucagon promoter. Electrophoretic mobility shift assays indicated that Alx3 binds specifically to the G1-54 and G1-52 sites of the G1 regulatory element, but not to the G1-50 site. The G1-54 site is known to be recognized by Pax6. Supershift, immunoprecipitation and GST-pull down assays indicated that Alx3 and Pax6 interact on this site. Transient transfection assays indicated that Alx3 and Pax6 enhance glucagon promoter activity synergistically.

Conclusion: Our results demonstrate a direct role of Alx3 in the transcriptional control of glucagon gene expression in pancreatic cells via heterodimeric interactions with Pax6.

GATA4 is involved in pancreas specification via direct activation of Pdx1 in the endodermM. Carrasco^{1,2}, I. Delgado¹, B. Soria^{1,2}, F. Martín^{1,2}, A. Rojas^{1,2};¹Centro Andaluz de Biología Molecular y Medicina Regenerativa (CABIMER), ²CIBER de Diabetes y Enfermedades Metabólicas (CIBERDEM), Sevilla, Spain.

Background and aims: The GATA family of zinc finger transcription factors have been shown to be involved in the specification and differentiation of the endoderm and its derivatives. GATA4 is the first member to be expressed in the mouse embryo. Inactivation of GATA4 in the germ line leads to embryonic lethality and Gata4 null embryos display defects in heart and endoderm morphogenesis. Lack of GATA4 impairs pancreas induction and the cells in the foregut do not express Pdx1, the earliest pancreatic marker. These results suggest that GATA4 is crucial for pancreas formation, although the mechanisms involved are not well established. We aim to establish a functional interaction between GATA4 and Pdx1 for pancreas induction.

Materials and methods: We are using in vitro and in vivo approaches to study the transcriptional regulation of Pdx1 by GATA4 transcription factors. We are using EMSA, ChIP, transfection analyses and transgenic mice harboring the Pdx1 promoter controlling the lacZ reporter gene.

Results: A 5Kb promoter region of the Pdx1 gene has been previously shown to recapitulate the embryonic expression from earliest stages of development. This promoter region contains several conserved GATA binding sites. We show that these GATA sites are able to bind GATA4 recombinant protein in vitro. We also show that the GATA sites in the PDX1 promoter are occupied by GATA4 in mPAC pancreatic cell line. Moreover, mutations of the GATA sites negatively affect the activation of a reporter construct containing the luciferase under the control of Pdx1 promoter region in transfection assays. Finally, our analyses in transgenic mice demonstrate the requirement of the GATA sites for the initial activation of Pdx1 in the foregut.

Conclusion: Our results suggest that GATA4 is involved in pancreas specification by directly activating the transcription of Pdx1 in the pre-pancreatic endoderm.

Conserved GATA sites in the Pdx1 promoter are required for the initial transcriptional activation in the foregut. Representative X-gal stained transgenic embryos harboring the wild type (A) or mutated GATA sites (B) of the Pdx1 promoter fused to lacZ reporter gene are shown.

Endothelial factors increase islet-cell proliferation in adult mouse and human pancreatic islets

F. Martín¹, P. Moreno¹, G. Berná¹, V. Rivero², E. Leon², M. Nacher³, J. Navarro²;

¹Stem Cells, Andalusian Center of Molecular Biology and Regenerative Medicine (CABIMER), Seville, ²Cardiovascular Research Laboratory, University Hospital Virgen Macarena, Seville, ³Endocrine Unit, University Hospital Bellvitge, L'Hospitalet de Llobregat, Spain.

Background and aims: One promising approach for the cure of diabetes is beta cell replacement and regeneration therapies. The short supply in beta cells from cadaveric donors and the low replication capacity of beta cells have stimulated efforts to find ways of re-generating beta cells *in vitro* and *in vivo*. One of the non-transcription factors that controls proliferation and differentiation of pancreatic stem/progenitor cells is the vascular endothelial and its angiogenic factors. In this regard, the studies raise the possibility that endothelial cells and its angiogenic factors create a permissive environment that helps proliferation and differentiation of pancreatic stem/progenitor cells. The aim of this study is to identify the angiogenic signals involved in proliferation of adult islet-cells, to characterize these signals and to study the molecular mechanisms of their action.

Materials and methods: In vitro experiments: mouse and human islets were cultured 48h in 1% hypoxia or in the presence of VEGFA, anti-VEGFR1 and both agents. In vivo experiments: mice were injected with PBS or VEGFA plus anti-VEGFR1. VEGFA, VEGFR1 and VEGFR2 mRNA expression was measured by RT-PCR. VEGFR1 and VEGFR2 protein presence was evaluated by immunofluorescence. Islet-cell proliferation was measured by BrdU incorporation and Ki67. Analysis of replicating cells were performed by double immunofluorescence (BrdU+Insulin, Ki67+Insulin, Ki67+CD31+Insulin and Ki67+Pdx1+Insulin). VEGFA production, insulin content and glucose-induced insulin release was assayed by ELISA. Akt expression and Akt phosphorylation (serine 473) were measured by Western blot.

Results: Pancreatic islets had a higher VEGFA, VEGFR1 and VEGFR2 expression than aortic tissue. Beta cells were positive for VEGFR1 and VEGFR2. 1% hypoxia culture increased VEGFA, VEGFR1 and VEGFR2 expression. In vitro culture in the presence of VEGFA plus anti-VEGFR1 induced: i) a significant increase ($p < 0,05$) in VEGFA, VEGFR1 and VEGFR2 expression; ii) a significant increase ($p < 0,01$) in islet-cell proliferation and iii) a significant increase ($p < 0,001$) in glucose sensitivity and glucose-induced insulin secretion. Proliferating cells were positive for insulin and Pdx1 and negative for CD31. In vivo administration of VEGFA plus anti-VEGFR1 induced: i) a significant increase ($p < 0,01$) in beta cell proliferation and ii) a significant increase ($p < 0,001$) in glucose sensitivity and glucose-induced insulin secretion. Akt phosphorylation (serine 473) significantly increased ($p < 0,05$) in the presence of VEGFA plus anti-VEGFR1.

Conclusion: Adult beta cells can successfully proliferate, *in vivo* and *in vitro*, in the presence of angiogenic factors, without losing their functionality. Probably, these effects are mediated via Akt signalling pathways.

Wnt4 is a novel regulator of pancreatic beta cell proliferation and upregulated in response to exendin-4

S. Schinner, C. Heller, M. Kühn, W.A. Scherbaum; Endocrinology, University Hospital Düsseldorf, Germany.

Background and aims: The Wnt-signaling pathway regulates beta-cell functions. It is not known how the expression of endogenous Wnt-signaling molecules is regulated in beta-cells. Therefore, we investigated the effect of antidiabetic drugs and glucose on the expression of Wnt-signaling molecules in beta-cells.

Materials and methods: Preparation of primary islets. Analyses of Wnt and TNFalpha molecules by semiquantitative PCR and western blotting. Transient transfections and proliferation assays of INS-1 beta-cells ($[^3\text{H}]$ -thymidine uptake). Quantification of insulin secretion. Knock-down (siRNA) of Wnt4 in beta-cells.

Results: Exendin-4 significantly increased the expression of Wnt4 in beta-cells on the mRNA level (2.8-fold) and the protein level (3-fold) ($p < 0.001$). The effect was dose-dependent with strongest stimulation at 10 nM and it was maintained after long term stimulation over four weeks. Addition of exd-(9-39), a GLP-1 receptor antagonist, abolished the effect of exendin-4. Treatment with glucose, insulin or other antidiabetic drugs had no effect on the Wnt4 expression. The expression of other Wnt-signaling components was not regulated by any of the stimuli. Functionally, Wnt4 antagonized the activation of canonical Wnt-signaling in beta-cells. Wnt4 had no effect on glucose-stimulated insulin secretion and insulin gene expression. Knocking down Wnt4 decreased beta-cell proliferation to 45% of controls ($p < 0.05$). In addition, Wnt4 and Exendin-4 treatment decreased the expression of TNFalpha mRNA in primary beta-cells.

Conclusion: These data demonstrate that stimulation with exendin-4 increases the expression of Wnt4 in beta-cells. Wnt4 modulates canonical Wnt-signaling and acts as regulator of beta-cell proliferation and inflammatory cytokine release. This suggests a novel mechanism through which GLP-1 can regulate beta-cell proliferation

415

Down regulation of sFRP5 in pancreatic islets promotes beta cells proliferation in obesity

S.A. Rebuffat^{1,2}, J. Oliveira^{1,2}, J. Altirriba¹, Y. Esteban^{1,2}, A. Garcia^{1,2}, B. Nadal^{1,2}, A. Novials^{1,2}, R. Gomis^{1,2};

¹Diabetes and Obesity Laboratory, ²CIBERDEM, Barcelona, Spain.

Background and aims: In obesity, beta cell compensates for insulin resistance through increased beta cell mass and function in order to maintain glucose homeostasis. Replication, neogenesis or apoptosis are the main mechanisms involved in beta cell plasticity and are essential in avoiding the onset of hyperglycemia. Therefore, mechanisms regulating this process must be fully characterized. There is growing evidence suggesting that expanding adipose tissue that occurs in obesity affects both the mass and function of beta cells. Data shows that the adipose tissue that surrounds the pancreas is able to specifically secrete some proliferative signals which are partially responsible for this increase in beta cell mass. The objective of this study is to investigate gene expression changes induced by adipose tissue in islets during the progression towards obesity and explore the involved signaling pathway using a diet-induced-obesity model, the Cafeteria rat.

Material and methods: Wistar rats were fed with either standard (STD) chow or a cafeteria (CAF) diet for 10 and 30 days. At the end of the treatment, pancreatic islets were isolated. Gene expression profiles were realized by Affymetrix GeneChip® Rat Genome 230 2.0 Array (n=10). Normalization and differential expression analysis were performed with RMA and LIMMA software. Gene and protein expression were carried out. Proliferation, cellular death and insulin secretion have been measured in INS1E cell line and dissociated islets transfected by sFRP5 siRNA. Protein signaling pathways were studied in isolated islets from STD and CAF rats using Panorama cell signaling antibodies arrays and the most relevant results confirmed by Western Blot analysis.

Results: After statistical analysis, some genes (n=6) were differentially expressed between CAF vs STD islets. Interestingly, one of these genes was sFRP5 (Secreted frizzled-related protein 5), negative regulator of the Wnt signaling pathway involved in developmental processes, including proliferation, growth control and cell fate determination. Microarrays analysis revealed a decrease in SFRP5 gene expression in CAF islets (Fold Change: 2.30;

$p < 0.05$). This reduction was confirmed by quantitative real time PCR (FC: 2.08; $p < 0.05$) and by Western Blot. To validate our results obtained in our animal model, sFRP5 down regulation was performed using siRNA transfection in INS1E cells and in dissociated rat islets. The decrease of sFRP5 expression was confirmed by RT PCR (INS1E: -81.4 %, islets: -76.0 %; $p < 0.05$), western blot and immunofluorescence analysis. Using BrdU incorporation we observed that this down-regulation promotes an increase of proliferation (INS1E: +51.1 %, islets: +40.2 %; $p < 0.05$), without changes in apoptosis measured by flow cytometric analysis (INS1E: $18.1\% \pm 2.76$, Control siRNA INS1E: $18.4\% \pm 1.41$, sFRP5 siRNA INS1E: $19.8\% \pm 1.98$) confirming *in vivo* results. The first studies suggest that insulin secretion was not affected. The analysis of protein arrays identified several up-regulated proteins involved in the progression of cell cycle and also proteins belonging to cell signaling pathways such as MAPK, JNK.

Conclusion: Results presented indicate that, in obesity, pancreatic islets sFRP5 down-regulation is involved in beta cell proliferation. This key finding will pave the way for understanding the mechanisms that regulate beta cell mass compensation for obesity.

Human mesenchymal stem cells modulate dendritic cells presentation of islet antigen GAD65 in type 1 diabetes

I. Miceli, E. Favaro, C. Caorsi, S. Occhipinti, G. Grassi, V. Inglese, E. Camussi, M. Giovarelli, P. Cavallo Perin, G. Camussi, M.M. Zanone; Internal Medicine, University of Turin, Italy.

Background and aims: Mesenchymal stem cells (MSCs) exert an immunosuppressive effect on virtually any component of the immune system, including suppression of monocyte differentiation and maturation into dendritic cells (DC). We recently demonstrated that human MSC abrogated *in vitro* a pro-inflammatory Th1 response to islet antigen GAD in type 1 diabetes, impairing IFN- γ and inducing anti-inflammatory IL-4 production. In the present study, we evaluated whether human MSCs have, *in vitro*, an immunomodulatory potential directly on DC, modulating the balance of Treg cells subset. **Materials and methods:** Human bone marrow-derived MSCs were isolated and characterised. Peripheral blood mononuclear cells (PBMCs) were obtained from 7 type 1 diabetic patients at disease onset. Monocyte derived dendritic cells (DC) were differentiated from CD14⁺ cells in the presence of GM-CSF and IL-4, then pulsed with GAD65, matured in the presence of TNF- α and IL-1 β and cultured with MSCs for 24-48 hours (optimal ratio 10:1). The expression of CD1a, CD14 as well as maturation/activation markers on DCs (CD83, B7H1, B7H2) were evaluated by flow cytometric analyses. Then DCs cultured or not in the presence of MSCs were subsequently cocultured with autologous CD14⁺ lymphocytes. After 5 days coculture, IFN- γ ELISpot responses of recovered lymphocytes were assayed. Moreover, levels of prostaglandin E₂ (PGE₂), IFN- γ , IL-6, IL-10, IL-17 and TGF- β in supernatants collected after 24-48h +/-MSCs/DCs culture and after 5 days T lymphocytes/DCs coculture were measured by ELISA. Furthermore, the induction of T regulatory (CD4/CD25 high FOXP3⁺) cells subset were evaluated by flow cytometric analyses.

Results: Four diabetic patients showed a positive IFN- γ T cell response to GAD65 (mean spots 40 ± 26). Pre-incubation of the respective GAD65-pulsed DC with MSCs, inhibited the T cell activation, resulting in a significant decrease in the number of IFN- γ spots (mean spots 22 ± 18). Cocultures with MSCs did not affect the expression of CD83, B7H1, B7H2 on DCs, while significantly decreased secretion of IFN- γ and IL-6 and increased secretion of IL-10, PGE₂ and TGF- β were observed in supernatants collected. Moreover, MSCs cocultures induced regulatory T cells.

Conclusion: Human MSCs impair islet GAD antigen presentation to autoreactive T lymphocytes and significantly modifies the cytokine secretion profile of DC and T cell subsets, promoting an anti-inflammatory environment; even if do not inhibit DC maturation.

The role of B1 cells in the early steps of type 1 diabetes

N. Duarte, J. Côrte-Real, C. Penha-Gonçalves; Disease Genetics, Instituto Gulbenkian de Ciência, Lisbon, Portugal.

Background and aims: Type 1 diabetes (T1D) is generally known as a T-cell mediated autoimmune disease where the pancreatic beta-cells are destroyed and insulin secretion abrogated with severe metabolic consequences. Yet, B lymphocytes have been proven necessary for pathogenesis and detection of autoantibodies (autoAbs) to beta-cell antigens is one of the earliest indicators of disease. In particular, insulin autoAbs have predictive value both in human patients and in the non-obese-diabetic (NOD) mouse, a widely used animal model that spontaneously develops T1D in a similar manner to the human condition. Nevertheless, the origin and the role of beta-cell specific autoAbs in T1D development remain obscure. Unraveling the root of autoAbs generation and identifying linked B cell dysfunctions leading to disease will allow optimal diagnosis and early therapeutic interventions in T1D. B1 lymphocytes constitute a distinct B cell population of fetal origin, characterized by the expression of CD5 molecule and secretion of Natural antibodies (NAbs). We put forward the unexplored hypothesis that B1 cells and the natural autoantibodies they produce, are involved in T1D early pathogenesis by modulating the autoAbs repertoire.

Materials and methods: We have analyzed the phenotype and function of B1 cells in several organs of the NOD mouse in comparison to the C57BL/6 con-

tol mouse strain. Thus we have characterized by flow cytometry the distribution of B1 cells in different organs as well as the expression of molecules on their cell surface. Also, we have isolated B1 cells and determined by ELISPOT their *ex vivo* ability to secrete antibodies recognizing T1D related autoantigens. In addition we have characterized by Real Time PCR the expression of the innate Toll-like Receptors (TLRs) and performed *in vitro* cell cultures of purified B1 cells with and without agonist to TLR4 (LPS) and TLR9 (CPG) to characterize their response to innate stimuli. Proliferation was measured through thymidine incorporation and ELISA and ELISPOT techniques were used to analyze the secretion pattern of the cytokine IL10 and of autoAbs in these cell cultures.

Results: We have observed that B1 cells from the peritoneal cavity are the main secretors of IgM recognizing T1D related autoantigens. Further, young NOD mice without pancreatic infiltration presented a B1 cell repertoire with increased self-reactive in comparison to C57BL/6 mice. Also NOD B1 cells showed a higher expression of activation markers prior to pathogenesis onset indicating an increased basal level of activation in these cells. Interestingly, the levels of expression of several TLR were increased in NOD B1 cells and *in vitro* stimulation with TLR agonist to TLR4 and TLR9 resulted in the secretion of higher amounts of IgM recognizing T1D related antigens and less IL10 secretion by NOD B1 cells in comparison to the control mouse strain.

Conclusion: NOD B1 cells present an antibody repertoire with increase self reactivity and are more prone to secrete autoantibodies upon innate stimulation. We hypothesize that B1 cells may contribute to T1D onset and will further explore how innate stimuli may determine the reactivity of the NOD B1 cell repertoire and contribute to the development of T1D.

Toll like-receptor 4: regulator of energy metabolism in the non-obese diabetic mouse

A.L. Reinbeck, S. Müller-Lühlhoff, H.-J. Partke, V. Burkart, M. Roden; Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany.

Background and aims: Type 1 diabetes results from the immune-mediated destruction of autologous insulin-producing beta cells. Recent studies implicate that mechanisms controlling energy metabolism could be involved in the progression of beta cell destruction and disease development. Toll-like receptor 4 (TLR4) not only serves as receptor for bacterial lipopolysaccharides on innate immune cells, but also for metabolites such as fatty acids. Aside from its involvement in the pathogenesis of autoimmune diseases, TLR4 could therefore contribute to metabolic abnormalities in pre-diabetic states. We hypothesized that TLR4 determines a diabetes-modulating metabolic phenotype in NOD mice. To assess the potential impact of TLR4 during the pre-diabetic state, we performed comprehensive metabolic phenotyping of a TLR4-expressing ($T4^{+/+}$) and a TLR4-deficient ($T4^{-/-}$) substrain of the non-obese diabetic (NOD) mouse.

Materials and methods: Body weight and food intake of female normoglycemic TLR4-expressing and TLR4-deficient NOD mice were monitored from 7 to 22 weeks of age. Metabolic phenotyping was performed during three 12-hours light- and dark-cycles in a modular calorimetric system to determine physical activity, food- and water-intake as well as respiratory activity. Glucose metabolism was determined in fasted mice with intraperitoneal glucose tolerance tests (IPGTT).

Results: Compared with $T4^{+/+}$ mice, $T4^{-/-}$ mice show accelerated body weight gain, which occurs independently of food intake. $T4^{+/+}$ and $T4^{-/-}$ mice have a comparable energy expenditure during both light- ($T4^{+/+}$: 15.5 ± 0.7 kcal/(h x kg); $T4^{-/-}$: 14.4 ± 0.7 kcal/(h x kg)) and dark-cycles ($T4^{+/+}$: 19.2 ± 1.3 kcal/(h x kg); $T4^{-/-}$: 17.4 ± 1.1 kcal/(h x kg)). Physical activity as assessed by the distance covered is higher ($p < 0.01$) in dark- than in light-cycles, but is not different between both groups during light- ($T4^{+/+}$: 113 ± 7 m, $T4^{-/-}$: 137 ± 8 m) and dark-cycles ($T4^{+/+}$: 290 ± 8 m, $T4^{-/-}$: 262 ± 178 m). However, $T4^{-/-}$ mice exhibit lower respiratory exchange rates (RER , VCO_2/VO_2) in both light- ($T4^{+/+}$: 0.95 ± 0.03 , $T4^{-/-}$: 0.85 ± 0.03 , $p < 0.05$) and dark-cycles ($T4^{+/+}$: 1.00 ± 0.03 , $T4^{-/-}$: 0.90 ± 0.03 , $p < 0.001$). Moreover, $T4^{-/-}$ mice have markedly lower glucose tolerance as assessed from the incremental area under glucose curve of the IPGTT (587.6 ± 152.4 mmol/h) than $T4^{+/+}$ mice (203.9 ± 102.8 mmol/h, $p < 0.05$).

Conclusion: Selective TLR4 deficiency impairs glucose tolerance in nondiabetic NOD mice which may relate to accelerated fat oxidation and accelerated body weight gain despite no effect on physical activity and food intake. These findings suggest that TLR4 contributes to the progression of insulin-deficient diabetes in NOD mice by affecting the energy metabolism.

Identification of a monomorphic humoral epitope in the ZnT8 C-terminal domain

J.C. Hutton, J.M. Wenzlau, L.M. Frisch, H.W. Davidson; Barbara Davis Center, Aurora, USA.

Background and aims: ZnT8 is a major target in human type 1 diabetes (T1D). The identification of key humoral epitopes in this autoantigen may provide clues to the etiology of the disease, and will increase the range of available biomarkers. Our initial studies demonstrated that the majority of ZnT8-reactive sera recognize the final 100aa of the molecule, and that residue 325 is a major determinant in 2 epitopes linked to a common genetic polymorphism. The goal of the current study was to identify non-polymorphic epitopes in ZnT8 that are recognized by “un-restricted” sera.

Materials and methods: The C-terminal domains of human and mouse ZnT8 are ~80% identical. However, the mouse probe is not precipitated by the majority of human T1D sera. Thus to identify key residues we systematically “humanized” the mouse probe, either by creating chimeras, or site directed mutagenesis of variant residues, and evaluated the probes in radioimmunoassays.

Results: Analysis of chimeric and truncated probes suggested that a major non-polymorphic epitope was dependent on residues located between aa 320 and aa 360, which contains 11 variant residues including the polymorphic aa 325. No single substitution gave significant restoration of binding to “un-restricted” human sera. However, when clusters of structurally adjacent variant residues were also changed a region of antigenicity was revealed that depended on residues R332, E333, K336 and K340. Using 112 sera from newly diabetic subjects tested with the human aa325Q and m-R₃₂₅R₃₃₂E₃₃₃K₃₃₆K₃₄₀ probes, 39.3% of the subjects were ZnT8(Q)A+, of which 38.6% (17/44) also recognized the mouse probe.

Conclusion: We conclude that the mRREKK probe identifies a major non-polymorphic epitope that may add further to the diagnostic utility of ZnT8 autoantibodies.

CXCR3+, CCR4+ and CD25hi T memory cells and cytokines levels: an analysis during the initial phase of type 1 diabetes

T. Milicic¹, N. Lalic¹, A. Jotic¹, I. Markovic², M. Zamaklar¹, K. Lalic¹, L. Lukic¹, N. Rajkovic¹, M. Macesic¹, J. Seferovic¹, S. Aleksic¹

¹Clinical Center of Serbia, Clinic for Endocrinology Clinical Centre of Serbia, ²Institute for Biochemistry Medical Faculty University of Belgrade, Serbia.

Background and aims: Previous studies have reported an important role of the chemokine receptors CXCR3 and CCR4, which are associated with Th1 and Th2 T memory cell subsets respectively and involved in their extravasations into inflamed pancreatic islets, together with changes in T regulatory (T reg) subset, in the initial phase of Type 1 diabetes (T1D). However, the significance of the changes in CXCR3+ (Th1 associated), CCR4+ (Th2 associated) and CD25hi subsets (T reg associated) of the T memory cells as well as in chemokine/cytokine levels, interferon- γ inducible chemokine (IP-10) (Th1 associated), thymus- and activation-regulated chemokine (TARC) (Th2 associated) and transforming growth factor β (TGF β) (Treg associated), in recent onset T1D, have not yet been clarified. Therefore, the aim of this study was to analyze (a) the percentage of CXCR3+, CCR4+, CD25hi subsets of T memory cells and (b) chemokine/cytokine levels IP-10, TARC and TGF β , in peripheral blood in 26 recent-onset T1D patients in insulin-requiring state (IRS) at the onset (group A), 12 T1D patients in the state of clinical remission (CR) (group B), as well as in 20 healthy, age-matched control subjects (group C).

Materials and methods: T1D was diagnosed in accordance to WHO criteria. The CR was defined as optimal metabolic control without insulin lasting >30 days. The percentages of CXCR3+, CCR4+ and CD25hi T memory cell subsets were analyzed in peripheral blood by using four-color immunofluorescence staining and flowcytometry. IP-10, TARC and TGF β were determined by ELISA.

Results: We found that there was no difference among the groups concerning the percentage of T memory cells (A: 27.33 ± 8.52 vs B: 24.15 ± 6.52 vs C: 27.63 ± 6.52 %, A vs B vs C, $p = \text{NS}$). However, when the percentage of CXCR3+ T memory cells was analyzed, we found that in groups A and B it was significantly lower than in group C (A: 40.15 ± 11.55 ; B: 42.13 ± 11.11 ; C: 53.12 ± 6.34 %; A vs C: $p < 0.001$; B vs C: $p < 0.01$), while there was no differ-

ence between groups A and B. Simultaneously, the percentage of CCR4+ and CD25hi T memory cells was also found to be significantly lower in groups A and B than in group C (A: 31.59 ± 9.80 ; 0.23 ± 0.03 , B: 31.42 ± 8.13 ; 0.23 ± 0.10 , C: 40.92 ± 7.20 ; $0.26 \pm 0.06\%$, respectively; A vs C and B vs C, $p < 0.05$), again without difference between groups A and B. On the other hand, IP-10 and TARC levels were significantly higher in groups A and B than in group C (A: 141.99 ± 69.59 ; 398.14 ± 333.09 , B: 133.03 ± 63.19 ; 387.06 ± 124.57 , C: 85.24 ± 19.82 ; 236.88 ± 89.19 pg/ml, respectively; A vs C and B vs C, $p < 0.05$), while TGF β levels were significantly lower in groups A and B than in group C (A: 4784.37 ± 1858.41 B: 5243 ± 1228.95 C: 10690.50 ± 7246.65 pg/ml; A vs C and B vs C, $p < 0.05$), also without differences between groups A and B.

Conclusion: Our results shown that the onset of T1D was associated with the decrease in CXCR3+, CCR4+, CD25hi subsets of T memory cells and TGF β levels, together with increase in IP-10 and TARC, which persisted during the clinical remission, presumably reflecting both Th1 and Th2 extravasation into pancreatic tissue and impairments in immunoregulation. The results imply that the onset of the disease could be modified on the level of these subsets of T memory cells and associated cytokines.

Coxsackievirus up-regulates IL-17 immunity in human type 1 diabetes
J.K. Honkanen¹, J.K. Nieminen¹, S. Skarsvik², M. Roivainen³, J. Ludvigsson², J. Ilonen^{4,5}, O. Vaarala¹

¹Department of Vaccination and Immune Protection, National Institute for Health and Welfare, Helsinki, Finland, ²Department of Clinical and Experimental Medicine, Linköping University, Sweden, ³Department of Infectious Disease Surveillance and Control, National Institute for Health and Welfare, Helsinki, Finland, ⁴Immunogenetics Laboratory, University of Turku, Helsinki, Finland, ⁵Department of Clinical Microbiology, University of Eastern Finland, Kuopio, Finland.

Background and aims: Coxsackievirus infections have been associated with beta-cell autoimmunity. In acute viral myocarditis, up-regulation of IL-17 correlated positively with the replication of Coxsackievirus B3 due to the interference with the induction of Th1 immunity and virus eradication. Our aim was to study the activation of coxsackievirus induced IL-17 and IFN- γ responses in human type 1 diabetes (T1D).

Materials and methods: We studied the gene expression levels of IL-17 and IFN- γ in Coxsackievirus B4 strain (CVB4) -stimulated peripheral blood mononuclear cells (PBMCs) from 14 children with T1D and from 13 healthy children with HLA risk genotype for T1D and from 14 children without a risk genotype. PBMCs were stimulated for 7d with heat inactivated CVB4 and cells were collected for gene expression analysis of IL-17 and IFN- γ with qRT-PCR. In addition, we studied the intracellular expression of cytokines supporting IL-17 immunity, namely IL-1 β (IL-1 β) and IL-6 in myeloid dendritic cells (mDCs) and monocytes in Coxsackievirus B5 (CVB5) -stimulated PBMCs from three healthy individuals.

Results: The IFN- γ /IL-17 ratio in CVB4 stimulated PBMCs differed between the study groups ($p = 0.03$ in Kruskal-Wallis test). Healthy children without genetic risk for T1D showed higher IFN- γ /IL-17 ratio than children with T1D (median values 80.2 vs. 24.6, $p = 0.02$ in Mann-Whitney U-test). A similar trend for higher IFN- γ /IL-17 ratio was found in healthy children without genetic risk when compared to healthy children with genetic risk (median values 80.2 vs. 11.9, $p = 0.08$). The healthy children with genetic risk for T1D and children with T1D did not show difference in IFN- γ /IL-17 ratio (median values 11.9 vs. 24.8, $p = 0.8$). In vitro stimulation with Coxsackievirus up-regulated IL-1 β and IL-6 in mDCs and monocytes.

Conclusions: We conclude that coxsackievirus induced IL-17 expression is increased in relation to IFN- γ in children with T1D. This may impair virus eradication mechanisms and lead to invasive, chronic or recurrent coxsackievirus infections in patients with T1D. Based on our previous data of detrimental effect of IL-17 on human islets and mouse beta-cells, the up-regulation of IL-17 immunity by CVB may also increase beta cell death and the release of beta-cell derived antigens in the pancreatic islets.

Adipocytes of non-obese diabetic mice exhibit enhanced toll-like receptor 4-mediated proinflammatory activity

V. Burkart, A.L. Reinbeck, T. Märker, J. Kriebel, C. Habich;
Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany.

Background and aims: Recent studies on the development of type 1 diabetes implicate a role of the adipose tissue mass in disease progression. Adipocytes, the major cellular component of the adipose tissue, had been identified as important source of mediators promoting the progression of inflammatory processes. As the release of inflammatory mediators from adipocytes is under strict control of the Toll-like receptor 4 (TLR4), we hypothesized that a genetic background, predisposing for diabetes, affects the TLR4-dependent reactivity of adipocytes thereby contributing to diabetes progression. We therefore performed comparative analyses of the TLR4 reactivity of adipocytes from mouse strains without diabetes risk (C57BL) or with a risk to develop insulin-deficiency diabetes (non-obese diabetic (NOD) mouse) or the metabolic syndrome (New Zealand obese (NZO) mice).

Materials and methods: Adipocytes were isolated from the visceral fat depot of C57BL-, NOD and NZO mice. TLR4-dependent stimulation of preadipocytes and in vitro matured adipocytes was assessed by incubation of the cells with the TLR4 ligand lipopolysaccharide (LPS, 24h). The release of the proinflammatory mediators monocyte chemoattractant protein-1 (MCP-1) and interleukin-6 (IL-6) was quantified by ELISA.

Results: After LPS exposure (100 ng/ml) (pre-)adipocytes of TLR4-expressing C57BL-mice release 7 - 8-fold higher concentrations of IL-6 and MCP-1 than cells of TLR4-deficient animals (< 0.2 ng/ml IL-6 and MCP-1) ($p < 0.01$), thus proving the TLR4-dependence of adipocyte reactivity. The release of proinflammatory mediators from (pre-)adipocytes of different mouse strains in response to LPS was determined. Unstimulated preadipocytes of NOD-mice released higher IL-6- (5.8 ± 2.1 ng/ml) and MCP-1-amounts (22.1 ± 8.3 ng/ml) than cells of C57BL- (2.4 ± 1.9 ng/ml IL-6; 11.4 ± 0.7 ng/ml MCP-1; $p < 0.05$) and of NZO-mice (0.7 ± 0.8 ng/ml IL-6 ($p < 0.001$); 20.1 ± 10.1 ng/ml MCP-1). LPS-exposed preadipocytes of NOD-mice released increased IL-6- (32.1 ± 9.1) and MCP-1-levels (78.9 ± 10.0 ng/ml) when compared to cells of C57BL- (15.0 ± 7.2 ng/ml IL-6; 56.9 ± 17.7 ng/ml MCP-1; $p < 0.05$) and NZO-mice (10.3 ± 7.7 ng/ml IL-6; 37.7 ± 16.2 ng/ml MCP-1; $p < 0.01$). Interestingly, unstimulated mature adipocytes of NOD- and C57BL-mice released similar levels of IL-6 ($6.2 - 6.5$ ng/ml) and MCP-1 ($20.8 - 27.1$ ng/ml) which were significantly higher than the levels released from NZO-mouse-derived cells (0.9 ± 0.8 ng/ml IL-6; 13.3 ± 8.4 ng/ml MCP-1; $p < 0.05$). LPS-stimulated mature adipocytes of NOD- and C57BL-mice released higher IL-6- ($19.9 - 23.3$ ng/ml) and MCP-1-levels ($75.7 - 84.9$ ng/ml) than cells of NZO-mice (7.7 ± 4.7 ng/ml IL-6; 35.8 ± 16.2 ng/ml MCP-1; $p < 0.01$).

Conclusion: Our findings demonstrate that the genetic background, which determines the risk to develop a disturbed glucose metabolism, affects the TLR4-responsiveness of adipocytes. Whereas NZO mouse-derived (pre-) adipocytes exhibit a reduced reactivity, the genetic background of the NOD mouse which predisposes for the development of insulin deficiency diabetes, is associated with an increased TLR4-dependent proinflammatory reactivity of preadipocytes.

423

Correlation of inflammatory response gene expression in blood mononuclear cells to islet infiltration stages in LEW.1AR1-iddm rat model of autoimmune diabetes

T. Schoeppe, H. Weiss, M. Tiedge;
IBIO, University of Rostock, Germany.

Background and aims: The LEW.1AR1-iddm rat is an animal model of spontaneous autoimmune diabetes. Islet infiltration occurs within a narrow time range between day 40 and 50 after birth resulting in progressive beta cell destruction and overt diabetes around day 60. It was the aim of this study to correlate the gene expression profile in mononuclear cell of the blood (PBMC) with islet infiltration and beta cell mass destruction at different stages of islet infiltration.

Materials and methods: LEW.1AR1-iddm rats were killed at day 40, 45, 50, 55 and 60 ($n = 4 - 8$ per time point) with subsequent sampling of organs. RNA was purified from isolated mononuclear blood cells and pancreas draining lymph nodes. Gene expression was quantified for proinflammatory cytokines (TNF α , IFN γ , IL-1 β), antiinflammatory cytokines (IL-4, IL-10), T cell

marker (CD25, CTLA-4/CD152, Neuropilin), L-Selectin, TGF- β and FoxP3 by RT-PCR analyses using specific oligonucleotide probes. Furthermore RT-PCR Array analyses (Rat Inflammatory Response and Autoimmunity, Qiagen) covering chemokine panels were performed with blood RNA samples at the early stage of islet infiltration. Serial pancreatic sections were stained for Haematoxylin-Eosin (HE), immune cells and insulin to document infiltration state and level of beta cell destruction.

Results: At the stage of organ preparation all rats were normoglycaemic with blood glucose levels in the range between 5 and 7.5 mmol/l. 34 % (18/52) of the rats showed infiltrated islets ranging from 27 % (day 40) to 50 % (day 60). At day 40 gene expression of TNF α , IFN γ , IL-4, IL-10, CTLA-4/CD152, Neuropilin, L-Selectin, TGF- β and FoxP3 was significantly ($p < 0.05$) higher in PBMC from rats with islet infiltration compared to rats without signs of insulinitis. However at this early time point of islet infiltration the expression levels of these markers were not increased in pancreatic draining lymph nodes. Gene expression of PBMC showed that pancreatic infiltration is accompanied with high expression levels of chemokines, chemokine receptors (Ccl17, Ccl3, Ccl6, Ccr1) and regulatory genes (Cebpb, Ripk2, Nfkb1). Infiltrated islets at day 40 showed minimal loss of beta cells in the range of 10–20 % but a drastic reduction of insulin immunostaining (Insulin/Dapi: 3.8 ± 0.4 vs. 0.6 ± 0.1). At day 50 the expression levels of all cytokine/T cell markers significantly decreased and did not show significant differences between cohorts with infiltrated and normal islets. At day 55 CTLA-4/CD152, CD25 and FoxP3 expression significantly increased in PBMCs from infiltrated islets with progressive insulinitis and loss of insulin producing cells. At day 60 the expression profile was characterized by expression of the proinflammatory cytokines TNF α , IFN γ and IL-10.

Conclusion: The data indicate that in PBMCs the gene expression of proinflammatory cytokines and chemokines are significantly increased at the early stage of islet infiltration around day 40. The expression state of cytokines and T-cell activation then follows a two-peak model with increases at early islet infiltration, a nadir during progressive T-cell infiltration and a second peak at day 55 and 60 when beta cell destruction is > 70 %. Thus, gene expression profiles of chemokines/cytokines in PBMCs may serve as surrogate markers for different stages of islet inflammation in type 1 diabetes.

Controlling autoimmunity and transplant rejection by targeting interleukin-7 mediated signalling

C.B. Stumpp, R. Paul, E. Bonifacio;

Preclinical Approaches to Stem Cell Therapy, Center for Regenerative Medicine Dresden, Germany.

Background and aims: Type 1 diabetes mellitus is an autoimmune disease characterized by the destruction of islet beta cells by autoreactive T cells. We have reported that increased concentrations of Interleukin-7 (IL-7) can lead to an expansion of memory T cells, including autoreactive T cell clones, leading to reduced graft survival. Thus IL-7 antagonists could be useful drugs to modulate autoimmunity. The aim of this work is to identify mutants of IL-7 that could act as antagonists.

Materials and methods: The IL-7 structure and hypothetical binding of IL-7 to the IL-7R complex and in particular the common gamma chain was used to identify candidate amino acids for mutants. The wild type and glycine substituted mutant IL-7 proteins were expressed in E coli, and purified from inclusion bodies with subsequent refolding. The biological activity of the mutants was analyzed by measuring STAT5 phosphorylation in CD4 $^{+}$ T cells after IL-7 treatment by FACS. Binding to the IL-7Ralpha chain was measured with a competition assay, in which biotinylated wild type IL-7 competes with the mutant protein for binding to immobilized IL-7Ralpha.

Results: Sixteen residues in the D helix of IL-7 were identified as candidate targets for mutation on the basis of their hypothesized interaction with the common gamma chain and their evolutionary conserved nature. Thus, far, 6 of 16 mutants, with and without His-tag, have been prepared and tested for STAT5 phosphorylation. Mutation of residue W142 to glycine leads to a complete loss of pSTAT5 signaling capacity (7% of wild type activity). Markedly decreased activity was observed for mutants I138G (16%), N143G (19%) and K144G (24%), while the mutants R133G (76%) and E137G (93%) showed activity in the range of wild type protein. His-tagging did not interfere with the biological activity facilitating further complete mutational studies at the relevant residues. In a competition assay it was shown that the W142G mutant bound to the IL-7Ralpha chain with low affinity and could displace wild type IL-7 if present in high concentration.

PS 019 Transplantation

425

Histological examination of human islet transplants

K. Cheng¹, W.J. Hawthorne², P.J. O'Connell², A. Boulghourjian³, J. Kench⁴, J. George², J.E. Gunton¹;

¹Diabetes and Transcription Factors Group, Garvan Institute of Medical Research, ²Centre for Transplantation and Renal Research, Westmead Research Institute, ³Histology Facility, Garvan Institute of Medical Research, ⁴Department of Medicine, University of Sydney, ⁵Storr Liver Unit, Westmead Millennium Institute for Medical Research, Sydney, Australia.

Background and aims: In Type 1 diabetes (T1D) the immune system destroys the beta cells. Islet transplantation is still experimental as only a relatively small percentage of patients remain insulin independent after two years. However, islet transplantation offers the potential to be a cure for T1D. The aim of this project was to determine whether protocol liver biopsies after islet transplantation would yield islets for histological analysis and to determine the cause of loss of islet function.

Materials and methods: Patients who received an islet transplant for severe hypoglycaemic unawareness had a liver biopsy performed at the time of the second and subsequent transplant. Every seventh section of the biopsies was stained with insulin and counterstained with H&E to identify the islets.

Results: Five patients had two liver biopsies performed. Islets were identified in 80% of the patients (see Table 1). There was significant lipid deposition surrounding the islets in two cases and also significant immune infiltrate in these same two patients, which included B cells. Both patients were C-peptide positive with evidence of graft-function at time of biopsy. Three of the five patients remained off insulin including one where doses of their immunosuppression therapy were increased.

Conclusion: Islet transplantation remains a potential alternative to whole pancreas transplant in T1D patients. Three of the five patients remained off insulin including one where immunosuppression therapy was changed in response to biopsy findings. This project has identified physiological changes that occur within the liver after the islet transplantation. The biopsy findings led to changes in immunosuppressive therapy in 2 of 5 patients. Protocol liver biopsies are useful for research and may also guide therapy in some patients.

Table 1

		Islet found	Immune infiltrate	Lipid deposition	Immuno-suppression change

Cellular senescence in type 1 diabetic patients: effect of organ transplantation

R. Lupi¹, M. Gabriele², S. Del Guerra², F. Pancani², R. Pandolfi², S. Del Prato²;

¹Endocrinology and Kidney, Metabolic Unit, Azienda Ospedaliero-Universitaria Pisana, ²Endocrinology and Metabolism, Metabolic Unit, University of Pisa, Italy.

Background: Organ transplantation has become a common procedure in individuals with end-stage organ failure. Restoration of the organ function has been associated with improved life expectancy in many though not all organ transplantations. We have hypothesized that measurement of the length of telomeres, nucleoprotein complexes that serve as protective caps of linear eukaryotic chromosomes, could provide a marker for changes in cell senescence after transplantation procedures. Therefore, we have determined

telomere length (number telomeric repetitions/albumin copies number) and telomerase activity (by telomerase subunits assessment) in diabetic patients before and after pancreas transplantation.

Materials and methods: We have recruited 19 non-diabetics (ND) (43±16yrs old; 10M/9F; BMI 22.3±3.4 Kg/m²), 19 type 1 diabetes (T1DM: 47±11 yrs; 8M/11F; BMI 25.5±2.2 Kg/m², Diabetes duration 26.6±10.3 yrs, HbA1c 8.4±0.3%) and 27 T1DM from the waiting list for pancreas alone or pancreas after kidney transplantation (L-TX: 44±9 yrs; 13M/14F; BMI 23.9±3.2; Diabetes duration 26.4±9.7 yrs, HbA1c 8.2±1.6%) and 15 transplanted T1DM (TX: 42±6 yrs; 10M/5F; BMI 21.7±3.0; Diabetes duration 27.5±9.4 yrs, HbA1c 7.3±1.0%). In all patients anthropometric data were collected and blood was drawn for lab tests. Genomic DNA and total RNA were extracted from circulating nucleated blood cells. Telomere length was determined by Real-Time qPCR, while Real-Time RT-PCR was used for assessment of telomerase subunits HTERT (catalytic component) and HTERC (RNA component), and CCR2 gene expression.

Results: Telomere length (median value 0.126) was determined in all subjects. In the study population as a whole, telomere length was inversely associated with age ($r=0.240$, $p=0.035$), BMI ($r=0.258$, $p=0.041$), total cholesterol ($r=0.290$, $p=0.021$), LDL ($r=0.281$, $p=0.025$), and C-peptide ($r=0.315$, $p=0.007$) (all $p<0.05$ or less), while the correlation was positive with HDL ($r=0.610$, $p<0.001$), and duration of diabetes (DD) ($r=0.421$, $p=0.004$) (both $p<0.05$ or less). By regression stepwise followed by multiple regression analysis, DD and HDL remained independently associated with telomere length. When the different subgroups were examined, telomere length was higher in L-TX (0.217 ± 0.028) than in ND (0.153 ± 0.015 ; $p<0.05$). Moreover, HTERT gene expression was higher (0.0354 ± 0.0009 and 0.164 ± 0.029 , respectively) in T1DM and L-TX than in ND (0.010 ± 0.002 ; all $p<0.05$ or less). Upon normalization of telomere length by telomerase activity (T/T), a significant telomere shortening became apparent in T1DM and L-TX (8.07 ± 1.48 and 12.57 ± 0.49 , respectively) as compared to ND (248.9 ± 44.6 ; both $p<0.05$). TX patients had telomere length and T/T similar to that found in ND. Finally, CCR2 (MCP-1) receptor mRNA expression was greater in L-TX ($+549\pm100\%$; $p<0.001$) as compared to ND, while there was no difference in TX. CCR2 mRNA expression correlated with T/T values ($r=0.458$, $p=0.047$) and HTERT component ($r=0.896$, $p<0.001$).

Conclusions: Our data demonstrate an apparent effect of T1DM on markers of cellular senescence with telomere length being affected by duration of diabetes and HDL-cholesterol levels. Pancreas transplantation may reduce the process of telomere shortening. Assessment of telomere length may help risk stratification in T1DM and be a marker of outcomes of pancreas transplantation.

Effect of tungstate on the survival and function of Langerhans islets transplanted into the anterior chamber of the mouse eye

R. Malpique^{1,2}, A. Garcia^{1,2}, M. Gomis^{1,3}, M. Calvo⁴, B. Nadal^{5,2}, A. Novials^{1,2}, R. Gomis^{5,2};

¹IDIBAPS - Hospital Clínic, ²CIBERDEM, ³Universitat Pompeu Fabra, ⁴CCiTUB-Universitat de Barcelona, ⁵IDIBAPS - Hospital Clínic / Universitat de Barcelona, Spain.

Background and aims: Islet transplantation is an alternative therapy to conventional ones for restoration of beta-cell function in type 1 and 2 diabetic patients. However, challenges remain related to the establishment of an appropriate immunosuppressive therapy and the ability to *in vivo* monitoring the transplanted islets. The anterior chamber of the eye was recently proposed as a privileged transplantation site for pancreatic islets, enabling non-invasive *in vivo* imaging, fast islet engraftment due to the high vascularization of the iris, and reduced graft rejection. Previous studies by our group have demonstrated that the treatment of diabetic animals with sodium tungstate salt (phosphatase inhibitor) is able to rescue the diabetic phenotype by increasing beta cell replication and diminishing apoptosis. Based on such observations, we hypothesize that the administration of tungstate to diabetic-induced mice transplanted with pancreatic islets into the anterior chamber of the eye should stimulate graft survival and function.

Materials and methods: After 3 days of culture following isolation from mice pancreas, 100-150 islets were transplanted into the anterior chamber of the eye of diabetic-induced mice (streptozotocin (STZ)-treated 8 days before transplantation). After transplantation, animals were divided into 4 group ($n=5$): WT - transplanted (T), treated with sodium tungstate (W) (0.5 mg/ml water); T - transplanted, untreated with tungstate; W- non-transplanted, tungstate-treated; C - control, non-transplanted, untreated with tungstate.

During 22 days of treatment, *in vivo* studies were performed to analyze glycemic levels, islet revascularization (staining with Evan's blue) and cell viability (staining with CFDA-SE cell tracer and propidium iodide). Post-mortem morphometric analysis and functional studies were conducted on graft-containing eyes and pancreas.

Results: Our results showed, for both WT and T groups analyzed, the efficient vascularization of the engrafted islets within 11 days and maintenance of islet viability and vasculature within 22 days after transplantation. Preliminary results showed decreased glycemic levels within 8 days after transplantation for the WT group when compared to the values obtained for the T and C groups (96 ± 14 vs 184 ± 38 and 351 ± 38 mg/dl, respectively). This tendency was maintained until the end of our study (96 ± 3 vs 245 ± 24 and 356 ± 42 mg/dl, for T and C groups respectively), suggesting the protective role of tungstate on the transplanted islets. These results are confirmed by observations of increased beta cell replication (expression of insulin and Ki67) and vascularization, and reduced cell death in the WT group when compared with the other groups analyzed, supporting the role of tungstate on graft survival.

Conclusion: Our results suggest that the combination of islet transplantation and tungstate treatment is the best strategy to achieve the reversion of the diabetic phenotype in STZ-diabetic mice by improving graft survival and recovery of endocrine function. Future work will be performed with human islets isolated from cadaver donors.

Effect of tacrolimus versus cyclosporine on glucose metabolism of pancreas and kidney recipients in the late post-transplant period

T. Havrdova¹, F. Saudek¹, T. Jedinakova¹, K. Lipar², J. Skibova³

¹Diabetes Center, Inst Clin Exp Medicine, ²Transplant Center, Inst Clin Exp Medicine, ³Statistical Department, Inst Clin Exp Medicine, Prague, Czech Republic.

Background and aims: The aim of our study was to compare the glucose metabolism in type 1 diabetic recipients of kidney and pancreatic grafts on tacrolimus versus cyclosporine-based immunosuppression in conjunction with mycophenolate mofetil in the late posttransplant period.

Methods: We examined 26 insulin-independent patients after simultaneous pancreas and kidney transplantation with systemic venous drainage of pancreatic graft. All recipients had a stable good function of the kidney graft. Fasting glycemia, insulin levels, glycosylated hemoglobin (HbA_{1c}), a standard intravenous glucose tolerance test (IVGTT) with coefficient of glucose assimilation (K_{it}) calculation and trough Tacro/Cyclo levels were assessed. Insulin sensitivity was evaluated using the homeostasis model assessment (HOMA-IR). Total C-peptide and insulin secretions were calculated as areas under the curves from the serum levels during the IVGTT.

Results: Tacro and Cyclo groups did not differ in age, BMI and posttransplant period (9.7 ± 1.9 [SD] vs. 10.9 ± 1.3 years). We did not find any significant difference in response of IVGTT. In Tacro group (n=13) 3 patients had an abnormal response to glucose stimulus, 3 patients had an impaired glucose tolerance and 7 patients had a normal glucose tolerance. In Cyclo group (n=13) the abnormal response was present in none, the impaired glucose tolerance in 5 and the normal glucose tolerance in 8 recipients. The other results are shown in the following table.

	HbA _{1c} DCCT (%)	Fasting glycemia (mmol/L)	HOMA- IR	K _{it} (%/min.)	Total C-peptide secretion (pmol/ mL/60min.)	Total insulin secretion (mIU/L/60min.)
Tacro group	5.8 ± 0.41	5.05 ± 0.49	2.72 ± 2.64	1.24 ± 0.48	92 ± 47	1742 ± 1110
Cyclo group	5.7 ± 0.24	4.9 ± 0.55	2.26 ± 1.69	1.48 ± 0.53	98 ± 51	1440 ± 1093
Difference	NS	NS	NS	NS	NS	NS

Trough levels of calcineurin inhibitors had no significant impact on any of examined parameters.

Conclusion: The use of different types of calcineurin inhibitors in type 1 diabetic pancreas and kidney recipients had no effect on glucose metabolism in the late posttransplant period.

Effects of dipeptidyl peptidase 4 inhibition with MK-0431 on syngeneic mouse islet transplantation

J.-H. Juang^{1,2}, C.-H. Kuo², Y.-H. Liu¹, C.-T. Chen³

¹Division of Endocrinology and Metabolism, Chang Gung Memorial Hospital, Taoyuan, ²Department of Biological Science and Technology, National Chiao Tung University, Hsinchu, ³Division of Biotechnology and Pharmaceutical Research, National Health Research Institutes, Zhunan, Taiwan.

Background and aims: Dipeptidyl peptidase-4 (DPP-4) inhibitors increase circulating levels of active incretin hormones-glucagon-like peptide-1 (GLP-1) and glucose-dependent insulintropic polypeptide (GIP) by blocking their degradation. In addition to their insulintropic actions, GLP-1 and GIP also promote beta-cell proliferation and survival. The aim of this study was to test if DPP-4 inhibition with MK-0431 is beneficial for diabetic recipients with a marginal number of fresh islets.

Materials and methods: We syngeneically transplanted 150 C57BL/6 mouse islets under the kidney capsule of each streptozotocin-diabetic mouse, and then treated recipients with (n=20) and without (n=14) MK-0431 (30 mg/kg, po) for 6 weeks. Before and after transplantation, recipients' blood glucose, body weight and intraperitoneal glucose tolerance test (IPGTT) were measured. At 6 weeks, islet grafts were removed to determine insulin content and beta-cell mass.

Results: After islet transplantation, blood glucose levels decreased progressively in both groups. The mean (\pm SE) area under the curve of IPGTT at 2 weeks (43659 ± 2097 vs. 42318 ± 2679 mg/dl), 4 weeks (32088 ± 3450 vs. 31722 ± 3653 mg/dl) and 6 weeks (32201 ± 3564 vs. 26169 ± 3711 mg/dl) were not significantly different between MK-0431-treated mice and controls ($p > 0.27$). The mean (\pm SE) blood glucose at 6 weeks was 233 ± 36 and 263 ± 48 mg/dl in the MK-0431-treated group and controls, respectively ($p = 0.62$). MK-0431-treated group exhibited increased body weight over time (19.5 ± 0.5 to 21.4 ± 0.6 g, $p = 0.003$) and controls maintained their weight (18.5 ± 0.9 to 19.6 ± 1.0 g, $p = 0.58$), but the difference between two groups was not significant throughout the study period. At 6 weeks after transplantation, the mean (\pm SE) insulin content (4.24 ± 0.85 vs. 6.27 ± 0.33 IU, $p = 0.18$) and beta-cell mass (7.7 ± 1.6 vs. 4.9 ± 1.4 mg, $p = 0.20$) of grafts were comparable in the MK-0431-treated group and controls.

Conclusion: These results indicate posttransplant DPP-4 inhibition with MK-0431 in the diabetic recipient with a marginal number of fresh islets did not improve transplantation outcome.

430

Liraglutide increases VEGF secretion in rat pancreatic islets

A. Langlois¹, K. Vivot¹, N. Jeandier², W. Bietiger¹, C. Dollinger¹, M. Pinget^{2,1}, S. Sigrist¹

¹Centre européen d'étude du Diabète, ²Service d'endocrinologie, diabète, maladies métaboliques, Pôle NUDE, Hôpitaux Universitaires de Strasbourg, France.

Background and aims: The formation of microvascularization by capillary sprouting at the site of islet transplantation is crucial for survival of the graft. Vascular Endothelial Growth Factor (VEGF), a major angiogenic factor, may be a key protein in modulating the angiogenesis of islets after transplantation. Development of a pharmacological approach enhancing VEGF synthesis could improve islet graft survival. Liraglutide has been shown to decrease islets apoptosis and increase survival in cultured or transplanted islets. The mechanisms of its role in islets viability in culture and during transplantation have to be identified. The aim of this work was to study *in vitro* the effects of liraglutide on islet viability and its relation to angiogenesis via VEGF secretion.

Materials and methods: Previous studies have determined a protocol allowing the systematic evaluation of pharmacological molecules. Following this protocol, cultures of rats islets were incubated in presence of 1 and 10 μ M of liraglutide (50 fold higher than pharmacological concentrations used) during 12, 24 and 48h. The islet viability was evaluated using fluorescein diacetate/propidium iodure dying and functionality was determined by glucose test stimulation. Islets insulin-secretion was expressed as an index of stimulation (IS). VEGF secretion was determined by ELISA assay.

Results: Islets viability was 100% in controls and with liraglutide. Ten μ M of liraglutide induced a significant stimulation of VEGF secretion as early as 24h with 10.57 ± 3.55 vs control with 4.42 ± 1.09 pg of VEGF/ μ g of protein ($p <$

0.05, $n=4$), and was maintained after 48h. It only appeared after 48h with 1 μM liraglutide. Levels of secretion were respectively: 39.28 ± 14.81 with 1 μM , 53.60 ± 25.03 with 10 μM ; 13.63 ± 4.48 pg of VEGF/ μg of protein with controls, $p < 0.05$, $n=4$). At the same time, a significant stimulation of the insulin-secretion was observed at 24h of culture with 1 and 10 μM of liraglutide and controls with respectively 7.86 ± 1.78 and 8.17 ± 2.43 vs 4.27 ± 1.46 μg of insulin/g of protein ($n=4$, $p < 0.05$). The effect was maintained after 48h with 1 μM : 2.63 ± 1.64 and 10 μM : 6.28 ± 4.74 for liraglutide vs controls: 2.29 ± 1.05 μg insulin/g of protein, $n=4$).

Conclusion: *In vitro*, suprapharmacological concentrations of liraglutide had no toxicity and significantly stimulated VEGF secretion in islets. Also, insulin-secretion increased during the first 24h of culture. VEGF secretion could be one of the mechanisms involved in the improvement of islet viability during transplantation. Increased angiogenesis remains to be assessed.

Vitamin D supports successful low-dose combination therapy with anti-CD3, cyclosporine A and islet transplantation in diabetic NOD mice

T.L. Van Belle¹, F. Baeke¹, C. Gysemans¹, L. Chatenoud², C. Mathieu¹;

¹LEGENDO, Catholic University Leuven, Belgium, ²Université Paris Descartes, Paris, France.

Background and aims: Anti-CD3 treatment has been considered the holy grail of immune therapies to revert recent-onset type 1 diabetes (T1D), but recent clinical trials have revealed a major drawback of anti-CD3 mAb therapy, namely its narrow therapeutic window in which low doses are ineffective and high doses can be efficacious but cause side-effects. In light of these issues, strategies that sidestep these limitations while preserving or improving the therapeutic efficacy of anti-CD3 monotherapy are essential.

Materials and methods: We investigated whether combination therapy with a potent vitamin D analog and cyclosporin A enhances the therapeutic efficacy of anti-CD3 mAbs (145-2C11 whole IgG) in diabetes recurrence upon syngeneic islet transplantation in diabetic NOD mice

Results: This combination therapy was well-tolerated based on weight, bone and calcium parameters. Remarkably, combining all three agents at low, sub-therapeutic doses strongly restrained immune-mediated islet destruction and subsequent recurrence of diabetes (79.5 ± 18.6 days; $p < 0.01$), by far exceeding the therapeutic efficacy of each of the mono- (24.8 ± 7.3 days for anti-CD3) and duo- (25.5 ± 12.4 days for anti-CD3 + CsA) therapies, even though dual-therapies prevented primary graft non-function. Despite this clear improvement in clinical outcome, anti-CD3 treatment was accountable for most of the early alterations in T cell numbers, Treg frequencies and expression of inflammatory homing receptor in the triple combination therapy.

Conclusion: Based on these preliminary data, we nevertheless propose that VDR agonists should be considered as a dose-reducing agent in combination therapies for autoimmune diseases.

A new method for human pancreatic cell purification

V. Pawlowski¹, B. Lukowiak¹, G. Angelborg², B. Lefebvre¹, V. Gmyr¹,

F. Kamme², F. Pattou¹, J. Kerr-Conte¹;

¹Biotherapies of Diabetes, University Lille Nord de France, France,

²In Situ Cytometry for Vital Cells, CynTellect, San Diego, USA.

Background and aims: Primary human beta cells have become indispensable in research on diabetes and obesity. In 2001, our team described FACS purification of viable human beta cells using the zinc-sensitive probe Newport Green. This technique has become routine worldwide in the last 5 years. However, shear forces inherent in this cell sorting technique can lead to low cell viability (<50%), poor RNA quality (28S/18S ratio <1.8), and low cell attachment in culture post sorting. Machine of the Year 2009, Laser-Enabled Analysis and Processing (LEAP[™], CynTellect Inc, USA) system was developed to address these limitations in cell purification, via laser-mediated in situ elimination of undesired cells in culture without physically manipulating the cells of interest. The aim of this study was to purify human insulin secreting pancreatic beta using the LEAP[™] (<http://www.cyntellect.com>).

Materials and methods: Briefly, human pancreatic islets (purity 61% \pm 10.3 : range 20–75%, $n=5$) were dissociated with Accutase[™] at 37°C into a single cell suspension, filtered and stained with the zinc chelator, Newport Green (Invitrogen) and Hoescht 33342. Cells were seeded on uncoated plates (384-

well C-lect[™] plates) or immobilized in Matrigel. Laser power and spot size were titrated to get optimal kill efficiency and minimal collateral damage. RNA integrity (% of full length GAPDH cDNA) was determined post sorting, and subsequent quantitative real-time RT-PCR.

Results: Starting cell preparations were 31.2% \pm 1.53 ($n=5$) Newport Green positive. After laser processing (3 iterations, 1000 shots/second) cells were 89.5% \pm 5.78 ($n=5$) Newport Green positive, corresponding to 100 cells/well. Laser processing did not impact RNA integrity (average length of GAPDH cDNA from laser processed cells as compared to control cells) nor cell viability.

Conclusion: The purification of Newport Green positive beta cells is feasible on LEAP[™] and high purity (90%) can be obtained, mRNA length is maintained in laser processed cells (i.e. no signs of RNA degradation), as is cell viability. The LEAP[™] provides the unique ability to purify small samples with far greater yield and purity than other technologies and is a new method allowing the study of pure human beta cells in culture.

Cytokine-induced endoplasmic reticulum stress regulates nuclear factor-kappa-B activation in pancreatic beta cells

J.Y. Chan, T.J. Biden, D.R. Laybutt;

Garvan Institute of Medical Research, Sydney, Australia.

Background and aims: Type 1 diabetes is characterised by the dysfunction and destruction of pancreatic β -cells which may be mediated by pro-inflammatory cytokines such as IL-1 β , TNF- α , and IFN- γ . Exposure of β -cells to these cytokines results in the activation of both endoplasmic reticulum (ER) stress and nuclear factor- κ B (NF κ B) signalling; but the significance of these responses in type 1 diabetes remains unclear. We investigated the role of ER stress in cytokine-induced NF- κ B signalling and β -cell destruction.

Materials and methods: β -cell responses to pro-inflammatory cytokines were examined in pancreatic β -cell lines and in mouse islets. Combination of IL-1 β (100U/ml), TNF- α (100U/ml), IFN- γ (250U/ml) was used for cytokine treatments. The chemical chaperone 4-phenylbutyric acid (PBA - 2.5 mM) was used to alleviate ER stress whilst pyrrolidinedithiocarbamate (PDTC - 50 μ M) was used to inhibit NF κ B activation. The role of the pro-apoptotic transcription factor CHOP in cytokine-induced β -cell toxicity was assessed by siRNA knockdown. β -cell death was measured using a cell death detection ELISA. NF κ B activity was examined in a β -cell line that stably expresses a luciferase reporter under the NF κ B promoter. Gene and protein expression changes were assessed by real-time PCR and Western blot.

Results: In MIN6 cells, exposure to cytokines resulted in increased cell death, elevated expression of ER stress markers, including CHOP, and activation of genes known to be regulated by NF κ B, including inducible nitric oxide synthase (iNOS), inhibitor of κ B- α (I κ B α), superoxide dismutase 2 (Sod2) and monocyte chemoattractant protein-1 (MCP-1/Ccl2). Unexpectedly, alleviation of ER stress with PBA caused a potentiation of cytokine-induced cell death, associated with further increases in cytokine-stimulated NF κ B-regulated gene expression. Cytokine-induced cell death or NF κ B-regulated gene expression were not affected by a knockdown of CHOP expression using siRNA, but they were completely inhibited when co-treated with the NF κ B inhibitor PDTC. Reporter assays demonstrated that PBA increased NF κ B activation, which was associated with a prolonged decrease in cytoplasmic I κ B α level. In addition, gene expression analysis showed that PBA treatment altered the downstream expression pattern of genes involved in the unfolded protein response (UPR), which is activated following ER stress to assist in its resolution. We also found in isolated mouse islets that alleviation of ER stress with PBA potentiated cytokine-induced cell death.

Conclusion: These data suggest a novel mechanism by which ER stress conferred by pro-inflammatory cytokines interacts with NF κ B signalling in β -cells, possibly by regulating the replenishment of its inhibitory protein I κ B α . The interface between UPR and NF κ B signalling pathways may be important in the regulation of β -cell survival in type 1 diabetes.

TNF α reduces ATP-binding cassette transporter A1 gene expression via p38 MAPK γ , resulting the pancreatic beta cells dysfunction

H. Imachi¹, T. Muraoka¹, T. Yoshimoto¹, F. Kikuchi¹, Y. Miyai², K. Mura³;

¹Division of Endocrinology and Metabolism, Department of Internal

Medicine, ²Department of Diagnostic Pathology, ³Department of Advanced Medicine and Clinical Laboratory, Faculty of Medicine, Kagawa University, Japan.

Background and aims: ATP-binding cassette transporter A1 (ABCA1) is a pivotal regulator of lipid efflux from cells to apolipoproteins and plays an important role in reverse cholesterol transfer. Recent report indicates that mice with specific inactivation of ABCA1 gene in β cells had markedly impaired glucose tolerance and defective insulin secretion. Pancreatic islets isolated from these mice demonstrated altered cholesterol homeostasis and impaired insulin secretion in vitro. These results establish a new role for ABCA1 gene in β cell cholesterol homeostasis and insulin secretion, indicating that cholesterol accumulation may contribute to β cell dysfunction in type 2 diabetes. On the other hand, TNF α is a proinflammatory cytokine produced by acti-

vated macrophages during the pathogenesis of diabetes. In the present study, we examined the effects of TNF α on ABCA1 expression in pancreatic β cells. **Materials and methods:** ABCA1 expression was examined by real-time polymerase chain reaction (PCR), western blot analysis, and reporter gene assay in both rat pancreatic islets and rat insulin-secreting cell line, INS-1 cells incubated with TNF α . We investigated the influence of the constitutively active form or dominant-negative mutant of p38 MAPK γ on ABCA1 expression by TNF α .

Results: TNF α suppressed ABCA1 protein expression dose-dependently in INS-1 cells. Real-time PCR analysis showed at significant reduction in the abundance of ABCA1 mRNA in response to TNF α in rat pancreatic islets. TNF α also decreased the activity of the luciferase reporter protein that was under the control of the ABCA1 promoter. Using several pharmacological inhibitors for the signal transduction pathways, the inhibitory effect of TNF α on ABCA1 promoter activity was abrogated by a specific inhibitor of p38 MAPK γ , but not for other isozymes. Activation of p38 MAPK γ by TNF α peaked after 15 min of exposure to TNF α . Furthermore, the constitutively active form of p38 MAPK γ decreased ABCA1 promoter activity in INS-1 cells. However, the dominant negative p38 MAPK γ abrogated the inhibitory effect of TNF α on ABCA1 promoter activity. When INS-1 cells were exposed to 10 nM TNF α , the insulin secretion or cholesterol ester content was decreased or increased, respectively, while the effects of TNF α on insulin secretion or cholesterol ester content were reduced in the cells treated with the ABCA1-specific siRNA.

Conclusion: Elevation of cholesterol levels in pancreatic islet cell reduces glucose-stimulated insulin secretion. This correlation is consistent with that between the reduction in insulin secretion and the elevation of pancreatic islet cell cholesterol levels in mice lacking β cell ABCA1, suggesting that cholesterol has a direct effect on reduction of β cell function. Our data showed that p38 MAPK γ mediates TNF α -suppressed transcription of the ABCA1 gene in pancreatic β cells, indicating that TNF α plays an important role in pancreatic β cells dysfunction. Activation of the p38 MAPK γ pathway by TNF α inhibits ABCA1 gene transcription, indicating that TNF α plays an important role in the lipotoxicity of pancreatic β cells.

Siglec 7 improves beta cell function and survival by inhibition of cytokine expression and secretion

G. Dharmadhikari¹, F. Paroni¹, J. Kerr-Conte², S. Kelm¹, K. Maedler¹;

¹Centre for Biomolecular Interactions, University of Bremen, Germany,

²INSERM / Université de Lille, Lille, France.

Background and aims: Local inflammation, cytokine and chemokine production within pancreatic islets is detrimental for the β -cell survival and function. Siglecs (Sialic-acid binding immunoglobulin like lectins) are cell surface receptors expressed on haematopoietic cells which participate in immune responses. Their ligands, sialic acids, have prominent position, negative charge and widespread distribution and thus are involved in cell-cell interactions as well as pathogen and toxin binding. Our investigations revealed a cell-type specific expression of Siglecs in pancreatic islets, which is altered in diabetic conditions. Siglec 7, expressed in the β -cell, was downregulated in diabetes and its ligands were oppositely regulated.

Materials and methods: To investigate the role of Siglecs in β -cell function, Siglec 7 over-expression by plasmid transfection was carried out in isolated human islets followed by glucose stimulated insulin secretion (GSIS) and TUNEL assay. For investigating the cellular mechanisms, isolated human islets were treated with the diabetogenic conditions of elevated glucose (33.3 mM), palmitate (0.5 mM) and the cytokine mixture IL-1 β (2 ng/ml) and IFN- γ (1000 U/ml). Cytokine production and secretion was analyzed by RT-PCR and by the Meso Scale Discovery® multi array technology.

Results: Siglec 7 mRNA was markedly downregulated in islets isolated from patients with T2DM with poorly functional β -cells (70% downregulation vs non-diabetic control islets) as well as in pancreases from autopsy from patients with T2DM (85% downregulation vs non-diabetic control pancreases). Hence, we aimed to know if over-expression of Siglec 7 has a protective effect on β -cell function and survival. Indeed, plasmid over-expression of Siglec 7 increased GSIS 1.5-fold in human islets isolated from patients with T2DM. In non-diabetic islets, the GSIS was increased 2.5-fold under basal conditions. Also, glucose and palmitate induced 3.5 and 4% β -cell apoptosis respectively, which was prevented by Siglec 7 overexpression (50 and 40% reduction respectively compared to lacZ transfected control islets). To investigate the mechanisms of this protective effect of Siglec 7, the secretion and expression of IL-1 β , IL-6 and TNF α was analyzed in Siglec 7 overexpressing isolated hu-

man islets subjected to stimulation of cytokine expression by diabetogenic conditions. The combination of 33.3 mM glucose and 0.5 mM palmitate induced the secretion of cytokines IL-1 β (1.75-fold), IL-6 (4-fold) and TNF α (2-fold), compared to control islets ($p < 0.05$). Siglec 7 overexpression led to inhibition of IL-1 β and TNF α secretion to basal levels and to a 40% decrease in IL-6 secretion by these islets. Treatment with the cytokine mixture also increased accumulation of cytokines in the islet supernatants after 4 days: IL-1 β (19-fold), IL-6 (4.6-fold) and TNF α (1.7-fold), which was inhibited in Siglec 7 overexpressing islets. This was also confirmed on the mRNA level. In isolated human islets from patients with T2DM Siglec 7 overexpression caused a reduction in basal IL-1 β (40%) and TNF α (50%) expression, compared to LacZ treated islets ($p < 0.05$).

Conclusion: Our data suggest that Siglec 7 is expressed in pancreatic islets, downregulated in T2DM and improves β -cell function and survival by inhibiting deleterious cytokine production and secretion.

Endosomal TLR3 activation by Coxsackievirus initiates strong immune response and death of beta cells

E. Domsgen¹, F. Paroni¹, J. Kerr-Conte², A. Dotzauer¹, K. Maedler¹;

¹Centre for Biomolecular Interactions, University of Bremen, Germany,

²Thérapie Cellulaire du Diabète, Lille, France.

Background and aims: Group B Coxsackievirus (CVB) infection of β -cells is associated with the development of diabetes. Intra-islet viral particles were detected in patients with T1DM and T2DM, but the mechanisms of a correlation between virus infection and diabetes progression are poorly understood. In this study we asked the question which intracellular signals are involved and which pattern recognition receptor (PRR) binds to CVB dsRNA.

Material and methods: Isolated human islets were infected with two different serotypes of CVB3 and 4. Replication of CVB was confirmed by immunostaining of viral protein 1 (VP1) and titration of islet lysate. CXCL10 secretion from the islets was measured by ELISA, CXCL10, IFN β , IFN γ , IL-1 β , TNF α , IL-6, MCP1, IL-8, RIG-I, TLR3, MDA-5 and PKR mRNA production by quantitative RT-PCR and β -cell apoptosis by double-staining for the TUNEL assay and insulin. Islet protein expression and phosphorylation were analyzed by western blot. Binding of CVB dsRNA to PRRs were investigated by the use of immunoprecipitation-RT-PCR coupled assays.

Results: Immuno- and TUNEL staining of infected islets revealed that β -cell apoptosis was 7-fold increased in CVB infected islets with a strong colocalisation of VP-1 and insulin positive β -cells. Immunoprecipitation-RT-PCR coupled assays showed that extracellular viral components bound to transmembrane-anchored, endosomal members of the Toll-like receptor family (TLR3) and transduced a signal via cytoplasmic adaptor proteins. The cytoplasmic receptor protein kinase R (PKR) mediated the induction of response genes from intracellular pathogen-produced substrates. In contrast, retinoic acid inducible gene I (RIG-I) and Melanoma differentiation associated protein 5 (MDA-5) were not involved in the recognition of CVB's dsRNA, despite the upregulation of RIG-I and MDA-5 mRNA in islets. TLR3 sensing resulted in increased mRNA levels of CXCL10, IFN β , IL-1 β , TNF α , IL-6, MCP1 and IL-8 in the infected islets. Among them, CXCL10 was the highest induced factor (~35-fold increase in secretion, 15-fold increase in mRNA, $p < 0.001$), compared to uninfected islets. In contrast, IFN γ remained unchanged; underlining that CXCL10 upregulation was TLR3 dependent. Additionally mRNA levels of the PRRs TLR3, RIG-I, MDA5 and PKR which are responsible to sense viral RNA were increased during infection resulting in amplified immune response. Analysis of survival and apoptotic pathways showed that the protein Akt was acutely activated during CVB infection and lasted for several hours, but switched to pro-apoptotic signaling at 24h p.i. with Akt downregulation, activation of pJNK and Caspase-3 and the appearance of the viral protein VP1.

Conclusion: Our data show that CBV infections have a direct deleterious effect on β -cell survival, resulting from virus-induced activation of pro-inflammatory cytokines and chemokines and upregulation of PRR mRNA triggered by TLR3 binding of CVB dsRNA. During the early phase of infection, the virus triggers the Akt pathway, possibly to initially maintain host survival and its own replication. Further understanding of the pathways involved in viral infection of β -cells will be of particular interest in order to develop new therapies to rescue the β -cell.

Prevention of multiple low dose streptozotocin (MLD-STZ) induced diabetes in mice by extract from gum resin of boswellia serrata and 11-keto-B-boswellic acids

H.P.T. Ammon, A.M. Shehata;

Pharmacology and Toxicology, Pharmaceutical Institute, Tübingen, Germany.

Background and aims: Type 1 diabetes and LADA are autoimmune diseases where a chronic inflammatory process destroys insulin producing β -cells. Boswellic acids which derive from the gum resin of Boswellia species have been shown to possess immunomodulatory properties and suppress proinflammatory cytokines including NF κ B. In the model of MLD-STZ diabetes which is thought to correspond to human type 1 diabetes it was tested whether or not an extract of the gum resin of Boswellia serrata (BE), 11-keto- β -boswellic acid (KBA) and acetyl-O-11-keto- β -boswellic acid (AKBA) could prevent increase of proinflammatory cytokines in the blood, insulinitis and subsequent hyperglycemia.

Methods: BK+/+ male mice were i.p. injected with 40 mg/kg STZ for 5 days. A second group received 150 mg/kg BE, a third group 15 mg/kg AKBA and a fourth group 7.5 mg/kg KBA simultaneously over a period of 10 days. Infiltration of lymphocytes into pancreatic islets and apoptosis of islet cells were determined histochemically (CD-3 antibodies and anticaspase-3) after day 10. In addition, proinflammatory cytokines were determined in serum. Blood glucose was measured over a period of 35 days.

Cytokines	Controls	STZ	STZ+BE	STZ+AKBA	STZ+KBA
G-CSF	28.44 \pm 3.39	74.816 \pm 12.60***	28.829 \pm 3.47**	8.323 \pm 2.08***	19.3 \pm 3.6***
GM-CSF	0.79 \pm 0.036	2.97 \pm 0.22***	1.610 \pm 0.430**	1.02 \pm 0.01***	1.10 \pm 0.29***
IL-1A	1.89 \pm 0.27	5.18 \pm 0.37***	2.65 \pm 0.38***	1.93 \pm 0.11***	2.04 \pm 0.28***
IL-1B	3.13 \pm 0.6	10.01 \pm 1.06***	4.44 \pm 0.75**	2.33 \pm 0.09***	3.35 \pm 0.56**
IL-2	1.31 \pm 0.19	7.55 \pm 0.84***	2.92 \pm 0.79**	1.16 \pm 0.04***	2.38 \pm 0.51**
IL-6	7.61 \pm 1.55	17.55 \pm 2.61***	8.62 \pm 1.53*	9.28 \pm 0.28**	6.41 \pm 1.22**
TNF- α	1.37 \pm 0.23	3.45 \pm 0.25***	1.31 \pm 0.22***	1.09 \pm 0.08***	1.88 \pm 0.45*
IFN- γ	2.98 \pm 0.96	8.61 \pm 1.55*	2.92 \pm 0.9**	1.95 \pm 0.05**	1.89 \pm 0.33**

Results: 10 days after first STZ injection there was infiltration of lymphocytes into pancreatic islets and appearance of apoptotic cell. Moreover, all tested proinflammatory cytokines in the serum were significantly increased. There was also a continuous increase of blood glucose. Simultaneous i.p. administration of BE, AKBA and KBA significantly reduced cytokines in the serum, infiltration of lymphocytes and apoptosis. After 21 days blood glucose levels showed no increase.

Conclusion: In MLD-STZ-treated mice an extract of the gum resin of Boswellia serrata and two of its constituents i.e. AKBA and KBA prevented development of diabetes probably through their inhibitory action on proinflammatory cytokines.

Reg1 and Reg3 β expression in the pancreas of adult diabetic Goto-Kakizaki rats

M.-H. Giroix¹, S. Calderari², J.-C. Irminger³, J.A. Ehses⁴, J. Coulaud¹, K. Rickenbach³, P. Serradas⁵, F. Homo-Delarche¹;

¹CNRS EAC 4413-BFA Unit, Univ Paris-Diderot, France, ²UMRS 872, Cordeliers Research Center, Paris, France, ³Dept Genetic Medicine and Development, Univ of Geneva, Switzerland, ⁴Dept of Surgery, Faculty of Medicine, Univ British Columbia and Child and Family Res Institute, Vancouver, Canada, ⁵INSERM U505, Univ Pierre et Marie Curie, Paris, France.

Background and aims: Reg protein expression is associated with islet development, β -cell damage, diabetes and pancreatitis. We previously reported that islets of 4-month-old (4-mo) Goto-Kakizaki (GK) rats, a spontaneous model of type 2 diabetes, overexpress Reg1, 3 α , 3 β and 3 γ vs age-matched Wistar control islets. Reg1 and 3 β are involved in cell growth/survival control and inflammation, respectively. Diabetic GK islets also exhibit progressive inflammatory reaction, consisting of high CCL2 (MCP-1), CCL3 (MIP-1 α), CXCL-1 (murine IL-8 analog) and IL-6 expression/release and mostly peri-islet mac-

rophage infiltration. Importantly, Reg1 gene promoters contain IL-6-responsive elements. Here we analyzed in greater detail the pancreatic expression of Reg1 and Reg3 β in diabetic GK rats.

Materials and methods: Isolated pancreatic islets and acinar (exocrine) tissue from male Wistar and GK rats were used for quantitative RT-PCR analysis, normalized with GAPDH. Islet IL-6, CCL2, CCL3 and CXCL1 release was measured by Luminex™ technology after a 48h islet culture on collagen. Pancreatic Reg immunohistochemistry (IHC) was performed on paraffin sections with a rabbit anti-human polyclonal antibody (Ab) and a mouse anti-rat monoclonal anti-Reg1 Ab. Macrophage infiltration was detected on cryostat sections using CD68 and MHC class II antibodies. Islet macrophage⁺ area was quantified and expressed as % of corresponding islet area. Statistical analyses used the Student's t-test for unpaired data.

Results: The exocrine/endocrine ratio of Reg mRNA expression in 4-mo normoglycemic Wistar and diabetic GK rats was: 1) Reg1: 41.3 \pm 2.4 and 5.0 \pm 1.5, respectively (n=3 different isolations/group, p<0.005); 2) Reg3 β : 74.2 \pm 17.0 and 7.0 \pm 4.9, respectively (n=3, p<0.02). Furthermore, Reg1 and 3 β were overexpressed in GK vs Wistar islets (x11.2 \pm 1.4, p<0.005 and 77.9 \pm 16.3, p<0.01, respectively, n=3 in both cases). Next, the polyclonal Reg Ab stained most islet insulin⁺ cells in 4-mo Wistar pancreas but much less so in GK pancreas. By contrast, the monoclonal anti-Reg1 Ab stained just a few peri-islet exocrine cells in Wistar pancreas but many more in GK rats, particularly around large islets. Since IL-6 stimulates Reg1 expression, we compared cytokine/chemokine release by small and large 2.5-mo Wistar and GK islets. Large GK islets released significantly more IL-6 and CCL3 than large Wistar islets (x4.7 \pm 0.9, p<0.02 and 2.7 \pm 0.2, p<0.005, respectively, n=3 in both cases). Concomitantly, CD68⁺ and MHC II⁺ peri-islet macrophage infiltration correlated with islet size in 2.5-mo GK rats (r=0.57 and r=0.95, respectively).

Conclusion: Reg1 and 3 β genes are strongly expressed in the exocrine pancreas of control rats. They are markedly overexpressed in islets of diabetic GK vs control Wistar rats, probably reflecting an adaptive stress response. While the polyclonal Ab mainly stains islet insulin⁺ cells, Reg1 protein is the hallmark of acinar tissue around large GK islets. Its peri-insular localization might result from increased islet release of IL-6 (a factor stimulating Reg1 expression) and is similar to that of macrophage infiltration.

A network based approach for identification of proteins involved in beta cell failure in type 1 diabetes

L.A. Berchtold¹, C. Brorsson², R. Bergholdt¹, F.M. Pociot², J. Størling^{1,2}; ¹Diabetes Inflammation, Hagedorn Research Institute, Copenhagen, Denmark, ²Glostrup Research Institute, Glostrup University Hospital, Denmark.

Background: Type 1 diabetes (T1D) is characterized by absolute insulin deficiency due to immune-mediated destruction of the insulin-producing pancreatic β -cells. Recent T1D genome-wide association studies have established a large number of loci contributing to T1D risk. Most causal genes within these loci are, however, still unknown and need to be identified.

Aim: To predict novel candidate genes/proteins important in T1D pathogenesis by the use of a bioinformatics approach and subsequent experimental *in vitro* validation.

Methods and Results: All positional candidate genes from 44 non-HLA T1D-associated regions were used to generate protein-protein interaction networks using the STRING software. The identified networks were further prioritised by detailed SNP enrichment analysis and expressional profiling in human pancreatic islets exposed to pro-inflammatory cytokines (IL-1 β , IFN γ and TNF α). Three networks consisting of 117 nodes in total were significantly enriched for associated SNPs and transcriptional regulation in human islets. Seventy-two of the 117 proteins could be categorized as either cell membrane- or secreted proteins. Of these, seventeen genes were significantly (p<0.05, n=8) upregulated by more than 1.5-fold or downregulated by at least 0.85-fold by cytokine treatment compared to baseline. Further expressional profiling substantiated that 14 of these genes are also expressed and differentially regulated upon cytokine stimulation in both primary rat islets and in the rat beta-cell line INS-1. These genes included the chemokines CXCL9, CXCL10 and CXCL11 and several cytokines such as IL15 and IL18, and the membrane bound proteins CXCR7, CD83 and CD276.

Conclusion: We have by an unbiased integrative network approach identified 14 proteins appearing in disease networks of type 1 diabetes which potentially play important roles in the failure of beta-cells. Most of the identified genes are known as immune genes, however, we show here that these genes are expressed and differentially regulated in a beta-cell line. Functional char-

acterization studies of these proteins in beta-cells and islets will establish the potential impacts on beta-cell failure.

PTBP1 and translation of diabetogenic viruses in beta cells

K.-P. Knoch¹, C. Wegbrod¹, M. Beck¹, A. Friedrich¹, M. Roivainen², M. Solimena¹;

¹Molecular Diabetology, Paul Langerhans Institute, Medical School "Carl Gustav Carus", Technical University Dresden, Germany, ²THL, National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: Glucose entry in the pancreatic beta cell triggers insulin secretion and the rapid biosynthesis of insulin granules (ISGs). We have shown that glucose and cAMP independently promote the nucleocytoplasmic translocation of polypyrimidine tract-binding protein-1 (PTBP1) in beta cells. Cytosolic PTBP1 binds the mRNAs encoding ISG proteins, thus enhancing their stability and translation. PTBP1 can also foster the IRES-mediated translation of picornaviruses, including enteroviruses. Several prospective studies have suggested that enterovirus infection may trigger type 1 diabetes. Thus, we investigated whether diabetogenic enteroviruses hijack the machinery for ISG biogenesis, and in particular PTBP1, for their effective propagation in beta cells.

Materials and methods: We used two different strains of Echovirus 9 (EV-9) to investigate whether PTBP1 is involved in the viral translation, the diabetogenic EV-9 DM and EV-9 Barty isolated from a nondiabetogenic child. We performed *in vitro* RNA binding assay and dual luciferase reporter assay as well as direct infection of INS-1 cells after knockdown of PTBP1.

Results: We could show that PTBP1 binds to the 5'-UTR of the diabetogenic EV-9 DM. The 5'-UTR of EV-9 DM is more efficient in promoting translation than the 5'-UTR of the non-diabetogenic EV-9 Barty. We found that glucose stimulation of insulinoma cells increases the translation of EV-9 DM in a PTBP1-dependent fashion.

Conclusion: Taken together, our findings support the hypothesis that diabetogenic enteroviruses exploit PTBP1 for their translation in beta cells, and thus may affect the biosynthesis of ISG components.

Endoplasmic reticulum stress precedes diabetes and its associated changes in differentiation and inflammation in db/db mouse islets

D.R. Laybutt, J.Y. Chan;

Garvan Institute of Medical Research, Sydney, Australia.

Background and aims: Type 2 diabetes (T2D) is accompanied by the dysfunction and destruction of pancreatic β -cells. This is associated with a loss of the unique expression pattern of genes that maintain β -cell differentiation and optimise glucose-stimulated insulin secretion (GSIS). Endoplasmic reticulum (ER) stress and inflammation have been proposed as potential mechanisms. However the temporal changes and the significance of these responses in the genesis or progression of T2D remain unknown. Here, we investigated the time-dependent gene expression changes in islets of db/db mice during their progression to diabetes.

Materials and methods: Pre-diabetic (5–6 weeks of age) and obese diabetic (12 weeks of age and above) db/db mice and age-matched db/+ (control) mice were studied. Glucose tolerance was assessed using i. p. glucose tolerance test. Islets were isolated and RNA extracted for gene expression analysis by real-time PCR.

Results: Pre-diabetic db/db mice displayed increased body weight and glucose intolerance compared to control mice. The most striking changes in gene expression in pre-diabetic db/db mouse islets were the highly elevated mRNA levels of multiple ER stress-inducible unfolded protein response (UPR) genes (spliced Xbp1, Atf4, Bip, Edem1, Erp72, Fkbp11, Grp94, p58, and Herpud1). Interestingly, the expression of most of these genes declined in diabetic db/db mice (with the exceptions being Edem1 and Herpud1 that are involved in ER-associated degradation). This suggests that the UPR may be maximally activated prior to the onset of diabetes in db/db mice. In contrast, expression of metabolic and secretagogue receptor genes were either unchanged (mGPR40, GPR40 and Gpr1r) or modestly reduced (Glut2, PC and Gpr) in pre-diabetic mice, whereas they were markedly reduced in diabetic mice. Similar patterns of time-dependent reductions in gene expression were observed for several transcription factors important for the maintenance of β -cell differentiation (Beta2, MafA, Nkx6.1 and Pdx1). On the other hand, anti-oxidant (Catalase, GPx and HO-1) and inflammation (Fas, Gro-1, IL-1 β , IL-6, Lipocalin2 and TNF α) genes displayed time-dependent increases in expression. Interestingly, the expression of a gene capable of inhibiting differentiation, Id1 was significantly increased prior to diabetes onset, and remained elevated in diabetic mice.

Conclusion: These data indicate that maximal changes in ER stress gene expression precede diabetes in db/db mice. In contrast, the major reductions in the β -cell differentiation genes accompany diabetes, as do the increases in inflammatory and oxidative stress gene expression. These findings suggest that ER stress is an early event in the maladaptation of β -cells during the progression to T2D and that the UPR may play a role in the loss of β -cell differentiation.

The islet inflammation and fibrosis precede structural and functional abnormalities of the pancreatic islets in obese diabetic db/db mice

M. Shimoda, Y. Kanda, S. Hamamoto, K. Tawaramoto, M. Hashiramoto, K. Kaku;

Division of Diabetes, Endocrinology and Metabolism, Kawasaki Medical School, Kurashiki, Okayama, Japan.

Background and aims: The BKS.Cg- $Lepr^{db}/+$ $Lepr^{db}/Jcl$ (db/db) mice develop severe hyperglycemia with marked insulin resistance and limited capacity of insulin secretion. On the other hand, the B6.V- $Lepr^{ob}/J$ (ob/ob) mice with a similar genetic background do not present severe hyperglycemia because of a compensatory hypersecretion of insulin. Previously, we demonstrated that the islet fibrosis is more significant in db/db mice than in ob/ob mice with the comparable islet function at an early stage of life. In this study, to further clarify the molecular mechanism that induces the pancreatic islet dysfunction in db/db mice, we compared a comprehensive gene expression profiles, function and structure in db/db with those in ob/ob mice.

Materials and methods: The pancreatic tissue sections and isolated islets from male db/db and ob/ob mice at the age of 6 weeks, when pancreatic islet function and structure were comparable, were applied to gene expression analysis by using real time RT-PCR with Sybr Green. Gene expression was quantified by the comparative Ct method with each result corrected by 18S rRNA quantity. The immunohistochemical analyses by using anti-F4/80, cluster of differentiation (CD)4 and CD8a monoclonal antibody were studied to reveal the degree of infiltration of inflammatory cell into the islets. To confirm the remaining of leptin signal in db/db mouse islets, we analyzed inflammatory cytokine-related gene expressions in the isolated islets by addition of recombinant mouse leptin (0, 25, 50, 100 ng/ml). The existence of functional short-form leptin receptor (Ob-Rs) in the islets was assessed by laser capture microdissection method and real time RT-PCR.

Results: The gene expressions associated with inflammatory cytokines and profibrosis were significantly upregulated in db/db compared with ob/ob mice (il1 β : 2.5×10^{-4} vs. 3.3×10^{-5} , tgfb β 1: 3.1×10^{-4} vs. 1.1×10^{-4} , collagen, type 1, α 1 (col1a1): 1.0×10^{-3} vs. 4.9×10^{-5} , collagen, type 3, α 1 (col3a1): 1.0×10^{-3} vs. 8.0×10^{-5}). In contrast, there was no difference in the mRNA level of matrix metalloproteinase 9 (mmp9), which is a type of collagenase, between two mouse strains. Consisted with the result of cd68 gene expression (db/db mice: 5.8×10^{-5} vs. ob/ob mice: 1.7×10^{-5} , $p < 0.05$), F4/80-positive ratio in the islet was higher in db/db than in ob/ob mice ($15.6 \pm 3.1\%$ vs. $7.4 \pm 0.9\%$, $p < 0.05$). The F4/80-positive cells were mainly observed in the mantle area of islets which prone to become fibrosis. Corresponding to the result of cd4 and cd8a gene expressions, both CD4 and CD8a cell positivity in the islet was comparable and very few in two strains of mice. The il1 β , il6 and tgfb β 1 gene expressions in isolated islets were upregulated dose-dependently in db/db mice, as well as in ob/ob mice, by addition of recombinant mouse leptin. The functional Ob-Rs was present in the islet core area mainly containing beta-cells.

Conclusion: The islet inflammation and fibrosis precedes the deterioration of pancreatic islet structure and function in db/db mice by the remaining of leptin signal through the functional Ob-Rs.

FABP5 depletion protects from gluco- and lipotoxicity in beta cells

K.S. Zien, M. Vaidya, G. Dharmadhikari, F. Paroni, K. Maedler;

Centre for Biomolecular Interactions, University of Bremen, Germany.

Background and aims: Fatty acid binding proteins (FABPs) facilitate the uptake, transport and metabolism of fatty acids within the aquatic environment of the cell. FABP5 (mal1, E-FABP) was previously reported to be expressed in rat islets and in the β -cell line INS1E of rat origin. Subsequently, we asked the question if FABP5 is also expressed in human and mouse islets and whether it regulates β -cell survival and function.

Material and methods: β -cell survival and function was monitored using double-staining for TUNEL and insulin and by glucose stimulated insulin secretion assays on isolated islets from FABP5-/- and wildtype mice at high fat/ high glucose diet (HFD) for 16 weeks. In another set of experiments, islets were treated with high levels of glucose (22.2 mM), palmitate (0.5 mM) or a mixture of IL-1 β (1 μ l/ml) and INF γ (1000 U/ml) for three days. These conditions were also applied to the human β -cell line CM9 and the rat β -cell line INS1E. FABP5 was silenced using siRNA and survival was analyzed by Western Blotting.

Results: FABP5 was expressed in human and mouse islets. Oppositely to previous reports in rats, FABP5 expression was restricted to α -cells. Since FABP5 is known to mediate the inflammatory response in macrophages, we exposed isolated islets from FABP5-/- and wildtype mice to a pro-diabetic milieu. While 3-day exposure of wildtype mice to elevated glucose concentrations, palmitate and the cytokine mix increased β -cell apoptosis (3.6-, 7.5- and 10-fold, respectively) and impaired glucose stimulated insulin secretion (1.4-, 1.8- and 2.1-fold, respectively). FABP5-/- islets were not affected by the treatments. No differences between FABP5-/- and wildtype islets were observed in control islets. After feeding FABP5-/- and wildtype mice a HFD for 16 weeks, islets were isolated and β -cell survival was analyzed. FABP5 -/- mice showed a 47% reduction in apoptotic β -cells compared to wildtype mice ($p < 0.05$). While FABP5 in mouse and human islets was only expressed in α -cells, the human CM9 and rat INS1E insulinoma β -cell lines expressed FABP5. 2-day treatment of both cell lines with elevated glucose, palmitate or the cytokine mixture induced cleavage of PARP and Caspase in control cells, in contrast silencing of FABP5 using siRNA prevented such effects, indicating improved survival in FABP5 depleted cells.

Conclusion: Our data show that depletion of FABP5 improved β -cell function and survival under diabetogenic conditions. This was mediated either di-

rectly in the β -cell in cell lines or by the crosstalk of α - and β -cells in isolated islets. Since we found FABP5 expressed in α -cells these results suggest a role of this lipid chaperon in α -/ β -cell interactions during diabetes progression.

Palmitoleate levels and palmitate-induced lipotoxicity in beta cells

V. Dejana¹, J. Staaf¹, K. Ubhayasekera², A. Forslund³, P. Bergsten¹;
¹Medical Cell Biology, ²Physical and Analytical Chemistry, ³Women's and Children's Health, Uppsala, Sweden.

Background and aims: Type 2 diabetes mellitus (T2DM) develops as a consequence of deteriorating β -cell function and insulin resistance. Chronically elevated levels of free fatty acids are known to affect the β -cells and thereby contribute to the pathogenesis of obesity-related T2DM. In vitro different effects of long-chain saturated and monounsaturated fatty acids on β -cell function have been described. Palmitate (C16:0) mediates lipotoxic effects including inducing β -cell apoptosis and impairing secretory function, whereas palmitoleate (C16:1) has been connected with cytoprotection. Indeed, when the two fatty acids were combined the negative effects of palmitate (PA) were counteracted by the addition of palmitoleate (PO). The aims of the present study were to determine PO/PA ratios in young individuals belonging to the Uppsala Longitudinal Study of Childhood Obesity (ULSCO) and in lean controls and use the values obtained for in vitro experiments. Finally we wanted to compare the effects of the fatty acids on β -cell function in vitro with the in vivo findings.

Material and methods: Fasting blood samples were obtained from 40 obese children, belonging to the ULSCO, and 13 lean controls. The children were 3 to 17 years old. All were normoglycemic. PO and PA levels were quantified by GS/MS. Insulin-producing cell lines MIN6 and INS-1E were treated with the same concentration of PA (0.25 mM) for 24 hours. To investigate the cytoprotective effect of PO, the monounsaturated fatty acid was added together with PA at three different ratios of PO/PA (1:2, 1:5, 1:10). Thus, concentrations of PO were 0.125, 0.05 and 0.025 mM, respectively. Glucose-stimulated insulin secretion (GSIS) was conducted after 24 hours. Secreted insulin was quantified by ELISA and normalized to DNA.

Results: In obese subjects belonging to ULSCO the ratio of PO/PA ranged from 1:2 to 1:10 with a mean ratio of 1:5. Interestingly, similar ratios between the fatty acids were determined in lean control subjects. When cells were cultured with the different PO/PA ratios the highest ratio between the fatty acids maintained a favorable secretory function in comparison to cells cultured at the same PA concentration but with lower levels of PO. After 24 hours treatment, cells cultured with the highest PO/PA ratio had low levels of basal insulin secretion and accentuated response to high glucose. In cells cultured with the lower ratios of PO/PA less difference between basal and stimulated insulin secretion was observed.

Conclusion: PO/PA ratios are not significantly different in obese subjects compared to lean. The cytoprotective effects of a high PO/PA ratio on β -cell function demonstrated in vitro, should be interpreted with caution with regard to implications for development of β -cell dysfunction in young obese subjects.

Ceramide generation pathways in palmitate-induced beta cell dysfunction and apoptosis

L. Manukyan, K. Thorn, O. Krantz, P. Bergsten;
Department of Medical Cell Biology, Uppsala University, Sweden.

Background and aims: During development of type 2 diabetes mellitus high blood lipid levels in combination with hyperglycaemia lead to beta-cell dysfunction and apoptosis. One of the proposed mechanisms of how free fatty acids negatively affect the beta-cell is change in the metabolism of sphingolipids leading to increased generation of ceramide. The sphingolipid metabolites play important roles in the regulation of cell proliferation and survival but also cell death. Whereas ceramide inhibits proliferation and promotes apoptosis, other sphingolipids promote proliferation and are anti-apoptotic. Ceramide can be generated by de novo synthesis by adding palmitate to L-serine catalyzed by serine palmitoyltransferase (SPT). Additional pathways of ceramide generation include hydrolysis of membrane sphingomyelin by sphingomyelinases (SMases) and conversion of sphingosine by ceramide synthetases (CerS). In conditions with elevated fatty acid levels such as obesity

ceramide formation may significantly influence beta-cell fate. The aim of the study was to determine what pathway(s) of ceramide synthesis contribute to beta-cell dysfunction and apoptosis in cells exposed to palmitate.

Materials and methods: Insulin-secreting mouse insulinoma (MIN6) cells were cultured for 48 hours in the absence or presence of 0.25 mM palmitate. Ceramide generation was inhibited by ISP-1 (SPT), GW4869 (SMases) and Fumonisin B1 (CerS), which were included or not during culture. After culture, apoptosis and glucose-stimulated insulin secretion (GSIS) were determined by ELISA, and ceramide levels by thin layer chromatography.

Results: Prolonged exposure of MIN6 cells to palmitate resulted in rise in total ceramide levels and an almost 3-fold increase ($P < 0.05$) in apoptosis. Cells exposed to palmitate had lowered GSIS compared to control cells. Inhibition of ceramide de novo synthesis by ISP-1 had no effect on either apoptosis or GSIS in palmitate-treated cells. The level of ceramide was decreased, however. Suppression of sphingosine conversion to ceramide by Fumonisin B1 decreased palmitate-induced apoptosis by 33% and lowered ceramide levels. Despite these effects no improvement in GSIS, in comparison to palmitate-treated cells, was observed. Ceramide generation from sphingomyelin in palmitate-treated MIN6 cells was inhibited by GW4869. The level of apoptosis was decreased by 29% compared to palmitate alone and ceramide levels were decreased. Again, these positive effects did not improve the impaired GSIS observed in cells treated with palmitate. Finally, when Fumonisin B1 and GW4869 were delivered together to palmitate-treated cells, apoptosis level was decreased by 46% and almost normalised. Also, ceramide amounts were substantially lowered. Despite this effective way of counteracting ceramide build-up the combined administration was not able to improve the insulin secretory characteristics.

Conclusion: Palmitate is inducing ceramide production in beta-cells via primarily sphingomyelin cleavage and conversion of sphingosine. Whereas ceramide synthesis seems to play a major role in palmitate-induced beta-cell apoptosis, it has no effect on restoring the impairments in the insulin secretory machinery induced by the fatty acid.

Transgenic mice with beta cell-specific p8 overexpression preserve insulin secretory function under high fat diet-induced lipotoxic beta cell stress

G. Páth, I.H. Pilz, P.J. Feilen, B. Dufner, N. Rimmer, M. Alt, J. Seufert;
Endocrinology & Diabetology - Research Lab B9, University Hospital Freiburg, Germany.

Background and aims: The intracellular protein p8 is acutely induced by pancreatitis and protects exocrine acinar tissue from inflammatory damage. Within the endocrine pancreas, own previous work has demonstrated in vitro that p8 is a glucose-induced mediator of beta cell proliferation and reduces STZ-induced beta cell apoptosis in an acute and transient manner. Here we investigated transgenic mice with pancreatic beta cell-specific p8 overexpression under basal conditions and high fat diet (HFD)-induced lipotoxicity.

Materials and methods: C57Bl/6NcrJ transgenic (tg) mice with beta cell-specific p8 overexpression were generated by pro-nucleus injection of a rat insulin promoter I driven p8 expression cassette. Tg mice and wt littermates were fed with normal and HFD chow for 10 weeks. Then unfasted serum insulin levels were measured and insulin function was tested by intraperitoneal glucose tolerance test (ipGTT) and insulin tolerance test (ipITT). Weight and blood were measured weekly. After experiments pancreases were removed for analysis of beta cell mass.

Results: Basal characterisation - 14 week old tg mice display about 5 fold (median) enhanced p8 gene expression in whole pancreas but not in other organs tested so far (liver, kidney). This confirms beta cell-specific expression of ectopic p8. Tg mice have a tendency to gain more weight but this is only significant in normal diet fed animals at week 10 when weight of tg animals comes close to that of HFD fed wt mice (27 vs. 28.5 g). No differences were observed between non-fasted blood glucose levels of tg vs. wt mice. Functional characterisation - Wt and tg mice do not differ regarding glucose tolerance (ipGTT), insulin resistance (ipITT) and non-fasted serum insulin. Upon HFD both wt and tg animals develop insulin resistance with substantially elevated non-fasted insulin levels. Tg mice demonstrate significantly enhanced glucose tolerance which is associated with enhanced beta cell mass. We expect that differences in beta cell mass, actually $p = 0.5688$ ($n = 5$) will become significant after analysis of the remaining mice.

Conclusion: Endogenous p8 is a beta cell proliferative and protective protein that is acutely upregulated upon beta cell injury in vivo. Transgenic beta cell specific overexpression of p8 improves insulin secretory function in response

to HFD-induced lipotoxic beta cell stress. p8 may represent a switch protein linking glucose-induced proliferation with anti-apoptotic signalling upon cellular stress.

Excessive food intake, obesity and inflammation process in Zucker fa/fa rat pancreatic islets

M. Chentouf, F. Castex, A.-D. Lajoix, R. Gross, S. Peraldi-Roux;
CNRS FRE 3400, CPID, Montpellier, France.

Background and aims: Inappropriate food intake-related obesity and more importantly, visceral adiposity, are major risk factors for the onset of type 2 diabetes. Evidence is emerging that nutrient-induced β -cell dysfunction could be related to indirect induction of a state of low grade inflammation. Our aim was to study whether hyperphagia associated obesity could promote an inflammatory response in pancreatic islets leading to β -cell dysfunction.

Materials and methods: In the hyperphagic obese insulin resistant male Zucker rat, we measured the level of circulating pro-inflammatory cytokines by Chemiarray rat cytokine kit from Chemicon, and Bio-Plex assay (Bio-Rad, Hercules) and estimated their production as well as the expression of their receptors in pancreatic β -cells using qPCR and immunofluorescence staining. Then, to get insight into the mechanisms involved in phenotypic alterations, Panorama antibody microarray (abArrays) (Sigma-Aldrich) were used to determine the expression profile of proteins implicated in different membrane receptors signaling, apoptosis, cell cycle, cytoskeleton, nuclear signaling, neurobiology. Finally, we have studied the effect of an exposure to IL-1 β of fa/fa and fa/+ rat islets on insulin release and β cells apoptosis.

Results: Our main findings concern intra-islet pro-inflammatory cytokines from fa/fa rats: IL-1 β , IL-6 and TNF α expressions were increased; IL-1R1 was also over-expressed with a cellular redistribution also observed for IL-6R. Ab Array analysis had showed that despite JNK overexpression, cell viability was unaffected probably because of decreases in cleaved caspase3 as well as in SMAC/DIABLO and APP, involved in the induction and amplification of apoptosis. Concerning β -cell proliferation, decreases in important cell cycle regulators (Cyclin D1, p35) and increased expression of SMAD4 probably contribute to counteract and restrain hyperplasia in fa/fa rat islets. Finally and probably as a result of IL-1 β and IL-1R1 increased expressions with sub-cellular redistribution of the receptor, islets from fa/fa rats were found more sensitive to both stimulating and inhibitory concentrations of the cytokine; this confers some physiopathological relevance to a possible autocrine regulation of β -cell function by IL-1 β .

Conclusion: These results support the hypothesis that pancreatic islets from prediabetic fa/fa rats undergo an inflammatory process. That the latter could contribute to β -cell hyperactivity/ proliferation and possibly lead to progressive β -cell failure in these animals, deserves further investigations.

Epigenetic and functional alterations induced by palmitate in the insulin-secreting clonal beta cell line INS-1 832/13

S. Malmgren, C.L.F. Nagorny, P. Spégel, C. Ling, H. Mulder;
Department of Clinical Sciences in Malmö, Lund University, Sweden.

Background and aims: Type 2 diabetes is caused by a combination of insufficient insulin release and insulin resistance in target tissues. Adiposity and high levels of circulating free fatty acids (FFAs) are associated with Type 2 Diabetes and beta-cell dysfunction such as impaired insulin secretion. The cellular mechanisms behind the perturbations of insulin secretion induced by lipotoxicity are of yet not fully understood. Previous studies have revealed an intricate relationship between epigenetic modifications and gene expression in human islets. We aim to examine the link between epigenetic marks, gene expression and beta-cell function and in lipotoxic beta-cells.

Materials and methods: The clonal beta-cell line INS-1 832/13, exposed to 0.5 mM Palmitate for 48h, was used to evaluate the effect of lipotoxicity on insulin secretion, oxygen consumption rate (OCR), gene expression and histone modifications. To assess gene expression and histone modifications, TaqMan real-time PCR with gene-specific probes, histone acetyltransferases (HAT) and histone deacetylases (HDAC) activity assays and ChIP for 3 histone marks (activating marks H3Ac and H3K4me3 and closing mark H3K27me3) were used.

Results: Exposure to 0.5 mM palmitate significantly decreased insulin secretion evoked by 16.7 mM glucose in INS-1 832/13 beta-cells ($p=0.046$). While 16.7 mM of glucose increased the OCR 1.36 fold in control cells, an 1.08-fold increase in OCR was generated after 1h in cells exposed to palmitate ($p<0.05$). HAT activity was elevated 5-fold ($p=0.01$) in cells exposed to 0.5 mM palmitate compared with control cells while HDAC activity remained unaltered. This suggests that lipotoxicity induces epigenetic changes in the clonal beta-cells. Gene expression was analyzed after exposure to 0.5 mM palmitate. Four genes, three which are previously known to affect beta-cell function, were found to have altered expression on the mRNA level in lipotoxic beta-cells. These genes were also found to be epigenetically regulated by enrichment of the histone modifications H3Ac, H3K4me3 and H3K27me3. Data were obtained from 5 independent experiments and significance was evaluated using students t-test or Wilcoxon signed-rank test. Significance was assumed when $p<0.05$.

Conclusion: Lipotoxicity reduced glucose-stimulated insulin secretion in clonal beta-cells, probably due to metabolic defects. Elevations in HAT activity indicate that lipotoxicity induces epigenetic changes in the clonal beta-cells. Also, the expression and histone mark enrichment of four genes were found to be regulated by lipotoxicity.

449

Involvement of p66Shc in FFA-mediated beta cell death

F. Tortosa¹, A. Natalicchio¹, R. Labarbuta¹, M.R. Orlando¹, A. Leonardini¹, A. Cignarelli¹, R. Ficarella¹, P. Marchetti², S. Perrini¹, L. Laviola¹, F. Giorgino¹;
¹Endocrinology & Metabolism, University of Bari, Italy, ²Endocrinology and Metabolism of Transplantation, AOU, University of Pisa, Italy.

Background and aims: The adaptor protein p66Shc mediates apoptosis and oxidative stress in multiple cell types. Chronically increased free fatty acid (FFA) levels induce beta-cell dysfunction and death, thus contributing to the pathogenesis of type 2 diabetes. The aim of this study was to investigate the potential regulatory effects of FFA on the p66Shc protein in rat insulinoma cells INS-1.

Materials and methods: Expression and phosphorylation levels of intracellular specific signaling molecules were assessed by immunoblotting techniques. Gene expression was evaluated by qRT-PCR. Beta-cell apoptosis was quantified by an ELISA assay evaluating oligosome release into the cytosol. Wild-type p66Shc and mutant p66Shc, in which Ser36 had been replaced by Ala (p66Shc-Ala36), were selectively overexpressed following infection with recombinant adenoviruses.

Results: Exposure of INS-1 cells to 0.5 mM palmitate induced a selective 2- to 3-fold increase in both mRNA and protein levels of p66Shc, evaluated by qRT-PCR and immunoblotting, respectively ($p<0.05$), without affecting the other Shc protein isoforms; furthermore, palmitate enhanced p66Shc phosphorylation on Ser36 ($p<0.05$). The effects on p66Shc were associated with a 2.5-fold increase in cell apoptosis, evaluated by measuring cytosolic oligosomes ($p<0.05$). When INS-1 cells were pretreated with pifithrin- α , an inhibitor of the tumor suppressor protein p53, the palmitate-induced increase in p66Shc expression was completely abrogated ($p<0.05$), suggesting the involvement of p53 in the FFA-p66Shc pathway. INS-1 cells with adenovirus-mediated overexpression of p66Shc (Ad/p66Shc) were next studied. Ad/p66Shc INS-1 cells showed increased rates of basal and palmitate-induced apoptosis, as compared with wild-type or mock-transduced cells ($p<0.05$). p66Shc overexpression was also associated with increased phosphorylation of p66Shc on Ser36, both under basal conditions and following exposure to palmitate ($p<0.05$). By contrast, overexpression of a phosphorylation-defective p66Shc protein, in which Ser36 had been mutated to Ala, did not enhance basal and reduced palmitate-induced apoptosis ($p<0.05$).

Conclusion: The FFA palmitate triggers the p53-mediated upregulation of the p66Shc protein in INS-1 cells. This is associated with increased cell apoptosis, which requires p66Shc phosphorylation on Ser36. Thus, p66Shc acts as a novel signaling intermediate in the FFA-mediated beta-cell damage, and may represent a potential therapeutic target to prevent the deleterious effects of lipotoxicity on pancreatic beta-cells.

PS 022 Stressed out islets: ER stress

450

Zcchc12/Sizn1 is a novel ER stress-responsive gene expressed in the pancreatic beta cell

H. Ishihara, S. Yamaguchi, Y. Otsuka;

Division of Diabetes and Metabolism, Nihon University, Tokyo, Japan.

Background and aims: Recent studies have shown decreased pancreatic β -cell mass to be a common feature of subjects with type 2 diabetes mellitus. Stress-mediated apoptosis is considered as one of the causes of β -cell loss. Especially, pancreatic β -cells are vulnerable to endoplasmic reticulum (ER) stress because of continuous and abundant production of insulin even in the physiological conditions. Therefore, we hypothesized that ER stress response or the unfolded protein response (UPR) in the β -cell could be different from that in other cell types, such as NIH3T3 fibroblasts.

Materials and methods: Microarray analysis was conducted employing RNA extracted from MIN6 β -cells and NIH3T3 fibroblasts exposed to 1.0 μ g/ml tunicamycin for 12 hours. Luciferase reporter assays were used to analyze promoter responsiveness to ER stress inducers. Stable transformants of MIN6 cells expressing shRNA against identified genes were created to explore their functions.

Results: There were many genes differentially expressed in response to the ER stress inducer between MIN6 and NIH3T3 cells. A gene expressed in MIN6 but not in NIH3T3 cells and induced more than two-fold was Zcchc12/Sizn1. Zcchc12 (zinc finger CCHC domain containing 12)/Sizn1 (Smad interacting zinc finger protein 1) is a recently identified transcriptional co-activator in the bone morphogenic protein signaling pathway. We confirmed by northern blot analysis that Zcchc12 mRNA was highly induced by thapsigargin and moderately by tunicamycin in MIN6 cells. We also found 2.5-fold increases in Zcchc12 mRNA levels in WFS1-knockout islets, which suffer from ER stress, as compared to wild-type islets. Northern blot analysis revealed that Zcchc12 is expressed in brain but not other tissues examined. The Zcchc12 gene contains 4 exons and the entire coding sequence is in the 4th exon. The upstream ~2 kbp fragment containing three introns was found to have promoter activity which was increased 2.7 ± 0.6 -fold by 0.5 μ M thapsigargin. The dominant-negative mutant of ATF4 suppressed thapsigargin-induced promoter activation by $72 \pm 14\%$. We also found that ZCCHC12 is located in the nucleus through double nuclear localization signals enriched in basic amino acid residues. Thapsigargin-induced expression of eif4E-binding protein 1, a UPR protein, was lower in MIN6 cell stable transformants expressing shRNA against Zcchc12 mRNA.

Conclusion: We identified the Zcchc12/Sizn1 gene as a novel ER-stress responsive gene expressed in the β -cell. Our data suggest that ZCCHC12 plays a role in modulation of the UPR in this cell type.

451

BIRC proteins provide rheostat control of stress signalling in pancreatic beta cells

B.M. Tan, S.N. Walters, S.T. Grey;

Immunology and Inflammation Program, Garvan Institute of Medical Research, New South Wales, Australia.

Background and aims: TNF- α contributes to the pathogenesis of Type 1 diabetes by impairing pancreatic beta cell function and causing beta cell apoptosis. How TNF- α directs these processes remains to be elucidated. Baculoviral Inhibitor of Apoptosis Repeat Containing (BIRC) proteins are shown to be associated with the TNF signaling pathways and may play a role in regulating apoptosis. This study aims to elucidate the role of BIRC proteins in pancreatic beta cells.

Materials and methods: BIRC mRNA expression was analysed by microarray and quantitative RT-PCR. All transfection experiments were performed in MIN6 pancreatic beta cells. The BIRC3 proximal promoter and the BIRC3 expression construct were cloned according to reference sequences from GenBank. For cytokine treatment, MIN6 and primary mouse and human islets were stimulated with TNF- α (200 U/mL) for 4 h. To block transcription, cells were pre-treated with 1 μ M Actinomycin D for 1 h. In silico BIRC3 promoter analysis was conducted using PROMO 3.0. For in situ promoter analysis, transfected cells were measured by luciferase assay. To block nuclear factor- κ B (NF- κ B) activation, cells were pre-treated with 50 μ M PDTC for 1 h. Western blotting was employed to study NF- κ B signaling in primary islets

of knockout mice (BIRC2^{-/-} and BIRC3^{-/-} and BIRC2^{-/-}BIRC3^{-/-} (DKO) mice) by measuring phosphorylated and total I κ Ba levels.

Results: Following ligation of TNF receptor, we found BIRC3 but not BIRC1, 2, 4-6 to be induced in MIN6 cells and in primary mouse and human islets. Blockade of gene transcription prevented TNF- α -induced BIRC3 expression (>80%, $p < 0.01$). Analysis of the BIRC3 promoter revealed 3 putative NF- κ B and an AP-1 binding sites. The BIRC3 proximal promoter region was inducible by TNF- α (2-fold, $p < 0.05$). Thus NF- κ B is a major regulator of BIRC3 transcription. Over-expression of BIRC3 induced activation of an NF- κ B reporter (~2-fold, $p < 0.05$) in MIN6 cells. Further, BIRC3 potentiated TNF- α -induced NF- κ B activation by 8-fold, $p < 0.001$. Contrary to other cell types, BIRC3^{-/-} islets showed normal NF- κ B activation. Some data show BIRC2 is able to compensate for loss of BIRC3. Therefore DKO mice were generated. We found DKO islets were still able to activate TNF- α -mediated NF- κ B signaling. These data suggest that BIRC2 and BIRC3 are not essential for TNF- α -mediated NF- κ B signaling in islet cells. However, BIRC2 and BIRC3 did show unexpected phenotypes independent of NF- κ B. BIRC2^{-/-} islets exhibited increased basal mRNA expression of CCL2 and CXCL10 ($p < 0.01$), as well as increased TNF- α -stimulated ICAM-1 and CCL2 mRNA expression ($p < 0.001$). In contrast, BIRC3^{-/-} islets showed reduced TNF-stimulated CCL2 and CXCL10 mRNA expression ($p < 0.01$).

Conclusion: Our data highlights the complex roles BIRC proteins play in islet stress signaling. On the one hand BIRC3 potentiates NF- κ B when increased but on the other BIRC3 is not necessary per se for TNF- α activation of NF- κ B. Further, in the absence of BIRC2 or BIRC3, expression of CCL2, CXCL10 and ICAM-1 are dysregulated. These data present the novel insight that BIRC2 and BIRC3 provide rheostat control of inflammatory pathways in islet cells.

Implication of SERCA3 Ca²⁺ channel in protective losartan effects from glucotoxic ER and oxidative stress on human pancreatic islets and MIN6B1 beta cells

R. Cassel, S. Dubois, Y. Pan, A. Mesnier, C. Thivolet, A.-M. Madec;

Faculté de médecine Lyon Sud, CarMeN Inserm U1060, Oullins Cedex, France.

Background and aims: Chronic high glucose concentrations increases glucose metabolism through oxidative phosphorylation. This causes mitochondrial dysfunction and excess of reactive oxygen species (ROS) in beta-cells, due to their low levels of ROS-detoxifying enzymes. Beta-cells present a developed ER in order to answer to high demand for synthesis of insulin. Recent data suggest that ER stress is present in human beta-cells and that this could be a common mechanism for the two major pathophysiological events in type 2 diabetes: insulin resistance and beta-cell failure. Prospective studies show a significant reduction in the risk of type 2 diabetes after blockade of the renin angiotensin system (RAS). Since RAS has been found in pancreatic islets, we hypothesized that these beneficial effects could be attributed to direct actions on islets. Our present study evaluates the effects of the angiotensin II receptor blocker Losartan on stress induced by glucose, and its potential implication on specific ER Ca²⁺ release channels, in human islets and in murine MIN6B1 beta-cells.

Materials and methods: Human islets from 8 distinct donors and MIN6B1 cells were studied following culture in presence of 5.5 mmol/l and 16.7 mmol/l glucose concentrations with or without 5 μ mol/l Losartan during the last 48 hrs. ER stress-related mRNA, Caspase-3, and Serca3 mRNA were detected by real-time RT-PCR, insulin secretion by IRMA. ROS levels were determined by measuring DCF oxidation. Mitochondrial human beta-cell morphology was analysed by electron microscopy.

Results: In human islets, chronic high glucose exposure reduced acute glucose-induced insulin secretion by 50% compared to 5.5 mmol/l glucose ($p < 0.05$). Losartan restored this response ($p < 0.05$). Chronic exposure to glucose up-regulated ROS levels by 60% ($p = 0.02$), and reversed by half with Losartan. Quantitative electron microscopy analysis revealed swollen beta-cell mitochondria with high glucose condition (size: 701 ± 144 vs. 405 ± 100 ; $p < 0.0001$), with inner membrane disruption and abnormal cristae. Losartan dramatically improved mitochondrial morphology and reduced mitochondrial size (701 ± 144 vs. 405 ± 143 ; $p < 0.0001$). GRP78, spliced XBP-1, and ATF4 mRNA expressions increased with high glucose concentration ($x_{2.2} p < 0.01$, $x_{1.5} p < 0.009$, $x_{2} p < 0.05$ respectively). The expression of CHOP, an ER stress marker of apoptosis, remained the same, but caspase-3 mRNA

clearly increased ($x2.2$; $p=0.03$). Addition of Losartan to 16.7 mmol/l glucose medium reduced significantly ER stress marker's expression: GRP78 mRNA by 55% ($p<0.01$), XBP-1s mRNA by 51% ($p<0.02$), ATF4 by 54% ($p<0.05$), and apoptose marker Caspase-3 mRNA by 43% ($p=0.02$) as compared to high glucose condition alone. Chronic exposure to glucose up-regulated Serca3 mRNA expression by 180% ($p=0.026$) and Losartan reversed this effect by 33% ($p=0.04$). In MIN6B1 cells, GRP78, spliced XBP-1, CHOP, and ATF4, Serca3 were increased in high glucose condition ($x1.3$, $x8.3$, $x1.3$, $x2.3$, $x1.3$ respectively). Losartan reversed these effects.

Conclusion: Chronic high glucose exposure of human islets and murine beta-cells increases oxidative and ER stress. Blockade of RAS protects them against ER and oxidative stress, prolongs beta-cell integrity, and modulates ER Ca^{2+} release channels. These findings may have important therapeutic consequences both for prevention of type 2 diabetes and islet transplantation. *Supported by: Centaure*

The role of the ubiquitin-proteasome system in type 2 diabetes beta cell dysfunction

M. Bugliani¹, L. Marselli¹, M. Suleiman¹, R. Liechti², H. Cheon³, F. Filippini¹, U. Boggi¹, M. Lee³, I. Xenarios², P. Marchetti¹;

¹University of Pisa, Pisa, Italy, ²Swiss Institute of Bioinformatics, Lausanne, Switzerland, ³Samsung Biomedical Center, Seoul, Republic of Korea.

Background and aims: Beta cell failure plays a fundamental role in the onset and progression of type 2 diabetes (T2D). Recent evidences in cell lines and rodent models suggest that the ubiquitin-proteasome system (UPS), a major intracellular degradative system, may be involved in the regulation of beta cell function and turnover. Limited information is however available on the UPS in beta cells of human T2D subjects.

Materials and methods: We studied islet preparations from 16 T2D and 25 Ctrl individuals with similar clinical characteristics. Gene expression was evaluated by microarray analysis (Affymetrix Human HG U133A) and quantitative RT-PCR of selected genes. Ubiquitinated proteins were assessed by immunohistochemistry and proteasome activity (trypsin-like) was measured by a luminescent assay. The direct effect of a proteasome inhibitor (MG132), 0.5 mmol/l palmitate and 2.4 µg/ml metformin was also assessed.

Results: Microarray analysis showed that 63 genes involved in the UPS were differently expressed in T2D islets (4 upregulated, 59 down regulated). When quantitative RT-PCR experiments of selected genes were performed significant upregulation of SAE-1 (of the ubiquitin-activating enzyme family E1) and significant downregulation of UBE2K (of the ubiquitin-conjugating enzyme family E2), UCHL1 (a de-ubiquitinating enzyme) and PSMB7 (proteasomal subunit with trypsin-like activity) were demonstrated in T2D samples. Immunohistochemistry revealed the presence of ubiquitinated proteins in beta cells, and proteasome activity was reduced in the diabetic islets (4364±1975 vs 8748±4238 RLU/ng DNA, $p<0.02$). MG132 suppressed proteasome activity of Ctrl HI by 80–90% ($p<0.01$), which was associated with lower glucose-stimulated insulin secretion (45±7% of untreated islets, $p<0.01$). In addition, 24 h exposure to palmitate reduced proteasome activity by 20%, which again was related with lower insulin release. T2D islets pre-exposed (24 h) to metformin showed increased proteasome activity (+35%), which was accompanied by improved glucose-stimulated insulin secretion.

Conclusion: These results show the importance of UPS alterations as a possible mechanism associated to beta cell dysfunction in human T2D, and propose that some of these changes may be corrected pharmacologically.

Metabolic stress-induced beta cell failure contributes to diabetes in Friedreich's ataxia

M. Igoillo-Esteve¹, Y. Serroukh¹, M. Rai², C. Depondt², A. Begu³, A.E. Musuaya¹, L. Ladrère¹, F. Moore¹, P. Marchetti⁴, M. Pandolfo², D.L. Eizirik¹, F. Féry³, M. Cnop^{1,3};

¹Laboratory of Experimental Medicine, Université Libre de Bruxelles, Belgium, ²Laboratory of Experimental Neurology, Université Libre de Bruxelles, Belgium, ³Division of Endocrinology, Erasmus Hospital, Brussels, Belgium, ⁴Department of Endocrinology and Metabolism, Metabolic Unit, University of Pisa, Italy.

Background and aims: Friedreich's ataxia (FA) is an autosomal recessive neurodegenerative disease caused by a GAA trinucleotide repeat expansion

in the first intron of the frataxin (Fxn) gene leading to a 60–90 % reduction in the mitochondrial protein Fxn. FA patients have a high prevalence of impaired glucose tolerance (IGT) and diabetes. Our aims were to study the relative contribution of insulin resistance and beta-cell failure and the pathogenic mechanisms involved in FA diabetes.

Materials and methods: 41 FA patients and 53 controls underwent oral and IV glucose tolerance tests (GTT). Insulin sensitivity index (SI) and acute insulin response to glucose (AIRg) were used to calculate the disposition index (DI). In vitro and in vivo disease models were used to study the impact of Fxn deficiency on beta-cell function and survival. Male Fxn-deficient mice (KIKO) underwent IP insulin (ITT) and GTT after 3 and 6 months on regular (RD) or high fat diet (HFD). KIKO and wild type (WT) beta-cells were examined by electron microscopy (EM). Fxn was knocked down by siRNA (siFxn) in clonal INS-1E cells, primary rat beta-cells and dispersed human islets. Beta-cell apoptosis was examined by Hoechst 33342/propidium iodide staining 24h after exposure to oleate (0.5 mmol/l, OL) or the endoplasmic reticulum (ER) stressors cyclopiazonic acid (25 µmol/l, CPA), tunicamycin (5 µg/ml, TU) or brefeldin A (0.1 µg/ml, BR), alone or in combination with the adenylate cyclase stimulator forskolin (20 µmol/l, FK).

Results: 50% of the FA patients had IGT and 10% diabetes, compared to 29% IGT and no diabetes in controls. FA patients were insulin resistant (SI 17 ± 2 vs $25\pm2 \times 10^{-5} \text{ min}^{-1}/(\mu\text{U/ml})$, $p<0.01$) and this was not compensated for by increased AIRg, resulting in a markedly reduced DI (FA 862 ± 156 vs controls $1507\pm169 \times 10^{-5} \text{ min}^{-1}$, $p<0.01$) indicating beta-cell failure. KIKO mice were also insulin resistant (ITT after 3 months on RD: area above glycemic curve 37 ± 8 vs 66 ± 6 in WT, $p<0.05$), and developed impaired beta-cell function after 6 months on HFD. Beta-cells from KIKO mice had clear ER dilation, as evaluated by EM, indicating ER stress. Fxn knockdown increased apoptosis in rat beta-cells ($10\pm1\%$ apoptosis for siFxn vs $8\pm1\%$ for control siRNA (siCT), $n=6$, $p<0.05$) and dispersed human islets ($27\pm1\%$ for siFxn vs $16\pm2\%$ for siCT, $n=4$, $p<0.01$). Fxn knockdown also sensitized INS-1E cells to OL- and ER stress-induced apoptosis (OL $20\pm2\%$ for siFxn vs $13\pm3\%$ for siCT, $n=6$, $p<0.01$; CPA $48\pm2\%$, TUN $25\pm3\%$, BR $37\pm2\%$ apoptosis for siFxn vs, respectively, $38\pm3\%$, $19\pm2\%$, and $22\pm4\%$ for siCT, $n=4$, $p<0.05$). FK treatment partially prevented OL- and ER stress-induced apoptosis in Fxn-deficient beta-cells (OL+FK $13\pm4\%$ apoptosis vs OL $19\pm4\%$, $n=8$, $p<0.01$; TUN+FK $9\pm2\%$ apoptosis vs TUN $27\pm2\%$, $n=3$, $p<0.01$).

Conclusion: Beta-cell dysfunction plays a key role for IGT and diabetes in FA patients. In line with these clinical findings, KIKO mice develop beta-cell failure after high fat feeding. This may be due to metabolic stress-induced beta-cell apoptosis, a process that seems to be mediated by ER stress. Inducers of cAMP have a protective role and may have therapeutic potential.

GLP-1 exerts a protective role in pancreatic beta cells with WFS1-deficiency

S. Yamaguchi¹, Y. Tanji¹, Y. Oka¹, H. Ishihara²;

¹Division of Molecular Metabolism and Diabetes, Tohoku University Graduate School of Medicine, Sendai, ²Division of Diabetes and Metabolism, Nihon University School of Medicine, Tokyo, Japan.

Background and aims: Recent development of incretin-based drugs demonstrates promising outcomes for treatment of type 2 diabetes. However, mechanisms whereby incretin hormones exert their effects on pancreatic β -cell failure are not fully understood. We investigated whether GLP-1 improves glucose homeostasis and β -cell failure under endoplasmic reticulum (ER) stress, which is now accepted as one of the causes of β -cell failure, commonly observed in type 2 diabetes.

Materials and methods: MIN6 cell viability was analyzed under the treatment with pharmacological ER stress inducers, thapsigargin (ER calcium pump inhibitor) and tunicamycin (N-glycosylation inhibitor) in the presence or absence of GLP-1 (100 nM) for 36 hours. In addition, mRNAs of several ER stress-related proteins and apoptosis-related proteins were analyzed by a semi-quantitative PCR analysis in MIN6 cells exposed to thapsigargin in the presence or absence of GLP-1. To further clarify the protective role of GLP-1 under ER stress in β -cells, vildagliptin (50 mg/kg), a DPP-4 inhibitor, was orally administrated twice a day to WFS1-knockout ($Wfs1^{-/-}$) mice, a mouse model of genetically defined human diabetes caused by ER stress in β -cells.

Results: GLP-1 increased cellular viability under ER stress induced by acute treatment with thapsigargin or tunicamycin in MIN6WT cells. We also found that thapsigargin-mediated induction of caspase-3 mRNA, a hallmark of apoptosis, was suppressed by GLP-1. Treatment of GLP-1 significantly sup-

pressed thapsigargin-induced mRNA levels of spliced XBP-1 and ATF4 with tendency toward reduction in GRP78 mRNA expression in MIN6WT cells. Wfs1^{-/-} mice at 9 weeks of age, which were given vildagliptin for 4 weeks, showed no change in blood glucose as compared with vehicle-treated Wfs1^{-/-} mice. However, an intraperitoneal glucose tolerance test showed improved glucose tolerance in vildagliptin-treated Wfs1^{-/-} mice with increased glucose responsiveness of insulin secretion. Moreover, vildagliptin-treatment significantly increased pancreatic insulin contents by 32% in Wfs1^{-/-} mice, and the effect was blocked by additional administration of the GLP-1 antagonist, exendin (9-39). Electronmicroscopic studies revealed that vildagliptin reduced cell numbers of β -cells with swollen ER in Wfs1^{-/-} mice.

Conclusion: The results in vitro suggested that GLP-1 ameliorated ER stress, resulting in less induction of three pathways of the UPR and improved cellular viability. Moreover, the protective role of GLP-1 against ER stress on β -cell was confirmed in Wfs1^{-/-} mice. Recent studies indicated sequence variants in WFS1 gene confer risk of type 2 diabetes. Thus, our results strengthen the mechanistic rational of using this drug for the treatment of type 2 diabetes.

Glucose-induced changes in mitochondrial redox status in rat pancreatic beta cells

L.P. Roma¹, J. Duprez¹, H.K. Takahashi¹, A. Wiederkehr², J.-C. Jonas¹;

¹Pole of Endocrinology, Diabetes and Nutrition, Université catholique de Louvain, Brussels, Belgium, ²Department of Cell Physiology and Metabolism, University Medical Center, Geneva, Switzerland.

Background and aims: Measuring reactive oxygen species (ROS) in living cells often relies on the use of fluorescent probes (hydroethidine, dichlorodihydrofluorescein). Besides their photosensitivity and low selectivity, these tools do not allow studying ROS production in subcellular compartments. Using new redox-sensitive ratiometric fluorescent proteins (FP) could overcome these technical limitations. HyPer, derived from OxyR and circularly permuted Yellow FP, is sensitive to H₂O₂. roGFPs, derived from Green FP, monitor changes in thiol/disulfide ratio (e.g. the GSH/GSSG ratio). Possible pH sensitivity of these probes may prevent their use in beta cells, for cytosolic and mitochondrial pH are affected by nutrients. In this study, we tested the adequacy of mitochondria targeted HyPer (mt-HyPer) and roGFP1 (mt-roGFP) to monitor glucose-induced changes in mitochondrial redox status in rat beta cells.

Materials and methods: Rat islet cell clusters were infected with an adenovirus coding mt-HyPer or mt-roGFP (CMV promoter driven), or the mitochondrial pH sensor mtAlpHi (under the control of the rat insulin promoter). Cell clusters were perfused with Krebs buffer (pH 7.4) containing 1 mg/ml BSA and gassed with O₂:CO₂ (94:6). Fluorescence at 535 nm was measured every 30s during excitation at 480/400 nm for mt-roGFP, 420/495 nm for mt-HyPer and 490 nm for mtAlpHi.

Results: Two days after adenoviral infection, mt-HyPer and mt-roGFP were expressed and correctly localized in the mitochondria of most beta cells within clusters. During perfusion with 10 mM glucose, mt-HyPer and mt-roGFP fluorescence ratios were stable. As expected, addition of 100 μ M H₂O₂ rapidly increased both ratios 2 to 3-fold, attesting the ability of these probes to sense H₂O₂. Unfortunately, mt-HyPer was highly pH sensitive: its fluorescence ratio rapidly decreased upon acidification with 30 mM Na⁺-acetate and increased upon alkalinisation with 30 mM NH₄Cl. Consistently, mitochondrial metabolism affected mt-HyPer and mtAlpHi signals similarly: an increase upon acute glucose stimulation from 2 to 10 mM that plateaued between 10 and 30 mM glucose, a transient increase followed by a slow decrease upon glucose reduction from 10 to 2 mM, and a rapid and reversible decrease upon addition of 3 mM azide to 10 mM glucose. In contrast, mt-roGFP fluorescence ratio was not affected by NH₄Cl or azide and responded differently upon changes in glucose metabolism. Thus, mt-roGFP signal increased upon glucose reduction from 10 to 2 mM and decreased upon return to 10 mM glucose. The signal was unaffected by a rise in glucose from 10 to 30 mM. Importantly, the increase by low glucose was abrogated by the catalytic antioxidant Mn(III) tetrakis(4-benzoic acid) porphyrin (50 μ M TBAP).

Conclusion: mt-HyPer fluorescence ratio is highly pH-sensitive, thereby preventing its use as a reliable indicator of glucose-induced changes in mitochondrial H₂O₂ in beta cells. In contrast, mt-roGFP1 fluorescence ratio is pH-insensitive and adequately monitors changes in mitochondrial redox status. Our results also show that low glucose rather than high glucose triggers mitochondrial oxidative stress in rat beta cells.

Wfs1 deficiency impairs glucose metabolism and induces XBP1(s) gene expression levels in mice with a diabetes related phenotype

K. Douroudis^{1,2}, E. Prans¹, M. Ivask¹, T. Visnapuu¹, E. Vasar^{1,2}, S. Köks^{1,2};

¹Department of Physiology, ²Centre of Translational Medicine, University of Tartu, Estonia.

Background and aims: Wfs1 gene encodes for an endoplasmic reticulum stress (ER) membrane protein and its deficiency causes Wolfram syndrome, which is associated with diabetes mellitus and optical atrophy. ER stress plays an important role in the pathogenesis of diabetes, contributing to β -cell loss and insulin resistance. The X-box binding protein 1 (XBP1) is a transcription factor and a key regulator in the unfolded protein response (UPR). The aim of the present study was to evaluate the impact of Wfs1 deficiency on hyperglycaemia in mice and to determine the relative expression levels of XBP1 spliced (s) gene in liver and kidney tissue.

Materials and methods: Wfs1 deficient mice were generated by invalidating the 8th exon of the Wfs1 gene. The study included 23 male mice [(129S6/SvEvTac \times 129S6/SvEvTac) \times (129S6/SvEvTac \times 129S6/SvEvTac)] assigned to three subgroups: Wfs1^{+/+} (WT, n=5), Wfs1^{+/-} (HZ, n=9) and Wfs1^{-/-} (KO, n=9). Breeding and genotype analysis of mice were carried out in the Department of Physiology, University of Tartu. Insulin plasma measurements, intraperitoneal glucose tolerance test (ipGTT) (2g/Kg) following fasting for 14 hours, non-fasting blood glucose and the XBP1 spliced gene expression levels in liver and kidney tissues have been analyzed. Data analysis performed using the Wilcoxon test and linear regression analysis was applied where appropriate. A p value of <0.05 was considered significant for all analyses.

Results: The ipGTT showed that the blood glucose levels on 60 min after glucose administration, were significantly higher in Wfs1KO mice when compared to Wfs1HZ (p=0.0039) and Wfs1WT (p=0.041) mice, respectively. The non-fasting glucose levels also found to be significantly higher in Wfs1KO mice when compared to Wfs1HZ (p=0.0046) and Wfs1WT (p=0.027) mice, respectively. The insulin plasma levels found to be significantly higher in the group of Wfs1HZ mice when compared to the group of Wfs1KO (p=0.00008) and Wfs1WT (p=0.041) mice, respectively. The expression of the XBP1(s) gene in liver tissue was found to be significantly higher in both the Wfs1HZ (OR=1.06, p=0.024) and Wfs1KO (OR=1.06, p=0.22) group when compared to the Wfs1WT group. Moreover, the XBP1(s) gene expression analysis in kidney tissue showed that the XBP1(s) levels were significantly higher in the group of Wfs1HZ mice (OR=1.08, p=0.012) in comparison to the Wfs1WT group.

Conclusion: Wfs1 deficiency increases blood glucose levels in Wfs1KO mice and induces the expression of XBP1(s) gene in liver tissue. A better knowledge on the protein homeostasis regulated by the ER signaling pathways and the Wfs1 gene with their interactions to β -cell biology will have a direct impact on future therapies for diabetes.

Characterisation of three novel human insulin-releasing pancreatic beta cell lines produced by electrofusion

J.T. McCluskey¹, M. Hamid¹, H. Guo Parke¹, N.H. McClenaghan¹, R. Gomis², P.R. Flatt¹;

¹School of Biomedical Sciences, University of Ulster, Coleraine, UK,

²IDIBAPS, Barcelona University, Spain.

Background and aims: Three novel human insulin releasing cell lines designated 1.1B4, 1.4E7 and 1.1E7 were generated by electrofusion of freshly isolated of human pancreatic beta cells and the immortal human PANC-1 epithelial cell line. This study aimed to characterize the in vitro and in vivo function of these 3 novel human beta cell lines.

Materials and methods: Dispersed human islet cells and PANC-1 cells were electrofused and hybrid colonies were selected and cloned for high insulin output. Insulin secretion in acute 60min test incubations and insulin content was measured by radioimmunoassay. Expression of key human beta cell genes and proteins were examined by RTPCR, Western blot and immunofluorescence. Measurements were made of enzyme activity, metabolism of glucose by radioactive scintillation counting and FLEXstation™ analysis of $[Ca^{2+}]_i$. In vivo analysis was carried out after subcapsular implantation of the 1.1B4 cell line in streptozotocin-diabetic immunocompromised SCID mice.

Results: 1.1B4 cells exhibited a stepwise 2.3-fold insulin-secretory response over the range 0–16.7mM glucose. Both 1.4E7 and 1.1E7 cells showed a maximal 1.6 and 1.5-fold secretory responses to 5.6mM and 11.1mM glucose respectively. Inclusion of 200uM IBMX significantly increased secretory responses by 20–100% ($p < 0.001$). Leucine, alanine, arginine (all 20mM), tolbutamide (200uM), glibenclamide (100uM), GLP-1, GIP or CCK-8 (all 10^{-9} M) significantly stimulated insulin release by 1.1–1.4 fold in each of the 3 cell lines ($p < 0.05$ – $p < 0.001$). Inhibitors, 400uM diazoxide, 20uM verapamil or Ca^{2+} chelation with EGTA significantly reduced insulin release from the cell lines by 20–50% ($p < 0.01$ – $p < 0.001$), 20–40% ($p < 0.05$ – $p < 0.001$) and 20–40% ($p < 0.01$ – $p < 0.001$) respectively. Cellular insulin content at passage 17 was measured as 3.5 ± 0.2 , 3.6 ± 0.2 and 3.9 ± 0.2 ng/ 10^6 cells, for 1.1E7, 1.4E7 and 1.1B4 respectively. Immunohistochemistry revealed the presence of human specific insulin, proinsulin and C-peptide in 1.1B4 cells and intact human proinsulin was detected in all 3 beta cell lines with proinsulin:insulin ratios of approximately 1:20. Western blot, RT-PCR and immunohistochemistry showed expression of the major genes involved in proinsulin processing and the pancreatic beta cell stimulus-secretion pathway including PC1/3, PC2, GLUT-1, glucokinase, K-ATP channel complex (Sur1 and Kir6.2) and the voltage-dependent L-type Ca^{2+} channel. Analysis of metabolic function showed that all 3 cell lines exhibited significantly higher ($p < 0.01$ – $p < 0.001$) glucokinase and lower ($p < 0.01$ – $p < 0.001$) hexokinase activity compared to parental PANC-1 cells with 1.1B4 and 1.4E7 showing significant increases ($p < 0.05$) in glucose oxidation rates at 1.1–16.7mM glucose compared to parental PANC-1. Acute exposure to 16.7mM glucose, 20mM alanine or depolarizing concentrations of 30mM K^+ were all able to significantly increase $[Ca^{2+}]_i$ ($p < 0.001$, $p < 0.05$ – $p < 0.001$ and $p < 0.001$, respectively). Streptozotocin-diabetic SCID mice implanted subcapsularly with 5×10^6 1.1B4 cells exhibited time-dependent decrease of hyperglycaemia and improved glucose tolerance.

Conclusion: These novel cell lines exhibit stable characteristics reminiscent of normal beta cells, thereby providing an unlimited source of human insulin producing cells for biochemical studies and pharmacological drug testing

Bile acids affect the function of murine pancreatic beta cells

K. Hörth, P. Krippeit-Drews, M. Düfer, G. Drews;
Pharmacology, Toxicology and Clinical Pharmacy, Institute of Pharmacy,
Tübingen, Germany.

Background and aims: Bile acids (BAs) play an important role in digestion and cholesterol metabolism but also function as signalling molecules in several metabolic pathways. In the liver BAs affect insulin action and interfere with glucose homeostasis. The aim of the study was to test whether BAs influence stimulus-secretion coupling in pancreatic beta-cells.

Materials and methods: Ion currents and the membrane potential (V_m) of mouse beta-cells were measured with the patch-clamp technique, cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) by fura-2 and insulin secretion by RIA.

Results: Taurochenodeoxycholic acid (TCDC) increased $[Ca^{2+}]_i$ ($n=9$, $p < 0.05$) in physiological concentrations (500 nM) due to Ca^{2+} influx through L-type Ca^{2+} channels which resulted in enhanced glucose-induced insulin secretion (GIIS) ($n=7$, $p < 0.05$). The stimulatory action of TCDC was due to changes in glucose-induced electrical activity. The fraction of plateau phase (FOPP), i.e. the percentage of time with spike activity, increased from 27.3 ± 4.4 % to 44.3 ± 6.0 % in the presence of 5 μ M TCDC ($n=7$, $p < 0.01$). At a threshold glucose concentration (6 mM) TCDC (10 μ M) depolarized V_m and action potentials appeared ($n=8$, $p < 0.001$). The underlying depolarisation was evoked by closure of K_{ATP} channels ($n=9$, $p < 0.001$). However, in excised inside/out patches TCDC had no effect ($n=11$). Therefore, TCDC-induced depolarization seems to require cytosolic components. It is known that BAs interact with several receptors including the nuclear farnesoid X receptor (FXR) that is involved in the regulation of glucose and energy homeostasis. The specific FXR agonist GW4064 mimicked the effects of TCDC on stimulus-secretion coupling in the same concentration range. GW4064 depolarized V_m ($n=5$, $p < 0.01$), triggered Ca^{2+} influx and enhanced GIIS ($n=10$, $p < 0.05$). In contrast, ursodeoxycholate (UDC) that had a much lower affinity to FXR than TCDC did not change $[Ca^{2+}]_i$ ($n=7$). Islets of FXR-KO mice did not show any increase in insulin secretion with TCDC ($n=6$). Likewise, all effects could be suppressed by the FXR antagonist guggulsterone. These results indicate that FXR activation is indispensable for the stimulatory effects of TCDC. In islets of SUR1-KO mice lacking functional K_{ATP} channels TCDC did not alter GIIS ($n=8$) suggesting that FXR activation influences K_{ATP} channel activity.

Conclusion: The results provide evidence for a novel link between FXR activation and inhibition of K_{ATP} channels. BA signalling in beta-cells may constitute a further connection between food intake and the control of insulin secretion and may give rise to a new pharmacological approach to interfere with beta-cell stimulus-secretion coupling.

The bile acids TGR5 receptor regulates insulin secretion through stimulation of pancreatic δ -cells somatostatin release

B. Lefebvre, G. Queniat, V. Gmyr, V. Pawlowski, J. Kerr-Conte, F. Pattou;
Biotherapies of Diabetes, University Lille Nord de France, France.

Background and aims: The bile acids G protein-coupled receptor TGR5 controls energy expenditure in brown adipose tissue and skeletal muscle as well as GLP-1 secretion in the gastro-intestinal tract by L-cells. We addressed whether TGR5 is expressed in human pancreatic islets and whether it is involved in insulin secretory function.

Materials and methods: Experiments were realized on human pancreata and on isolated islet of Langerhans ($n=12$, mean age= 53.3 ± 4.0), pancreas were procured from brain-dead non-diabetic ($n=8$, mean HbA1C= 5.7 ± 0.1) and diabetic ($n=4$, mean HbA1C= 8.2 ± 1.1). TGR5 expression was analyzed by immunohistochemistry, western-blot and QPCR. Functional parameters were studied (insulin content, acute insulin release in response to glucose stimulation, somatostatin release) on isolated islets in presence or absence of 3-(2-Chlorophenyl)-N-(4-Chlorophenyl)-N,5-dimethylisoxazole-4-carboxamide a specific TGR5 agonist.

Results: TGR5 was detected in pancreatic islets and localized specifically on δ -cells. In addition, we found a three fold higher expression of TGR5 in diabetic islets correlated with an increased number of δ -cells (30%). Basal insulin was not affected by addition of TGR5 agonist (50 μ M) to human islets culture medium with 2.8mmol/l glucose concentration. However, we show an increase (25%) in somatostatin release and potent inhibition of Glucose Stimulated-Insulin secretion (20mmol/l glucose concentration) led to significant decreases (30%) of stimulated insulin release.

Conclusion: TGR5 is a new player in the control of the Glucose Stimulated-Insulin release through control of somatostatin release. Altogether, these data identify a new role for bile acids and TGR5 in the regulation of glucose homeostasis directly in pancreatic islet cells.

Insulin stimulation leads to oscillatory interactions between insulin receptor B-type and PI3K-C2α or Shc in pancreatic beta cells

T. Moede, B. Leibiger, P.-O. Berggren, I.B. Leibiger;

Dept. Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: It has been shown that stimulation of glucokinase and c-fos gene transcription by insulin in pancreatic beta cells requires the activation of the insulin receptor B-type (IR-B) and signaling through PI-3-kinase C2α (C2α) or Shc respectively. The activation of c-fos gene transcription is dependent on clathrin mediated IR-B-endocytosis and on the C-terminal YTHM-motif, while glucokinase gene activation is generated from membrane standing IR-B requiring an intact juxtamembrane NPEY-motif. However it remains unclear whether and how these two signaling cascades are interrelated. Temporal analysis of the interaction of IR-B with either Shc or C2α after insulin stimulation by FRET-analysis in combination with mutations in the insulin receptor is used as a tool to investigate this question.

Materials and methods: MIN6 cells were grown on coverglasses and transfected with IR-B-Venus or its respective mutants and CFP- C2α or CFP-Shc. 48h post transfection, cells were pre-incubated in medium containing 2 mM glucose for 6 h and stimulated with 5mU/ml insulin for up to 10 min. Cells were fixed with 3% PFA in PBS in 1 min intervals post stimulation. FRET-analysis by acceptor photobleaching using confocal microscopy was performed for 10 cells per timepoint and condition. FRET-efficiency (Ef) was calculated by the following formula: (CFP-Intensity after bleaching - CFP-intensity before bleaching)/CFP-intensity before bleaching.

Results: Interaction of IR-B with either C2α or Shc changed after insulin stimulation in an oscillatory manner. Interaction of IR-B and Shc started with a high Ef of 0.213 ± 0.023 and oscillated with a period of 4 min (minimum -0.009 ± 0.021 at 10 min, maximum 0.259 ± 0.023 at 4 min). In contrast, IR-B and C2α interaction started with a low Ef of 0.046 ± 0.016 . FRET efficiency here also oscillated with a period of 4 min (minimum -0.035 ± 0.013 at 8 min, maximum 0.225 ± 0.23 at 10 min), but phase-shifted by 0.5 periods towards the oscillations of the interaction of IR-B and Shc. Mutation of the juxtamembrane NPEY motif to NPEA abolished both interaction of C2α with IR-B and the changes triggered by insulin. It lead to an increase in Ef for IR-B-Shc interaction (0.465 ± 0.031 unstimulated) and slower oscillations after stimulation (period 6 min, minimum 0.288 ± 0.012 , maximum 0.492 ± 0.033) on a higher baseline. Mutation of the C-terminal YTHM motif to FTHM abolished Shc-IR-B interaction. The oscillatory interaction between this mutant and C2α was still present (starting at 0.059 ± 0.022), albeit slower (Period 6 min, minimum 0.059 ± 0.022 at 0 min, maximum 0.238 ± 0.022 at 3 min).

Conclusion: Interaction between IR-B and C2α or Shc after insulin stimulation occurs in an oscillatory manner. The oscillations of IR-B/ C2α and IR-B/ Shc interaction are antiparallel towards each other suggesting that the same receptor might activate both signaling cascades sequentially. Mutation of the two motifs YTHM or NPEY abolishes the interaction of either Shc or C2α respectively, but does not lead to an abolishment of oscillation of the interaction of IR-B with the other protein per se, but to change in period and amplitude of oscillation. These data suggest that binding of either Shc or C2α is not a pre-requisite of IR-B interaction with the other binding partner.

Tigerinin-1R from the skin secretions of Vietnamese frog *hoplobatrachus rugulosus* exerts potent insulinotropic effects both *in vitro* and *in vivo*Y.H.A. Abdel-Wahab¹, O.O. Ojo¹, P.R. Flatt¹, J. Michael Conlon²;¹School of Biomedical Sciences, University of Ulster, Coleraine, Northern Ireland, UK, ²Department of Biochemistry, Faculty of Medicine and Health Sciences, Al-Ain, United Arab Emirates.

Background and aims: Frog skin represents a valuable source of biologically active peptides that have potential for development into therapeutic agents. Studies have shown that several peptides from frog skin, first identified on the basis of antimicrobial activity, stimulate the release of insulin from pancreatic beta cells at non-cytotoxic concentrations. This study investigated the effects of a 12 amino-acid-residue cyclic, C-terminally α-amidated peptide termed tigerinin-1R (Arg-Val-Cys-Ser-Ala-Ile-Pro- Leu -Pro-Ile-Cys-His. NH₂), isolated from an extract of the skin of the Vietnamese frog *Hoplo-*

batrachus rugulosus (Dicroglossidae), on insulin secretion both *in vitro* and *in vivo*.

Materials and methods: Insulin-releasing effects of tigerinin-1R were studied using the glucose-responsive clonal pancreatic cell line, BRIN-BD11, while effects on glucose tolerance were investigated in high fat fed insulin resistant Swiss TO mice. Acute insulin-release studies were performed in Krebs Ringer bicarbonate buffer supplemented with 5.6mM or 16.7mM glucose in the absence (control) or presence of the synthetic forms of the peptide (0 - 3μM) and various known modulators of insulin secretion. Insulin release was measured by radioimmunoassay while membrane potential and intracellular calcium ([Ca²⁺]) were both determined by fluorometric assay using FLEXstationTM.

Results: At 5.6mM glucose, tigerinin-1R stimulated insulin release by 138% at 0.01nM ($P < 0.01$) with a maximum response at 3μM of 410 % above basal (4.10 ± 0.40 ng/10⁶ cells/20min; $P < 0.001$). At 16.7mM glucose, tigerinin-1R stimulated insulin secretion by 1.5-3.0-fold over the concentration range 0.03nM - 3μM ($P < 0.05$, $P < 0.001$ respectively). Tigerinin-1R (1μM)-induced insulin release was also enhanced ($P < 0.001$) by 200μM IBMX (2.0-fold at 5.6mM glucose) and 200μM tolbutamide (3.2-fold). At 16.7mM glucose in the presence of 30mM KCl, tigerinin-1R further enhanced ($P < 0.001$) insulin release (1.4-fold). Chelation of extracellular calcium caused a 12 % reduction ($P < 0.001$) in stimulatory effects of tigerinin-1R, whereas 50 μM verapamil decreased insulin release by 26% ($P < 0.001$). At 5.6mM glucose, 1μM tigerinin-1R induced membrane depolarization and significantly increased intracellular calcium (by 3.0 and 2.5-fold, respectively; $P < 0.001$). C-terminal amidation of tigerinin-1R was necessary for effective insulin releasing activity. The free acid form of tigerinin-1R was 10-fold less potent and produced a much lower maximum response (188 % of basal rate, $P < 0.001$). *In vivo*, intra-peritoneal administration of tigerinin-1R (75 nmol/kg body weight) together with 18mmol/kg glucose significantly ($P < 0.05$) enhanced insulin-release (1.7-fold) and improved glucose tolerance by 62% ($n=6$, $P < 0.05$) in mice with diet-induced insulin resistance. *In vitro* tests also showed that tigerinin-1R lacked antimicrobial activity and was non-hemolytic at concentrations up to 400μM.

Conclusion: Tigerinin-1R exerts strong insulinotropic effects on pancreatic beta cells both *in vitro* and *in vivo*. The glucose lowering action of tigerinin-1R encourages further investigation of its longer-term effects in type-2 diabetes.

463

Chronic high glucose and pyruvate levels differentially effect beta cell functionI. Göhring¹, S. Malmgren¹, V.V. Sharoyko¹, D. Nicholls^{1,2}, H. Mulder¹;¹Unit of Molecular Metabolism, Lund University Diabetes Centre, Malmö, Sweden, ²Buck Institute for Age Research, Novato, USA.

Background and aims: Glucose-stimulated insulin secretion is coupled to increased cellular metabolic activity and an increase of the ATP/ADP ratio, leading to plasma membrane depolarization and exocytosis. Prolonged elevated glucose levels are, however, known to impair beta cell function and have been associated to both cytoplasmic and mitochondrial disturbances in glucose metabolism. We investigated whether overstimulation of pancreatic beta cells with high pyruvate is as deleterious as high glucose. This was thought to provide a better understanding of whether triggering factors of glucotoxicity are mainly of mitochondrial or cytoplasmic origin.

Materials and methods: INS-1 832/13 cells were cultured in either 2.8 mM glucose, 16.7 mM glucose or 2.8 mM glucose + 33.4 mM pyruvate for 48 h. Glucose-stimulated insulin secretion and glucose utilization were determined by radioimmunoassay and scintillation counting, respectively. Intracellular metabolite alterations were determined by gas chromatography-mass spectrometry. Plasma and mitochondrial membrane potential changes were determined in real-time, using laser scanning microscopy.

Results: After a 48 h culture in 16.7 mM glucose, glucose-stimulated insulin secretion was significantly suppressed ($p < 0.05$; 28.4 ± 3.3 ng/mg/ml) in comparison to cells cultured at 2.8 mM glucose (83.1 ± 4.2 ng/mg/ml) for 48 h. In addition, the insulin content was decreased by 92%. Furthermore, the mitochondrial membrane hyperpolarization response was greatly impaired. Moreover, the plasma membrane potential response was significantly suppressed (-71.3 ± 0.8 mV) in comparison to control cells, where raising glucose from 2.8 mM to 16.7 mM increased the potential from -80 ± 0.5 mV to -58 ± 4.7 mV. Glucose utilization was increased 1.3 fold by the chronic glucose culture at 16.7 mM. Several glycolytic and mitochondrial metabolites, including pyruvate, lactate and alpha-ketoglutarate, were greatly elevated in the chronic high glucose-treated cells. In contrast, cells cultured for 48 h at 2.8 mM glc +

33.4 mM pyruvate maintained their acute glucose-stimulated insulin secretory response (86.7 ± 8.9 ng/mg/ml), and even released 2.2 times more insulin into the medium than cells exposed to 16.7 mM glucose over the whole 48 h stimulation period. The insulin content of chronic high pyruvate-treated cells was reduced by 40%. However, the mitochondrial membrane was still hyperpolarized in response to 16.7 mM glucose and the plasma membrane potential increased to -61 ± 3.5 mV similarly to control cells.

Conclusion: After chronic high glucose exposure, the insulin secretory response of the beta cells is greatly perturbed. Several factors such as reduced insulin content, altered glucose metabolism and impaired mitochondrial function appear to be involved. However, despite of fuel-overload of mitochondria during cultivation of INS-832/13 cells with supraphysiological pyruvate concentrations, the beta cells remained excitable and maintained their secretory response to glucose. We suggest that extramitochondrial factors, due to perturbed glucose metabolism upstream of pyruvate, largely contribute to a perturbation of fuel-dependent regulation of insulin secretion.

³Endocrinology & Metabolism Service, The Hebrew University-Hadassah Medical Center, Jerusalem, Israel.

Background and aims: Intermittent periods of hyperglycemia activate 'priming' or 'memory' pathways that amplify insulin release from β -cells. This phenomenon may trigger the compensatory and adaptive phases of β -cell function in the early stages of type 2 diabetes. Recently, a role for PPAR δ as a lipid sensor that regulates insulin secretion has been proposed. We addressed the hypothesis that glucose-induced release of polyunsaturated fatty acids (PUFAs) from membrane phospholipids and their subsequent peroxidation generate bioactive lipid mediators that amplify insulin secretion from β -cells in a PPAR δ -dependent manner.

Materials and methods: High glucose-dependent release of fatty acids from β -cell membrane phospholipids was determined by lipidomic analysis. HPLC was used to identify peroxidation products of PUFAs in β -cell cultures. Static and dynamic glucose-stimulated insulin secretion assays were performed on isolated rat pancreatic islets and INS-1E cells. The role of PPAR δ in this process was ascertained with pharmacological agents and by manipulating PPAR δ expression in β -cells, and with a PPAR-Response-Element (PPRE)-dependent transactivation of luciferase gene.

Results: High glucose incubations (24h) activated cPLA2 in INS-1E cells, which consequently released linoleic acid and arachidonic acid from membrane phospholipids. Glucose-derived reactive oxygen species enhanced the non-enzymatic peroxidation of these fatty acids and augmented the generation of the bioactive aldehyde 4-hydroxy-2E-nonenal (4-HNE). Similar to GW501516 (a selective PPAR δ agonist), 4-HNE increased insulin secretion from INS-1E cells and isolated rat islets; these effects were blocked by GSK0660 (a potent PPAR δ antagonist) or by silencing PPAR δ expression. High glucose, GW501516 or 4-HNE markedly induced luciferase activity in INS-1E cells expressing the PPAR δ -PPRE transactivation system.

Conclusion: This study suggests that β -cells respond to high glucose exposures by remodeling membrane phospholipids and releasing PUFAs. Enhanced peroxidation of both linoleic acid and arachidonic acid generates 4-HNE, an endogenous ligand for PPAR δ . The activation of this nuclear receptor then augments insulin secretion in a manner characteristic of the adaptation of β -cells to hyperglycemic episodes.

Novel mechanistic link between focal adhesion remodelling and glucose-stimulated insulin secretion

D. Rondas¹, A. Tomas², P.A. Halban¹

¹Genetic Medicine and Development, ²Biochemistry, University of Geneva, Switzerland.

Background and aims: Actin cytoskeleton remodelling is well known to be positively involved in glucose-stimulated pancreatic beta cell insulin secretion. We have observed glucose-stimulated focal adhesion remodelling at the beta cell surface and have shown this to be crucial for glucose-stimulated insulin secretion (GSIS). However, the mechanistic link between such remodelling and the insulin secretory machinery remained unknown and was the major aim of this study.

Materials and methods: All experiments were performed on MIN6B1 cells posed on 804G matrix (having demonstrated previously that under these conditions MIN6B1 behave similarly to primary beta cells regarding focal adhesion remodelling in response to glucose). For immunoprecipitation and protein phosphorylation, MIN6B1 were incubated for 2h at 0 mM glucose followed by 20 mM glucose for 10 min. RNAi was used to knockdown paxillin expression: cells were transfected (Lipofectamine 2000) 3 days prior to testing GSIS (2 h pre-incubation at 0 mM glucose; 1 h 0 mM glucose (basal); 3–60 min 20 mM glucose (stimulated)).

Results: Total internal reflection fluorescence (TIRF) microscopy revealed the glucose-responsive co-localisation of Focal Adhesion Kinase (FAK) and paxillin with integrin β 1 at the basal cell surface after 10 min of stimulation. Blockade of the interaction between β 1 integrins and the ECM with an anti- β 1 integrin antibody (Ha2/5) inhibited glucose-induced phosphorylation of FAK (Tyr-397), paxillin (Tyr-118) and ERK1/2 (Thr-202/Tyr-204) by 50.7 ± 1.0 ($p < 0.001$), 56.5 ± 5.1 ($p < 0.01$), and $68.3 \pm 11.8\%$ ($p < 0.05$) respectively. A 78.6 ± 5.1 ($p < 0.001$), 86.7 ± 3.3 ($p < 0.0001$) and $42.1 \pm 12.6\%$ ($p < 0.05$) inhibition in glucose-induced phosphorylation of FAK, paxillin and ERK1/2 respectively, was observed when cells were treated with the actin filament stabilizing compound jasplakinolide (5 μ M). Furthermore, both pharmacological inhibition of FAK by compound Y15 (1 μ M) and RNAi-mediated knockdown of paxillin inhibited glucose-induced phosphorylation of ERK1/2 (Thr-202/Tyr-204) and its direct substrate synapsin 1 (Ser-62/Ser-67) coinciding with the inhibition of both early and late phases of GSIS. The t-SNARE SNAP-25 was found in newly formed focal protrusions in close proximity to FAK, paxillin at the extremity of actin fibres. GSIS is known to involve the disassociation SNAP-25 with actin and we postulated that FAK may be involved in this process. This was confirmed by FAK inhibition by compound Y15 that resulted in a $73.3 \pm 24.3\%$ ($p < 0.05$) increase in SNAP-25/actin association (assessed by co-immunoprecipitation) compared to the control glucose-stimulated condition.

Conclusion: We show here that glucose-induced phosphorylation and activation of FAK, paxillin and ERK1/2 in beta cells is mediated by β 1 integrins. Additionally, the data suggest FAK and paxillin to be upstream of glucose-induced actin cytoskeleton remodelling which leads to phosphorylation of ERK1/2 and its substrate synapsin 1, both known to be important in GSIS. FAK activation furthermore liberates SNAP-25 from its association with the actin cytoskeleton, allowing to participate in granule exocytosis. Taken together, these results indicate a novel mechanistic link between focal adhesion remodelling and the insulin secretory machinery in pancreatic beta cells.

Exocytotic release of ATP triggers diacylglycerol spiking in insulin-secreting cells

A. Wuttke, O. Idevall-Hagren, A. Tengholm;

Medical Cell Biology, Uppsala University, Sweden.

Background and aims: The lipid diacylglycerol (DAG) plays an important role in various signaling processes by membrane recruitment and activation of C1-domain-containing proteins, such as different isoforms of protein kinase C (PKC). DAG is generated in the β -cell plasma membrane in response to receptor and nutrient stimuli, and DAG-mediated activation of PKC amplifies insulin secretion. The aim of this study was to characterize the spatio-temporal pattern of DAG signals in β -cells and to clarify the mechanism underlying plasma membrane DAG generation by glucose and depolarizing stimuli.

Materials and methods: A biosensor based on the two adjacent DAG-binding C1 domains of rat protein kinase C γ tagged to green fluorescent protein

(C1aC1b-GFP) was used to monitor DAG in individual living MIN6 β -cell. The probe redistributes to the plasma membrane (PM) upon DAG formation, and this translocation was monitored on-line with confocal or evanescent wave microscopy. A proline in each of the C1 domains (positions 20 and 85) was replaced by glycine to yield a mutant sensor with markedly reduced affinity for DAG.

Results: Confocal imaging of MIN6 β -cells expressing C1aC1b-GFP showed diffuse cytoplasmic fluorescence under basal conditions. The probe redistributed to the plasma membrane in response to 1 μ M of the functional DAG mimetic phorbol myristate acetate. This translocation was detected as a marked increase of PM fluorescence with evanescent wave microscopy. A step increase of the extracellular glucose concentration from 3 to 11 mM triggered pronounced spikes of C1aC1b-GFP translocation with 3–16 s duration ($118 \pm 10\%$ fluorescence increase; $n=33$), occurring either irregularly or in bursts with a frequency of $0.25 \pm 0.1 \text{ min}^{-1}$ ($n=11$). No spiking was observed with the DAG-binding-deficient mutant sensor. Membrane depolarization with 30 mM K^+ induced an immediate increase of PM C1aC1b-GFP fluorescence followed by a decline and brief, high-amplitude spikes similar to those induced by glucose. Ca^{2+} omission prevented C1aC1b-GFP spiking, as did inhibition of exocytosis with 10 μ M adrenaline. Whereas 100 nM insulin had no effect, ATP induced detectable C1aC1b-GFP translocation at concentrations as low as 10 nM. Higher ATP concentrations (0.1–10 μ M) induced a dose-dependent initial rise of C1aC1b-GFP PM fluorescence ($89 \pm 11\%$ maximal fluorescence increase, $n=16$), followed by a decline to a stable plateau. Most of this effect was blocked by 10 μ M of the purinergic P2Y1 receptor antagonist MRS 2179, which also prevented C1aC1b-GFP fluorescence spiking induced by 30 mM K^+ or 11 mM glucose. Similarly, the DAG spiking was reversibly suppressed by exposure to a high ATP concentration (100 μ M) known to desensitize purinoceptors.

Conclusion: Glucose and depolarizing stimuli evoke pronounced DAG spiking in the β -cell plasma membrane. The effect is mediated by autocrine purinoceptor-phospholipase C activation by ATP co-released with insulin from the secretory vesicles. These complex DAG signals should have implications for kinetic control of exocytosis and other cellular functions.

Role of glucose-6-phosphate in regulation of glucose-stimulated gene expression in the pancreatic beta cell line INS-1E

K. Iizuka, Y. Horikawa, R. Tomita, J. Takeda;

Department of Diabetes and Endocrinology, Gifu University, Japan.

Background and aims: In the liver, glucose (Glc) induces expression of glycolytic and lipogenic genes by activating the carbohydrate response element-binding protein (ChREBP). Further, ChREBP is dephosphorylated and activated by protein phosphatase 2A, which in turn is activated by xylulose-5-phosphate, an intermediate metabolite of the pentose phosphate pathway. In pancreatic islets, Glc induces metabolic gene expression in a manner similar to that observed in primary rat hepatocytes; however, pentose phosphate shuttle flux is very low in pancreatic beta cells. In adipocytes, glucose-6-phosphate (G6P) plays an important role in regulation of Glc-stimulated fatty acid synthase gene expression. In this study, we confirm the role of G6P in regulation of Glu-stimulated gene expression in the pancreatic beta cell line INS-1E.

Materials and methods: After a 24-h preincubation in a medium containing 2.5 mM Glc, INS-1E cells were further incubated for 2 h under three different conditions; 2.5 mM Glc, 25 mM Glc and 25 mM 2-deoxyglucose (2DG). 2DG is converted to 2-deoxyglucose-6-phosphate (2DG6P) but is not further metabolized by the glycolytic pathway. The cells were analysed using DNA microarray, TaqMan PCR, ChIP assay and reporter assay.

Results: Using DNA microarray, we observed that expression of 194 known genes changed significantly at a threshold of 2-fold on switching from 2.5 mM Glc to 25 mM Glc conditions. Of these, expression of 62 genes was induced at a threshold of 2-fold under 25 mM 2DG conditions, and the expression of 46 genes remained unchanged or repressed under this condition. Out of these 194 glucose-response genes, 9 genes were previously reported as ChREBP target genes, such as liver-type pyruvate kinase (Lpk) and thioredoxin-interacting protein (Txnip). In contrast, expression of 173 known genes changed at a threshold of 2-fold on switching from 2.5 mM Glc to 25 mM 2DG conditions. Of these, the expression of 25 genes remained unchanged or repressed under 25 mM 2DG conditions. Out of these 173 glucose-response genes, only 2 genes were previously reported as ChREBP target genes, such as Class E basic helix-loop-helix protein 40 (Bhlhe40) and thioredoxin-interacting protein (Txnip). 2DG6P concentration in the medium containing 25 mM 2DG was much higher than G6P concentration in the medium containing 25 mM Glc. The potency of 2DG in inducing Lpk and Txnip mRNA was weaker and less persistent than that of Glc; this result was consistent with that of DNA microarray. Moreover, the reporter assay, which involved the pGL3 promoter with $3 \times$ Lpk and $3 \times$ Txnip ChoRE, and the ChIP assay, which involved the anti-ChREBP antibody, revealed that 2DG does not increase ChREBP transactivity in INS-1E cells. Finally, transfection of siRNA against ChREBP partly inhibited Glc-stimulated, but not 2DG-stimulated, Lpk and Txnip expression.

Conclusion: Compared with Glc, 2DG weakly induces Lpk and Txnip expression without modulating ChREBP transactivity. The role of G6P in Glc regulation of ChREBP target genes appears insignificant.

468

Regulation of core clock genes in human islets

J.A. Stamenkovic¹, A.H. Olsson², C.L.F. Nagorny¹, M. Dekker-Nitert², S. Malmgren¹, J. Taneera¹, C. Ling², H. Mulder¹;

¹Molecular Metabolism, ²Diabetes and Endocrinology, Lund University, Malmö, Sweden.

Background and aim: Recent genome-wide association studies have demonstrated that there is an association between circadian clock function (CRY2) and development of metabolic diseases, such as Type 2 Diabetes. Therefore, we investigated how expression of core CLOCK genes is regulated in human islets from donors suffering from Type 2 Diabetes.

Materials and methods: Islets from human donors were received from the Nordic Center of Islet Transplantation. We had access to islets from 9 patients with Type 2 Diabetes and 57 non-diabetic donors [66 patients; 35 males, 31 females; Age 56 ± 10.7 ; BMI (kg/m^2) 26 ± 3.8 ; HbA1c 5.9 ± 1]. We used the Affymetrix GeneChip® Human Gene 1.0 ST assay following the Affymetrix standard protocol; transcript levels of selected genes were also determined

by qRT-PCR, using Tacman® assays. For analysis of glucotoxic conditions, the glucose medium concentration was kept at either 3.3 or 16.7 mM for 48 h. Lipotoxic conditions were induced by keeping the islets in medium supplemented with 1 mM palmitate complexed to 1% bovine serum albumin for 48 h.

Results: Microarray analysis showed that the core clock genes *CLOCK*, *PER1-3* and *CRY1-2* are expressed in human islets. The mRNA levels of *PER2*, *PER3* and *CRY2* were lower in Type 2 Diabetes donors. To investigate the functional relevance of these *CLOCK* genes, we correlated their expression to insulin secretion (fold change) and HbA1c levels. mRNA levels of *PER2* ($\rho=0.510$; $p=0.001$), *PER3* ($\rho=0.445$; $p=0.005$) and *CRY2* ($\rho=0.881$; $p=0.004$) correlated positively with insulin secretion. Among them, only *PER3* correlated negatively with HbA1c levels ($\rho=-0.345$; $p=0.037$). Furthermore, in vitro induction of pathogenetic conditions (gluco-lipotoxicity), *PER1-3* mRNA levels were reduced in non-diabetic human islets compared to untreated ones ($p=0.003$).

Conclusion: Our data demonstrate that core molecular clock components are being regulated in human islets. In addition, these data suggest that impairment of the circadian clock may be part of the islet pathophysiology of Type 2 Diabetes in humans.

The metabolite profile underlying insulin secretion: involvement of the pentose phosphate pathway in beta cell stimulus-secretion coupling

P. Spégel¹, A.P.H. Danielsson¹, V.V. Sharoyko¹, S. Malmgren¹, C.L.F. Nagorny¹, I. Goehring¹, G.W.G. Sharp², S.G. Straub², C. Wollheim³, T. Koeck¹, H. Mulder¹

¹Lund University Diabetes Center, Unit of Molecular Metabolism, Malmö, Sweden, ²Cornell University, Department of Molecular Medicine, Ithaca, USA, ³University of Geneva, Department of Cell Physiology and Metabolism, Switzerland.

Background and aims: Glucose stimulated insulin secretion is regulated by the triggering pathway (K_{ATP} -dependent) and the amplifying pathway (K_{ATP} -independent). Several metabolites, most of them emanating from mitochondrial metabolism, have been suggested to account for the latter mechanism. Conflicting results from these studies that mainly have focused on single metabolic pathways could be explained by the fact that only part(s) of cellular metabolism has been monitored. Here, we have attempted to characterize metabolic regulation provoked by glucose in a more global and unbiased fashion. Changes were assessed within 15 min after stimulation and correlated with levels of insulin secretion.

Materials and methods: INS-1 832/13 cells were pre-incubated at 2.8 mM glucose for two hours, followed by a 16.7 mM glucose stimulation. Metabolism was subsequently quenched at 0, 3, 6, 10, and 15 min after stimulation. Intracellular metabolites were extracted and analyzed by gas chromatography/time-of-flight mass spectrometry (GC/TOF-MS). In addition, oxygen consumption rate, NADPH/NADP⁺-ratio, static and dynamic insulin secretion was also assessed. Orthogonal projection to latent structures (OPLS) was used to correlate the metabolic profile with the level of insulin secretion.

Results: A clear correlation was observed between changes in the pattern of 195 detected metabolites and the level of insulin secretion. Analysis of this pattern revealed a rapid response in the major metabolic pathways of glucose, involving several previously suggested metabolic coupling factors. The complexity of metabolite changes observed disagreed with the concept of one single metabolite or pathway controlling insulin secretion. Instead, the complex alterations in metabolite levels suggest that a coupling signal should reflect large parts of the β -cell metabolic response. This was fulfilled by the NADPH/NADP⁺-ratio, which was transiently elevated at 6 min after glucose stimulation. Changes in this ratio paralleled the level of ribose 5-phosphate and coincided with rising insulin secretion. Inhibition of the pentose phosphate pathway abolished 15 min insulin secretion and reduced 60 min insulin secretion by 50%.

Conclusion: Our findings support involvement of NADPH and call for a reassessment of the role of the pentose phosphate pathway in β -cell stimulus-secretion coupling.

Key role of AMPK in glucose-evoked Na,K-ATPase modulation

A.C.R. Costa¹, F. Capela e Silva¹, C.M. Antunes², J. Cruz-Morais¹

¹ICAAM - Institute of Mediterranean Agricultural and Environmental Sciences, ²Center of Neuroscience and Cell Biology, University of Évora, Portugal.

Background and aims: Na,K-ATPase is an integral plasma membrane protein responsible for generating and maintaining transmembrane ionic gradients. In pancreatic β -cells, Na,K-ATPase is regulated by glucose and this regulation is impaired in glucose intolerant subjects, however, the underlying mechanism is still unclear. Since glucose has marked effects on intracellular ATP and AMP levels and AMP-activated protein kinase (AMPK), a key player in energy homeostasis providing exquisite sensitivity to small changes in AMP levels, the involvement of AMPK in the cascade of events regulating Na,K-ATPase in pancreatic β -cell was postulated. The aim of this work was to evaluate the putative role of AMPK in the glucose-evoked regulation of Na,K-ATPase activity in the pancreatic β -cell.

Materials and methods: Pancreatic β -cells from normal (control) or glucose-intolerant Wistar rats (GIR) were isolated and cultured (48h). After a pre-incubation (30min) with 2.1mM glucose (G2), cell batches were challenged with G2 or G8 (8.4mM glucose) for 20min, in the presence or absence of AMPK agonist (AICAR 1mM) and antagonist (compound C (CC), 10 μ M). Na,K-ATPase activity was assessed in intact cells by quantification of Pi, in the absence and presence of 1mM ouabain. Immunocytochemistry (ICC) of β -cells treated as previously described was performed using anti- α 1-Na,K-ATPase and anti-phospho(ser-23)- α 1-Na,K-ATPase antibodies. Western blots (WB) were performed in lysates of islets incubated in similar conditions plus AICAR or CC to evaluate α 1-Na,K-ATPase (ser-23) phosphorylation.

Results: In G2 the activity of Na,K-ATPase from control and GIR pancreatic β -cells was similar (0.184 ± 0.030 and 0.186 ± 0.020 μ molPi/min/mgProt, respectively). Challenging the GIR β -cells with G8 evoked a significantly lower inhibition (40%) of Na,K-ATPase activity compared to a 62% inhibition observed in control β -cells. In control β -cell, the addition of AICAR abolished glucose-induced Na,K-ATPase inhibition (0.166 ± 0.011 μ molPi/min/mg) whereas CC had no effect (0.063 ± 0.003 μ molPi/min/mg). In the contrary, in GIR β -cells CC significantly potentiated glucose-evoked inhibition of Na,K-ATPase to values similar to those observed in the controls (66%). WB analysis revealed that Na,K-ATPase- α 1 (ser-23) phosphorylation was increased by G8 (28 \pm 6% over basal) and abolished by AICAR. Additionally, CC induced an increase in phosphorylation equivalent to that observed in G8 (22 \pm 5% over basal). ICC showed an equivalent immunostaining intensity for α 1-Na,K-ATPase despite glucose concentration. However, for the phosphorylated (ser-23) α 1-Na,K-ATPase, a higher intensity was observed in cells exposed to G8 compared to G2.

Conclusions: The AMPK agonist AICAR counteracted the glucose inhibitory action on Na,K-ATPase from control β -cells whereas CC amplified the glucose-induced inhibition of Na,K-ATPase from GIR β -cells. These results suggest that AMPK plays a key role in the cascade of events regulating Na,K-ATPase and that the defect in GIR β -cells must be upstream of AMPK. AMPK inhibition by glucose metabolism and subsequent activation of PKC, phosphorylating Na,K-ATPase in ser23, may constitute steps of the mechanism underlying glucose-induced inhibition of Na,K-ATPase that might be uncoupled in GIR. Occurring prior to overt type 2 diabetes, this might be a feature of the disease development.

Glycogen metabolism in glucose-responsive and -unresponsive beta cells
L.E. Andersson, A. Tamaddon, V.V. Sharoyko, C.L.F. Nagorny, H. Mulder, P. Spégel;
Unit of Molecular Metabolism, Lund University Diabetes Center, Malmö, Sweden.

Background and aims: β -cell metabolism is suggested to be supply-driven to yield a dose-response of glucose-stimulated insulin secretion over a wide range of blood glucose concentrations. As a result, the rate of β -cell glycogen synthesis is assumed to be low. However, an increase in β -cell glycogen accumulation has been observed in type-2 diabetes (T2D). This has been proposed to reflect a pathogenetic role of glycogen metabolism in β -cells. This notwithstanding, no casual relation between glycogen synthesis and T2D has been established. We suggest that glycogen synthesis plays an important role in healthy β -cells and that this function is perturbed in T2D, resulting in excessive glycogen accumulation.

Materials and methods: INS-1 832/13 and INS-1 832/2 clonal β -cells were challenged at varying concentrations of glucose for 48 hours. Protein, mRNA, glycogen and metabolite analyses were performed to assess the regulation of glycogen metabolism and its impact on β -cell metabolism. Glycogen was quantified using a novel method based on gas chromatography/mass spectrometry.

Results: Our data show that glycogen synthase and phosphorylase are expressed at both the mRNA and protein levels in 832/13 β -cells. Furthermore, a dose-response of glycogen accumulation in response to increasing glucose concentrations was obtained. An abrupt increase in glucose concentration caused a fast and continuous accumulation of glycogen, reaching saturated levels already after 6 h. An abrupt drop in glucose concentration, on the other hand, resulted in a slow glycogen catabolism. Levels of glycogen synthase protein were found to decrease with increasing glycogen accumulation. The glucose unresponsive 832/2-cells did not produce glycogen, despite an increased stabilization of hypoxia induced factor 1 α (HIF-1 α). HIF-1 α responds to oxidative stress and has been suggested to be increasingly stabilized in T2D and to result in increased glycogen synthesis.

Conclusion: Our data suggest that glycogen synthesis in the β -cell functions to adjust β -cell metabolism to hypo- and hyperglycemia, the later presumably serving to hinder oxidative stress.

Acute triggering of insulin release concomitant with a decrease in cytosolic free Ca^{2+} concentration by a combination of glucose and cAMP
M. Takei, H. Ishii, S.-I. Nisio, Y. Sato, M. Komatsu;
Aging Medicine and Geriatrics, Graduate School of Medicine, Shinshu University, Matsumoto, Japan.

Background and aims: It is assumed that an elevation of cytosolic free Ca^{2+} concentrations ($[\text{Ca}^{2+}]_i$) is mandatory for triggering insulin secretion in response to glucose, although glucose also exhibit KATP channel-independent amplifying effect on Ca^{2+} -triggered insulin release. Previously, we demonstrated that cAMP synergistically interacts with the KATP channel-

independent glucose action. In this study, we show that glucose can trigger prompt insulin secretion under conditions in which elevation of $[\text{Ca}^{2+}]_i$ is inhibited by the presence of diazoxide, a KATP-channel opener, and nifedipine, a calcium channel blocker.

Materials and methods: By using isolated rat pancreatic islets, we measured insulin release in static incubation and perfusion experiments. All experiments with some exceptions, insulin release was measured in the presence of 250 μM diazoxide and 10 μM nifedipine to inhibit Ca^{2+} -influx and to prevent an acute increase in $[\text{Ca}^{2+}]_i$. Forskolin was used to increase intracellular concentration of cAMP. Temporal profile of $[\text{Ca}^{2+}]_i$ was monitored with fura-2 loaded rat pancreatic beta cells in the presence of diazoxide and nifedipine.

Results: Under regular Ca^{2+} -containing (2.5 mM) conditions, 22 mM glucose stimulated insulin release by 10-fold for 30 minutes. Forskolin (10 μM) doubled insulin release in response to 22 mM glucose. Glucose-stimulated insulin release was abolished in the presence of both diazoxide and nifedipine as expected. In contrast, when forskolin was included during incubation experiments, 22 mM glucose induced a 5-fold increase in insulin release even in the presence of both diazoxide and nifedipine. This glucose effects is dependent on the presence of extracellular Ca^{2+} , because removal of Ca^{2+} from buffer deteriorated glucose action. These results suggest that glucose-induced Ca^{2+} -influx is not required for insulin release under the presence of diazoxide and nifedipine, but ambient Ca^{2+} is critical for it. Perfusion experiments revealed that 22 mM glucose increased the rate of insulin release within 2 minutes and peaked at 6 minutes after the stimulation followed by gradually increasing level of insulin secretion. The temporal profile of $[\text{Ca}^{2+}]_i$ changes are quite different from that of insulin release. Upon the stimulation with glucose, $[\text{Ca}^{2+}]_i$ sharply went down within 3 minutes. Thereafter, it went up almost lineally. The $[\text{Ca}^{2+}]_i$ level was kept at higher than basal level after 10 minutes of stimulation. Alpha-KIC (20 mM), a metabolizable nutrient, mimics glucose effect under the same condition. Metabolic inhibition of glucose by 2 mM NaN_3 strongly inhibited glucose effect. Cerulenin, an inhibitor of protein acylation, also inhibited glucose-induced insulin release in the presence of forskolin, nifedipine and diazoxide in a concentration-dependent manner.

Conclusion: Our results show that glucose and cAMP can trigger insulin release even when the KATP channel was forced to open and the voltage-dependent Ca^{2+} channel was closed. The effect was occurred concomitant decrease in $[\text{Ca}^{2+}]_i$. Glucose metabolism is required for the effects and protein acylation might be a responsible mechanism for triggering insulin release. A possible reason for extracellular Ca^{2+} dependency is that ambient Ca^{2+} concentration beneath the plasma membrane has permissive role for the triggering of insulin release.

Glucose regulates free cytosolic Zn^{2+} concentrations by altering Slc39a and metallothionein gene expression in mouse pancreatic beta cells

E.A. Bellomo, G. Meur, G.A. Rutter;
Section of Cell Biology, Division of Diabetes, Endocrinology and Metabolism, Department of Medicine, Imperial College London, UK.

Background and aims: Zn^{2+} is an important cofactor for insulin biosynthesis and storage in pancreatic β -cells. Conversely, elevated intracellular Zn^{2+} levels are expected to be toxic. The high total concentration of Zn^{2+} in the pancreas suggests that its homeostasis may be tightly controlled by transporters and binding proteins (eg metallothioneins). There are two main families of zinc transporters: the ZnT family (coded by the Slc30a genes) diminish the concentration of the ion in the cytosol by transporting it either into the extracellular space or in intracellular organelles; the ZiP family members (coded by the Slc39a genes), on the other hand, act as importers localised either on the plasma membrane or on the membrane of intracellular compartments. Importantly, a polymorphism, rs13266634, in the human SLC30A8 gene encoding the secretory granule Zn^{2+} transporter ZnT8, is associated with altered type 2 diabetes risk. Despite recent finding, relatively little is known about how Zn^{2+} homeostasis is achieved in pancreatic β -cells and whether, and under what circumstances, changes in cytosolic Zn^{2+} ($[\text{Zn}^{2+}]_{\text{cyt}}$) may occur. Here, we explore the effect of glucose on $[\text{Zn}^{2+}]_{\text{cyt}}$ and the possible mechanisms through which the sugar is able to modify Zn^{2+} homeostasis.

Materials and methods: We used CD1 mouse pancreatic islets (for quantitative real time PCR and Western (immuno) blot analysis) or dissociated primary islet cells (for imaging). Real-time intracellular free Zn^{2+} measurements were achieved by adenovirus-mediated delivery into dissociated islet cells of a genetically engineered Förster resonance energy transfer (FRET)-based sensor, eCALWY-4, and epifluorescence imaging.

Results: We show here that elevated (16.7 vs 3 mM) glucose concentrations increase, in a time-dependent manner, free $[Zn^{2+}]_{cyt}$ in mouse pancreatic β -cells. These changes became highly significant (853 ± 96 pM vs 452 ± 42 pM, $p < 0.001$) after 24 h and were associated with increased expression of the ZiP family members Slc39a6, 7 and 8, and decreased expression of metallothionein-1 and -2 (Mt-1 and Mt-2). Arguing that the altered expression of these genes may be a cause of altered $[Zn^{2+}]_{cyt}$, an imposed elevation of extra (and intra-) cellular $[Zn^{2+}]$ failed to mimic the effects of glucose. By contrast, increases in intracellular cAMP, prompted by the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine and the adenylate cyclase activator forskolin, partially mimicked the effects of glucose on metallothioneins, though not on ZiP expression. Furthermore, modulation of intracellular Ca^{2+} and insulin secretion by pharmacological agents (tolbutamide and diazoxide) suggested a possible role for the latter in the regulation of Slc39a6 and 7, but not Slc39a8 or metallothionein, expression by glucose.

Conclusion: We demonstrate that (1) glucose increases free $[Zn^{2+}]_{cyt}$ concentrations in mouse β -cells, presumably facilitating the processing and storage of insulin, and (b) these changes are achieved, at least in part, by modulation of the expression of metallothioneins and Zn^{2+} importers, albeit via distinct intracellular signalling mechanisms. Sustained hyperglycaemia, and the resulting increases in $[Zn^{2+}]_{cyt}$ may, however, contribute to β -cell dysfunction and death in type 2 diabetes, and these events may conceivably be modulated by ZnT8 genotype.

Mathematical model of the mechanism by which alanine potentiates glucose-stimulated insulin secretion

M. Salvucci¹, Z. Neufeld², P. Newsholme¹;

¹School of Biomolecular and Biomedical Science (SBBS), ²Complex & Adaptive Systems Laboratory (CASL), University College Dublin (UCD), Ireland.

Background and aims: Pancreatic beta-cells maintain glucose homeostasis, secreting insulin according to blood nutrients' fluctuations. Amino acid alanine can acutely stimulate insulin secretion alone or synergistically enhance glucose-stimulated insulin secretion (GSIS) both in vivo and in vitro. A systems biology approach was employed to integrate biological experimental work with mathematical tools to gain novel insights about the role played by alanine in both stimulating on its own and enhancing GSIS.

Materials and methods: Experimental work was carried out on a functional clonal insulin-secreting cell line (BRIN-BD11) to validate the model and fine-tune the parameters. BRIN-BD11 cells were starved for 40 minutes at basal glucose level (1.1 mM) and then stimulated for 20 minutes with different concentrations of only glucose (1.1, 5, 16.7, 30 mM), only alanine (0.5, 1, 2, 5, 10 mM) and various combinations. Samples were assayed for consumption/production of key components of the mathematical model: glucose, alanine, lactate, glutamate, ATP and insulin. A mathematical model of GSIS in pancreatic beta-cells, based on mass action kinetics, which takes into account glycolysis, Krebs cycle, NADH shuttles and glutamate and alanine aminotransferase was built. The model's input is made up of glucose and/or alanine, while the output is ATP (as an increasing monotonic function between ATP production and insulin secretion was identified).

Results: Acute insulin secretion was concentration dependent with respect to glucose: increasing glucose concentration from 1.1 to 30 mM increased insulin secretion from 0.48 ± 0.09 to 0.83 ± 0.08 ng/mg protein/20min. Acute insulin secretion showed a robust dose-response curve with respect to alanine: increasing alanine concentration in the range 0.5–10 mM increased insulin release from 1.18 ± 0.11 to 2.43 ± 0.09 ng/mg protein/20min. The addition of 10 mM alanine significantly increased ($p < 0.001$) GSIS by 3.8–4.3 fold (2.08 ± 0.07 and 2.49 ± 0.05 ng/mg protein/20min at 1.1 mM and 30 mM of glucose, respectively). Both glucose consumption and lactate production showed a dose-dependent increase (from 0.13 to 3.02 and 0.057 to 0.16 μ mol/mg protein/20 min, respectively) which was significantly enhanced by addition of 10 mM alanine ($p < 0.001$). Alanine consumption showed a dose-dependent increase (from 0.08 to 1.22 μ mol/mg protein/20 min in the range 0.1–10 mM alanine), but was found unaffected by the presence of glucose intracellular glutamate concentration was 0.25 ± 0.04 , 0.32 ± 0.05 and 0.49 ± 0.1 1.22 μ mol/mg protein/20 min in the presence of 16.7 mM glucose, 10 mM alanine and their combination, respectively.

Conclusion: The model is able to describe both qualitatively and quantitatively the salient features of stimulus-secretion coupling in the beta cell. The model predicts high ATP production and thus strong insulin secretion if the

system is fuelled with either high glucose flux only or high alanine flux only, or both, confirmed by cell based experimental results. High ATP production levels are achieved at lower glucose concentrations when in combination with alanine. At high rates of alanine flux, a high steady state concentration of glutamate is achieved which predicts that alanine may enhance insulin release by increasing ATP levels and by generating glutamate, a putative messenger in insulin secretion.

Glucose triggers cyclic Epac2 translocation and Rap activation at the beta cell plasma membrane

I. Jakobsson, O. Idevall-Hagren, A. Tengholm;

Department of Medical Cell Biology, Uppsala, Sweden.

Background and aims: Glucose stimulation of β -cells results in pulsatile release of insulin. This process is controlled by synchronized oscillations of the cytoplasmic Ca^{2+} and cAMP concentrations beneath the plasma membrane ($[Ca^{2+}]_{pm}$ and $[cAMP]_{pm}$). Important effects of cAMP are mediated by the guanine nucleotide exchange factor Epac2, which promotes insulin secretion through activation of the Rap family of small GTPases. The aim of the present study was to investigate spatio-temporal regulation of Epac2 and the effect of glucose stimulation on the activity of Rap GTPases.

Materials and methods: Evanescent wave fluorescence imaging was used to monitor plasma membrane association of fluorescent protein-tagged Epac2 in individual MIN6 β -cells. Mutants of Epac2 deficient in cAMP- and Ras-binding were generated by introducing G114E/G422D and K684E substitutions, respectively. Active (GTP-bound) Rap was visualized with a green fluorescent protein-tagged Rap-binding domain from RalGDS (GFP-RalGDS_{RBD}).

Results: cAMP-elevating agents and the Epac2-activating nucleotide analogue 007 caused translocation of GFP-Epac2 from the cytoplasm to the plasma membrane. Elevation of the glucose concentration from 3 to 11 mM often triggered cyclic translocation of Epac2, reflecting oscillations of $[cAMP]_{pm}$ and $[Ca^{2+}]_{pm}$. This translocation was suppressed after inhibition of adenylyl cyclases or removal of extracellular Ca^{2+} . Epac2 mutants deficient in cAMP- or Ras-binding failed to translocate in response to glucose stimulation or cAMP elevation, and expression of a dominant negative Ras mutant reduced translocation of wildtype Epac2. To investigate if Epac2 translocation was associated with activation of effector proteins at the plasma membrane, Rap activity was monitored with GFP-RalGDS_{RBD}. A step increase of the glucose concentration from 3 to 11 mM induced cyclic plasma membrane translocation of GFP-RalGDS_{RBD}. Activation of Epac with 007 or a combination of forskolin and IBMX induced stable translocation of the Rap reporter. Subsequent depolarization of the cells with 30 mM KCl, which promotes translocation of Epac2 to the plasma membrane, induced further GFP-RalGDS_{RBD} translocation.

Conclusion: Glucose stimulation of β -cells induces cAMP- and Ras-dependent Epac2 translocation to the plasma membrane, which in turn is associated with activation of the plasma membrane pool of Rap GTPases. Cyclic Epac2 and Rap signaling at the plasma membrane should contribute to the generation of pulsatile insulin secretion.

Mitochondrial function parameters during metabolic amplification of insulin secretion

H. Ghaly, U. Panten, I. Rustenbeck;

Pharmacology and Toxicology, TU-Braunschweig, Germany.

Background and aims: The amplifying pathway of insulin secretion is known to involve the export of mitochondrial intermediates. However, it is neither known which metabolites are critical nor is there an undisputed target structure. Recently, we have observed that under an experimental condition which permits to compare the amplification by the nutrient secretagogues glucose and KIC (alpha-ketoisocaproic acid), the secretory response to glucose was entirely lacking while a virtually immediate response was elicited by KIC. This experimental situation should permit to gain further insight into nutrient signalling in the beta-cells.

Materials and methods: Primary mouse pancreatic islets were isolated by collagenase digestion and cultured for up to three days. When attached to a

glass cover slip they were inserted into a purpose-built perfusion chamber on the stage of an epifluorescence microscope. Successively, the fluorescence of NADH, FAD and tetramethylrhodamine ethyl ester (TMRE; as indicator of the mitochondrial membrane potential) were excited and registered by a photon-counting multiplier. ATP and ADP were determined by luciferase luminescence. Insulin secretion of batch-perfused islets was determined by ELISA.

Results: After perfusion for 1 h in the absence of glucose (to down-regulate the beta cell glucose memory) and the presence of 2.7 μmol glipizide (to close KATP channels), maximally effective concentrations of the following nutrients were added: glucose (30 mM), KIC (10 mM) or KIV (alpha-ketoisovalerate; 10 mM). While glucose had no insulinotropic effect under this condition KIC led to a 10-fold increase within 10 min, which slowly declined thereafter. KIV had a fast monophasic effect which returned to basal within 30 min. Despite the lack of insulinotropic effect, glucose still markedly increased the NAD(P)H autofluorescence (70% compared to prestimulatory values) and hyperpolarized the mitochondrial membrane potential (40% increase of TMRE fluorescence). Similar, but less extensive changes were produced by KIC (20%), while KIV was the least effective in this regard. The ATP- and ADP-contents after glucose or KIC incubation were not significantly different. There was however, a qualitative difference in the FAD autofluorescence, which was reduced by glucose (about 10%), increased by KIC and remained virtually unaffected by KIV.

Conclusion: Under a condition when the amplifying response to glucose is specifically abolished, the global mitochondrial function appears unimpaired. The qualitative difference in the FAD autofluorescence may indicate that the critical metabolite enabling amplification is derived from a pathway involving the FAD/FADH₂ redox couple.

Ca²⁺-dependent regulation of Kv2.1 channels in pancreatic beta cells

M. Yoshida¹, M. Nakata², S. Yamato³, K. Dezaki², S.-E. Ishikawa¹, T. Yada², M. Kakei¹, M. Kawakami¹;

¹Internal Medicine, Jichi Medical University, Saitama, ²Integrated physiology, Jichi Medical University, Shimotsuke, ³Anesthesiology, Jichi Medical University, Saitama, Japan.

Background and aims: ATP-sensitive potassium (KATP) channel is known to determine the resting membrane potential that is approximately -70 mV at lower glucose level in pancreatic β -cells. In normal subjects, however, fasting plasma glucose level is maintained in the range of 5–6 mM. Under these conditions, ATP/ADP ratio is unchangeable because the glucose concentration is nearly constant. Thus, a fine-tuning of insulin secretion to maintain these plasma glucose levels in normal state should be explained with a factor other than KATP channel unless the KATP-channel is mechanistically involved in slow potential oscillations. We examined whether the voltage-dependent potassium channel (Kv channel) are regulated by cell metabolism including Ca²⁺ and energy metabolism.

Materials and methods: We measured the Kv-channel current in rat pancreatic β -cells or in HEK293 cells expressed with Kv2.1-channels by using whole-cell clamp mode. Insulin secretion was measured in islets in static incubation at 37°C for one hour. Electrophysiological experiments were performed at room temperature.

Results: Exposure of islets to TEA increased insulin secretion at 8.3 mM glucose (22.1 ± 1.1 ng/ml/10 islets vs 60.7 ± 5.6 ng/ml/10 islets, $P=0.0003$) but not at 2.8 mM glucose (10.1 ± 0.7 ng/ml/10 islets vs 9.3 ± 1.0 ng/ml/10 islets, $P=0.88$). When we compared the current-voltage relations of Kv channels recorded at 0 and 10 min after establishment of whole cell clamp mode using the pipette solution including 5 mM MgATP in the presence of 2.8 mM glucose in the external solution, Kv currents were increased at negative potentials between -40 mV and -10 mV ($P<0.01$). The same time-dependent increases in Kv-channel currents were observed upon exposure to 0 mM glucose, 1 μM FCCP, 0 mM ATP (in pipette) and 5 mM AMPPNP (in pipette). When we tested effects of presence of 5 U/ml alkaline phosphatase in the cell interior through the pipette, Kv-channel currents were increased at the same negative potential range ($P<0.01$) and activation and inactivation curves revealed a leftward shift. To test whether Kv2.1 channel is regulated by Ca²⁺, we applied high Ca²⁺ (1.5 μM , using two chelators two metal calculators) or low Ca²⁺ (16 nM) solution into the cytoplasm through the pipette in HEK293 cells expressed with Kv2.1 channels. Kv2.1-channel current was increased by Ca²⁺ increase at negative potentials ($P<0.02$) as observed in metabolically inhibited β -cells. This Ca²⁺-induced increase of Kv2.1-channel current was attenuated by a calcineurin inhibitor, 200 nM fenclerolate or 1 μM deltamethrin. In HEK293 cells without expression of Kv2.1 channels, Ca²⁺ increase did not change the background current. β -cell Kv channel currents were also increased by 1.5 μM Ca²⁺ in the pipette and the resting membrane potentials were hyperpolarized from -20.2 ± 1.4 mV at 16 nM Ca (n=8) to -33.2 ± 1.8 mV at 1.5 μM Ca²⁺ (n=9, $P<0.001$).

Conclusion: We conclude that the Kv2.1 channel in rat β -cells is mediated by glucose metabolism, phosphorylation/dephosphorylation (calcineurin) and cytoplasmic Ca²⁺. These Ca²⁺-dependent regulation of the channel may produce hyperpolarization of the membrane potential during glucose stimulation. This may consequently contribute to regulation of insulin secretion at intermediate glucose concentration in concert with KATP channel-based regulation of membrane potential.

478

Low concentration of GLP-1 increases insulin secretion and calcium current by activating protein kinase C pathway in pancreatic beta cells

M. Shigeto^{1,2}, R. Ramracheya¹, O. Braha¹, M. Braun¹, M. Katsura², K. Kaku², P. Rorsman¹;

¹Oxford Centre for Diabetes, Endocrinology and Metabolism, UK, ²Diabetes and Endocrine Division, Department of Medicine, Kawasaki Medical School, Kurashiki, Okayama, Japan.

Background and aims: GLP-1 is known to be the most potent promoter of insulin secretion in the body, and its concentration in human peripheral

blood is a few pM. Administration of DPP-4 inhibitors increases the peripheral blood concentration of GLP-1 by 2–3 fold, resulting in a significant potentiation of insulin release. On the other hand, almost all of *in vitro* experiments studying the effect of GLP-1 on pancreatic islet cells have routinely used much higher concentrations of GLP-1 (nM range) than physiological one. We have previously reported that a low concentration (1 pM) of GLP-1 stimulated insulin secretion through a cAMP-PKA independent pathway in MIN6 cells. In this study, we further assessed a precise action mechanism of physiologically low concentrations of GLP-1 on insulin secretion from primary cultured beta-cells.

Materials and methods: Mouse islets were isolated by collagenase digestion. Secreted insulin was quantified using the RIA kit. Dispersed islet cells were plated on plastic tissue culture dishes for electrophysiological recordings. The recordings were made using the perforated-patch whole-cell configuration. Membrane currents were recorded using an EPC-9 patch-clamp amplifier (HEKA). The cells were voltage-clamped at -70 mV , and the voltage-dependent calcium channels were activated by 20-ms depolarizations to 0 mV.

Results: GLP-1 stimulated insulin secretion in a dose dependent manner. In mouse beta-cells, 1 pM GLP-1 increased calcium current (I_{Ca}) by approximately 120% of the control (2.38 ± 0.61 vs 2.85 ± 0.74 pC, $N=5$, $p<0.05$). The increase in I_{Ca} was completely inhibited by addition of 100 nM exendin9-39, the GLP-1 receptor blocker. Insulin secretion induced by 10 nM GLP-1 was completely inhibited by 100 μM Rp-cAMPS (PKA inhibitor), while the effect of 1 pM GLP-1 was not significantly affected (16.3 ± 1.6 vs 23.0 ± 4.0 pg/islet/h, $N=7$). The stimulatory effect of 1 pM GLP-1 on I_{Ca} was still observed (116% of the control; 2.06 ± 0.20 vs 2.39 ± 0.19 pC, $N=5$, $p<0.05$) even in the presence of the PKA inhibitor Rp-cAMPS. The PKC inhibitor, 100 nM bisindolylmaleimide, completely blocked the effect of 1 pM GLP-1 on insulin secretion and I_{Ca}. Insulin secretion stimulated by GLP-1 was significantly inhibited by 2 μM isradipine, a L-type calcium channel blocker (49.6 ± 7.0 vs 20.2 ± 2.4 pg/islet/h, $N=7$). Surprisingly, GLP-1 further decreased calcium currents in the presence of isradipine. Neither 1 pM nor 10 nM stimulated insulin secretion from islets of GLP-1 receptor knockout mice.

Conclusion: The present results demonstrate that a low, but physiological, concentration of GLP-1 increases calcium currents and insulin secretion, and suggest that PKC is involved in its signal pathway, which is different from classical PKA dependent pathway. Further study should be required to identify the site of action of both higher and lower concentrations of GLP-1. Investigating the effects of physiological concentration of GLP-1 may contribute to bring forward the action mechanism of GLP-1 as an anti-diabetic agent.

479

Fast and easy evaluation of beta cell function and activity

P. Krippeit-Drews¹, S. Schönecker², T. Pfeiffer², M. Düfer¹, E. Guenther², U. Kraushaar², G. Drews¹;

¹Pharmacology, Toxicology and Clinical Pharmacy, Institute of Pharmacy, Tübingen, ²Department of Electrophysiology, NMI Reutlingen, Germany.

Background and aims: Glucose-induced electrical activity of beta-cells in intact islets consists of membrane potential (V_m) oscillations, so-called slow waves. Bursts of Ca^{2+} action potentials trigger oscillations of $[\text{Ca}^{2+}]_c$ which in turn induce oscillating insulin secretion. The length of these oscillations is glucose dependent at concentrations between ~6–20 mM. Thus, the fraction of plateau phase (FOPP = percentage of time with burst activity) is an excellent marker of beta-cell activity and metabolic integrity. So far all tools to measure the FOPP require high technical skills, are invasive, and/or very time-consuming. Our aim was to determine the FOPP in islets of Langerhans with a non-invasive easy-to-use method.

Materials and methods: Changes of V_m of whole islets were recorded as field potentials using microelectrode arrays (MEA). For comparison V_m of beta-cells was recorded with the patch-clamp technique.

Results: Glucose-induced slow waves of mouse beta-cells exhibited very similar patterns of electrical activity regardless whether they are recorded by extra- or intracellular techniques. Extracellular recordings could be sufficiently resolved to clearly discriminate burst and interburst phases, enabling the precise determination and calculation of the FOPP. The concentration-FOPP curve was measured for glucose concentrations of 3 mM ($n=10$), 6 mM ($n=5$), 8 mM ($n=5$), 10 mM ($n=8$), 15 mM ($n=11$), and 30 mM ($n=5$). The data were fitted with the Hill equation giving a half-maximal glucose concentration of 12 ± 1 mM, similar to “classical” recordings of V_m , $[\text{Ca}^{2+}]_c$ or insulin secretion. Modulators of K_{ATP} channels (diazoxide ($n=8$) and tolbutamide ($n=8$)) changed the FOPP according to their well known action on the

channels. Moreover, TRAM34 (1 μM), an inhibitor of SK4 channels, increased the FOPP 1.25fold ($n=9$).

Conclusion: Here we present a new method using MEA technology as an easy-to-use tool to measure electrical activity from pancreatic beta-cells in intact islets of Langerhans. The simplicity of the method promises versatile applications from academic research to the development of medium-throughput systems for non-academic beta-cell research which may considerably profit from a routine use of this method. Importantly, the new technique may suit to test islets for metabolic integrity before transplantation.

Hybrid bioelectronic sensor development for long-term functional screening on islets and insulin therapy improvement

M. Raoux¹, Y. Bornat², A. Quotb², B. Catargi¹, S. Renaud², J. Lang¹;

¹UMR CNRS 5248, Université Bordeaux 1, Pessac, ²UMR CNRS 5218, Université Bordeaux 1, IPB, Talence, France.

Background and aims: Sensor technology for insulin therapy has made considerable progress but hormonal regulation, detection of hypoglycaemia and real-time as well as closed-loop functioning are still open questions. Innovative sensors should also considerably advance long-term functional screening of healthy or diseased β -cells/islets. We report here the development of a hybrid biosensor based on the combination of electrophysiological recording of islet cells with multielectrode arrays (MEAs) and microelectronics devices.

Materials and methods: Clonal β -cells and mouse islets were cultured for 2–7 days on MEAs containing 60 extracellular microelectrodes (Multichannel Systems, MCS). Electrical signals were recorded with a MEA1060-Inv-BC-Standard amplifier (MCS) and off-line analyzed with MC_Rack software (MCS). An innovative low-power integrated circuit was also developed to optimize the real-time detection of spikes with low signal-to-noise ratio, the detection being based on wavelet transforms followed by adaptive thresholding.

Results: We succeeded for the first time in the culture and the long-term recording of electrical signals of both clonal and primary β -cells on MEAs. In clonal β -cells, spike frequencies increased in response to glucose in reversible and reproducible manner. In addition, glucose effects on spike frequencies were dose-dependent for concentrations mimicking hyper- and hypoglycaemia. The intestinal hypoglycaemic incretin hormone GLP-1 as well as the incretin-mimetic agent forskolin increased the firing rate of clonal β -cells. On the other hand, the hyperglycaemic hormone adrenalin, released during high-glucose-consuming situations, decreased electrical signals generated by primary β -cells and increased those from α -cells. The device is thus well-suited for simultaneous electrophysiological investigations on different islet cell types from the same biological sample. Functional monitoring over several days was feasible as we measured electrical responses of clonal β -cells to glucose on the same MEAs, 3 and 6 days after seeding. Glucose-evoked firing rates were reduced in β -cells exposed to glucotoxicity during these 3 days as compared to those exposed to normal glucose levels. In addition, we have shown the feasibility of acute pharmacotoxicological screenings on β and non β -cells with several compounds targeting islet ion channels such as nifedipine, tetraethyl ammonium, iberiotoxin, stomatocytin-1 and tetrodotoxin. The device was also used for electrophysiological phenotyping using islets from glucose-intolerant knock-out mice (adenylyl cyclase 8). Finally, algorithms were designed to improve the detection of very small amplitude spikes using adaptive thresholds after wavelet transform. A dedicated very large scale integrated circuit was manufactured, compatible with the MEA-amplifier and with adjustable approximation orders and thresholds. Real-time detection performances of the hybrid bioelectronic sensor were successfully tested online in *in vitro* experiments with clonal β -cells.

Conclusion: Our results demonstrate the feasibility of long-term functional screening on islet cells with MEAs, the improvement of real-time spike detection by online microelectronics, and the interest of hybrid biosensor developments for high-throughput screening and for the treatment of diabetes.

Interplay between sub-plasma membrane oscillations of Ca^{2+} and ATP in mouse beta cells

J. Li, E. Gylfe, A. Tengholm;
Medical cell biology, Uppsala, Sweden.

Background and aims: ATP plays an important role in β -cell stimulus-secretion coupling by linking glucose metabolism to closure of K_{ATP} channels, which results in membrane depolarization, Ca^{2+} influx and insulin secretion. Substantial evidence indicates that β -cell metabolism oscillates, and that such oscillations are affected by the cytoplasmic Ca^{2+} concentration. However, Ca^{2+} may exert both positive and negative effects on ATP levels and the aim of the present study was to clarify how the ATP dynamics is influenced by the cytoplasmic Ca^{2+} concentration beneath the plasma membrane $[\text{Ca}^{2+}]_{\text{pm}}$ in individual β -cells.

Materials and methods: Islets isolated from C57BL/6 mice were infected with adenovirus expressing the fluorescent ATP sensor perceval, which is based on circularly permuted Venus fluorescent protein fused to the ATP-binding bacterial protein GlnK1. $[\text{Ca}^{2+}]_{\text{pm}}$ was recorded with the fluorescent indicator Fura Red. Fluorescence was recorded from the sub-plasma membrane space with total internal reflection microscopy.

Results: Perceval fluorescence was stable in most islet cells exposed to 3 mM glucose. Elevation of the glucose concentration to 11 mM induced an immediate, pronounced ($144 \pm 5\%$) increase of fluorescence, typically with superimposed oscillations with a frequency of $0.28 \pm 0.02 \text{ min}^{-1}$ ($n=25$ cells). Hyperpolarization of the glucose-stimulated cells with the K_{ATP} channel opener diazoxide or inhibition of voltage-dependent Ca^{2+} channels with methoxyverapamil resulted in an additional marked increase of perceval fluorescence, sometimes with remaining small oscillations. Subsequent depolarization with 30 mM K^{+} instantly reduced perceval fluorescence with small oscillations occurring in about 50% of the cells. Simultaneous measurements of $[\text{Ca}^{2+}]_{\text{pm}}$ showed that the initial glucose-induced rise of perceval fluorescence preceded the increase of $[\text{Ca}^{2+}]_{\text{pm}}$. Subsequent oscillations were anti-synchronous, with each increase of $[\text{Ca}^{2+}]_{\text{pm}}$ coinciding with lowering of perceval fluorescence.

Conclusion: Glucose stimulation of mouse β -cells triggers oscillations of the ATP concentration in the sub-plasma membrane space. Ca^{2+} reduces the ATP levels, but metabolic oscillations can occur without $[\text{Ca}^{2+}]_{\text{pm}}$ oscillations. The dynamic interplay between ATP and $[\text{Ca}^{2+}]_{\text{pm}}$ in β -cells should be important for the generation of pulsatile insulin secretion.

Actions of the BK channel blocker charybdotoxin on glucose-induced electrical activity in whole mouse islets

J.I. Real¹, H.A. Figueiredo¹, A.M. Silva¹, R.M. Barbosa^{1,2}, R.M. Santos^{1,3}, L.M. Rosário^{1,3};

¹Center for Neuroscience and Cell Biology (CNC), ²Faculty of Pharmacy,

³Department of Life Sciences, Faculty of Science and Technology, Coimbra, Portugal.

Background and aims: Bursting electrical activity is a distinctive trait of β -cells in intact islets, related to oscillatory Ca^{2+} influx and pulsatile insulin release. The possible physiological role of the large-conductance Ca^{2+} -sensitive K^{+} (BK) channel as a 'bursting channel' or modulator of action potential (AP) firing has been challenged by the reiterated lack of effect of prototypical peptide inhibitors on the electrical activity of whole islets. We have now investigated the effects of charybdotoxin (ChTx, 50 nM) on β -cell spiking activity, recorded from rather superficial islet cell layers to enhance access of the peptide. The hydrophobic BK channel inhibitor penitrem A (PTA, 10–100 nM) was also used to probe pharmacologically cells located deeper within the islet.

Materials and methods: The membrane potential was recorded from micro-dissected mouse islets, using high-resistance microelectrodes.

Results: Both inhibitors greatly increased spike amplitude and reduced (i.e. made more negative) the burst plateau potential in 11 mM glucose, effects that peaked at 10–15 min. These actions probably reflect a reduction in the voltage threshold for AP firing. In addition, both ChTx and PTA accelerated spike repolarization, increased spike afterhyperpolarization and augmented the inter-spike interval, effects that probably reflect enhanced activation of delayed rectifier K^{+} (K_{v}) channels and/or K_{Ca} channel types distinct from BK channels. Similar effects were observed in presence of 11 mM glucose and tolbutamide (500 μM), a blocker of ATP-sensitive K^{+} channels which depo-

larizes β -cells and generates a pattern of continuous spiking activity. Both inhibitors slightly reduced burst duration in 11 mM glucose alone, although in some experiments the electrical activity became so disrupted that this parameter was difficult to quantify.

Conclusion: Superficial intracellular recording revealed potent actions of charybdotoxin on β -cell electrical activity. BK channels contribute to shaping action potential firing by controlling its amplitude and frequency, being essential to sustain burst plateau and regularity.

 K_{ATP} channel and mitochondrial pH: estimation of mitochondrial matrix pH in cultured living beta cells using an improved ratiometric biosensor

M. Ogata¹, N. Iwasaki¹, T. Awaji², R. Fujimaki¹, M. Takizawa¹, K. Maruyama², Y. Iwamoto¹;

¹Diabetes Center, Tokyo Women's Medical University, ²Pharmacology, Saitama Medical University, Japan.

Background and aims: Mitochondrial pH and changes in pH are key determinants of mitochondrial energy metabolism, and metabolite transport is important for cell activation. However, methods to estimate mitochondrial pH in living cells are suboptimal and do not provide a direct quantitative measurement. Here we report a new ratiometric biosensor which we employed to calculate organelle pH in living cells using fluorescence. Because β cell mitochondrial function is vital for insulin secretion, we used the new system to measure mitochondrial pH in two β cell lines, INS-1 (rat) and MIN6 (mouse).

Materials and methods: The pH measurement probe MitpHGV thus comprised two probes, a pH-dependent mutant fluorescent Venus with a pKa ranging from 7.2 to 8.0, and a pH-independent fluorescent mutated GFPuv. A cytochrome-C subclass IV localization signal was fused with our pH-sensitive probe (MitpHGV; Fig.1A), then stably transfected into Chinese hamster ovary (CHO) cells or cultured β -cells, INS-1, and MIN6 cells, using Lipofectamine. Mitochondrial pH in these cells was calculated serially and quantitatively under conditions that stimulated the secretion of insulin. MitpHGV-INS1 and MitpHGV-MIN6 cells were incubated with 2 μM Fura-2AM and Ca signals were calculated as previously reported. MitpHGV-MIN6 cells were incubated for 45 min with 1 μM BCECF-AM with 0.0025% F127 added at room temperature and pH of the cytoplasm was monitored.

Results: Rotenone and carbonyl cyanide 3-chlorophenylhydrazone (CCCP) treatment quickly decreased mitochondrial pH in cultured β cells. After loading the cells with rotenone, however, the addition of CCCP increased mitochondrial pH. In cultured β cells, glucose and pyruvate also quickly decreased mitochondrial pH, and the pH recovered upon washout of these compounds. In contrast, treatment with arginine or tolbutamide without glucose induced a slow decrease in mitochondrial pH. Glucose (in a step change from 0 to 1.5 mM) also decreased mitochondrial pH in MIN6 cells, and further decreased with 25 mM glucose. On the other hand, treatment of MIN6 cells (in 0 glucose for 180min) with 1.5 mM glucose induced a Ca^{2+} response only in a subpopulation of MIN6 cells, while following 25mM glucose all MIN6cell showed a Ca^{2+} response. Furthermore mitochondrial pH decrease occurred following stimulation with 25mM Glucose even in the presence of diazoxide (100 μM).

Conclusion: We found that mitochondrial pH is decreased by insulinotropic stimulation in cultured β cells, and it occurs independent of functional K_{ATP} channels. Our new system for measuring intracellular pH using a targeted biosensor was sensitive across a physiologically useful range and will be a useful tool for evaluating mitochondrial function in insulin secreting cells.

Involvement of K_{ATP} channels in the loss of beta cell function induced by human islet amyloid polypeptide

M. Soty^{1,2}, M. Visa^{1,2}, S. Soriano^{3,2}, L. Cadavez^{1,2}, Á. Nadal^{3,2}, A. Novials^{1,2};

¹Laboratori Diabetis i Obesitat, IDIBAPS, Barcelona, ²Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERdem), Barcelona, ³Instituto de Bioingeniería, Universidad Miguel Hernández, Elche, Spain.

Background and aims: Type 2 diabetes is characterised by islet dysfunction that lead to the impairment of insulin secretion. The presence of islet amyloid

deposition is a recognised hallmark in islets of type 2 diabetes patients. Amyloid deposits are formed by human islet amyloid polypeptide (hIAPP). There is now very strong evidence supporting the key role of amyloidogenesis in the progressive loss of pancreatic beta-cell mass and function. The main objective of this work is to investigate the mechanisms by which hIAPP overexpression could affect beta-cell function.

Materials and methods: We have used two models of long-term hIAPP overexpression. First, rat pancreatic beta-cell line, INS1E, was stably transfected with a hIAPP plasmid (hIAPP cells) and second, rat pancreatic islets were infected with a hIAPP lentivirus. To characterise the impact of hIAPP on beta-cell function, we measured insulin secretion in both models. Then, to determine by which mechanism hIAPP alters beta-cell secretory function, we studied in hIAPP cells, the intracellular Ca^{2+} mobilisation in response to glucose or sulphonylurea drug using Fura-2 labelling. By immunogold labelling, we studied the presence of intracellular hIAPP deposits (oligomers) and their interaction with ATP sensitive potassium channels (KATP) subunit, Kir6.2. Mitochondrial function was also evaluated by respirometry (OROBOROS system).

Results: In response to 16.7 mM glucose, insulin secretion was strongly decreased in hIAPP compared with control cells (3.5 ± 0.7 vs 15.6 ± 2.9 % insulin release expressed as a percentage of insulin content, $p < 0.05$). hIAPP-infected islets showed lower insulin secretion in response to glucose than control islets (1.7 ± 0.4 vs 2.5 ± 0.8 % insulin release expressed as a percentage of insulin content, $p < 0.05$). According to these results, the study of calcium signals demonstrated an absence of response to glucose in hIAPP cells. Whereas 76.61% of control cells (194/201) exhibited a normal response to 16.7mM glucose, none of the hIAPP cells tested were able to respond to glucose (0/192). Consistent with a defect in KATP channel function, hIAPP cells responded poorly to tolbutamide. Indeed, whereas 97.05% of control cells (132/136) showed a normal response to tolbutamide, only 9.6% of hIAPP cells (9/93) were able to respond. The immunogold labelling for oligomers was mostly detected in hIAPP cells. Double immunogold labelling for Kir6.2 and oligomers detected colocalisation of both proteins. In addition, the maximal respiratory capacity was increased in hIAPP cells compared to controls (79.62 ± 8.84 vs 46.56 ± 6.25 pmol/s/million of cells).

Conclusion: We suggest that hIAPP alters KATP channel activity leading to a defect in insulin secretion in response to glucose. The increase in mitochondrial activity may be a compensatory mechanism to counteract these defects. *Supported by: FIS (PI08/0088)*

Enhanced functional capacity of human pseudoislets generated from the novel electrofusion-derived human insulin-secreting 1.1B4 cell line

P.R. Flatt, H. Guo Parke, C. Kelly, M. Hamid, N.H. McClenaghan, J.T.

McCluskey;

School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: We have recently developed a novel human pancreatic beta cell line, designated 1.1B4, by electrofusion of freshly isolated of human pancreatic beta cells with immortal human PANC-1 epithelial cells. The current study describes, for the first time, the functional enhancement of these cells by configuration as human pseudoislets.

Materials and methods: Pseudoislet formation was achieved by seeding 1.1B4 cells at a density of 5×10^4 in ultra-low attachment, 6-well flat-bottomed plates with culture in RPMI-1640 for up to 7 days. Cellular insulin content and insulin secretory responses in acute 20 min incubations were determined by radioimmunoassay. Expression of gap junction and beta cell genes and proteins were measured by RT-PCR, Western blot and immunohistochemistry. Cellular proliferation and integrity were assessed by BrdU enzyme-linked immunosorbent assay and the colorimetric MTT assay.

Results: Pseudoislets formed readily over 3-7 days in culture attaining a static size of 100-200 μm , corresponding to approximately $6,000 \pm 417$ beta cells. Insulin content was comparable between monolayers and pseudoislets (approx. 3.2 ng/ 10^6 cells). Monolayers exhibited a stepwise 1.3-1.9 fold increase of insulin secretion at 0-16.7mM glucose which was enhanced 1.7-2.5 fold by pseudoislet formation ($p < 0.001$). Leucine, alanine, arginine and α -ketoisocaproic acid (all 20mM) stimulated insulin release from 1.1B4 monolayers by 2.4, 1.4, 2.2 and 2.1-fold ($p < 0.01$ to $p < 0.001$) respectively. However, cellular arrangement as pseudoislets greatly enhanced these responses, with insulin output attaining values 5.7 to 12.5-fold greater than monolayers ($p < 0.001$). Similarly, the gut hormones, GIP, GLP-1 and CCK-8 (all 10^{-9}M) significantly stimulated insulin release ($p < 0.01$ to $p < 0.001$) with 5.8-7.6 fold greater responses from pseudoislet configured 1.1B4 cells ($p < 0.01$ to $p < 0.001$). Evaluation of second messenger pathways showed that 30mM KCl, elevated extracellular Ca^{2+} (6.4mM), 25uM forskolin, 200uM IBMX or the K-ATP channel blocker tolbutamide (200uM) each stimulated insulin release ($p < 0.01$ to $p < 0.001$) from 1.1B4 cells with 2.8-5.8 fold greater responses from pseudoislets. Expression of E-cadherin, connexin 36 and connexin 43 were all enhanced in pseudoislets with significant differences ($p < 0.001$) evident from Western blot and immunohistochemistry analysis. Pseudoislets and monolayers exhibited similar levels of glucokinase gene expression, with significantly higher levels ($p < 0.01$) of the Glut1 glucose transporter detected in pseudoislets. Pseudoislets showed a 30% decrease in proliferation and a 21 % reduction in cell viability compared with monolayers ($p < 0.001$).

Conclusion: Novel electrofusion-derived 1.1B4 human beta cells readily formed pseudoislets in tissue culture. Enhanced beta cell to beta cell interactions mediated through the 3-dimensional cell formation and increases in gap junction communication, resulted in greatly improved secretory function. Such human pseudoislets may provide an attractive model for future islet research and represent an alternative limitless source of human-derived tissue for possible future cell replacement therapy of type 1 diabetes.

The role of microRNAs in compensatory beta cell mass expansion

C. Jacovetti¹, A. Abderrahmani², R. Regazzi¹;

¹Department of Cell Biology and Morphology, ²Service of Internal Medicine, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland.

Background and aims: Diabetes mellitus is a metabolic disease characterised by impaired glucose homeostasis resulting from defective function and/or loss of beta-cells. Pregnancy is associated with diminished insulin sensitivity of maternal tissues that is compensated by an expansion of the beta-cell mass and an increase in insulin release. A better understanding of this physiological process could help identifying new possible approaches for the treatment of diabetes. MicroRNAs are small non-coding RNAs acting as translational repressors. Some of these gene regulatory molecules are known to be involved in the control of beta-cell functions, including insulin secretion and apop-

tos. The aim of our study is to identify microRNAs that are differentially expressed in pancreatic islets in a context of insulin resistance and to assess their involvement in compensatory beta-cell expansion.

Materials and methods: We used expression profiling methods to compare the level of microRNAs in the islets of pregnant rats at d14 of gestation to non pregnant rats. Differential microRNA expression was verified by quantitative real-time PCR. The functional impact of selected microRNAs on insulin secretion, cell proliferation and survival was studied by modifying their expression in the insulin-secreting cell lines MIN6 and INS832/13 and in dissociated rat islet cells.

Results: Microarray and real time PCR analysis identified two down-regulated (miR-218 and -338-3p) and two up-regulated microRNAs (miR-144 and -451) in rat islets of pregnant rats. Interestingly, we found that miR-338-3p is also down-regulated in the islets of obese db/db mice and in high-fat fed mice, two other animal models characterized by compensatory beta-cell mass expansion. In vitro experiments with insulin-secreting cell lines and isolated rat islets revealed that miR-338-3p expression is diminished both in the presence of estradiol and upon exposure to the GLP-1 analogue exendin-4. Reduction of miR-338-3p expression in MIN6 and INS832/13 cells using antisense molecules resulted in an increase in proliferation, as evidenced by a rise in Ki67 and BrdU staining, without any impairment in glucose-induced insulin secretion. Moreover, anti-miR-338-3p treatment protected MIN6, INS832/13 cells and dissociated rat islet cells from apoptosis induced by prolonged exposure to pro-inflammatory cytokines.

Conclusion: We have identified changes in microRNA expression in pancreatic islets of pregnant rats. Our data suggest that miR-338-3p might be implicated in beta-cell compensation during pregnancy and in the setting of insulin resistance in different animal models. The identification of miR-338-3p downstream signalling pathways could provide important information for the design of new microRNA-based therapeutic strategies to expand the functional beta-cell mass.

Relationships between pancreatic islet features and clinical characteristics

M. Suleiman, M. Bugliani, F. Filippini, U. Boggi, P. Marchetti, L. Marselli; University of Pisa, Italy.

Background and aims: To shed light on the relationships between pancreatic islets and clinical characteristics, we studied properties of islets from multiorgan donors, to be correlated with a few anthropometric and metabolic features

Materials and methods: Histological samples and/or isolated islets were obtained from 83 subjects; 56 non-diabetic individuals (Ctrl) [age: 61±16 yrs; 32 male (M) and 24 female (F); BMI: 26.2±3.8 kg/m² (n=49); mean blood glucose (BG) during ICU stay: 140±26 mg/dl (n=42)], and 27 type 2 diabetes mellitus (T2DM) patients [age: 67±8 years (p=0.01 vs Ctrl); 15 M e 12 F; BMI: 27.5±3.7 kg/m² (n=26) (p=0.1); BG: 219±50 mg/dl (n=21) (p<0.01)]. Morphometric analysis was performed by an Olympus microscope equipped with a specific software. Islets were prepared by enzymatic digestion and density gradient purification, and insulin secretion was assessed after stimulation with glucose, glibenclamide and arginine. An ELISA assay was used to evaluate cell death.

Results: Islet insulin-positive area was lower in T2DM subjects than in Ctrl (56.0±17.4% vs 71.9±9.5%, p<0.01), as it was insulin release in response to glucose (stimulation index, SI: 1.4±0.4 vs 2.8±1.6, p<0.01), glibenclamide (SI: 1.4±0.4 vs 2.7±1.5, p<0.01) and arginine (1.5±0.6 vs 2.5±1.1, p<0.01). The apoptotic rate was higher (0.88±0.72 vs 0.42±0.47 arbitrary units, p<0.01) in T2DM islets. Islet insulin area was positively correlated with basal (r=0.273, p<0.05) and arginine stimulated (r=0.320, p<0.01) insulin secretion from isolated islets, and was also inversely correlated with patients' BG levels (r=0.379, p<0.01). In addition, glucose and glibenclamide stimulated insulin release was inversely related to glycemic control (r=0.402, p<0.01). Finally, the higher the apoptotic rate, the lower the insulin area (r=0.248, p<0.05).

Conclusion: Correlations were found between pancreatic islet properties and donors' clinical characteristics, with beta cell amount seemingly representing an important variable for islet function and glucose control. These results confirm that the amount of beta cells is reduced in T2DM islets, probably due to increased apoptosis; more importantly, our data suggest that beta cell amount and glucose or glibenclamide stimulated insulin release are not related each other, although both contribute to control blood glucose levels.

The ultrastructure of pancreatic beta cells in human type 2 diabetes

M. Masini¹, L. Martino¹, V. De Tata¹, M. Bugliani², L. Marselli², P. Marchetti², P. Masiello¹;

¹Dip. Patologia Sperimentale B.M.I.E., ²Dip. Endocrinologia e Metabolismo, University of Pisa, Italy.

Background and aims: Type 2 diabetes (T2D) results from a combination of genetic and acquired factors which reduce insulin sensitivity and cause pancreatic beta cell damage. To date, very limited information is available as for the ultrastructure of beta cells in human T2D. In this study we performed morphological and morphometric electron microscopy evaluation of pancreatic islet cells in T2D and non-diabetic (ND) individuals.

Materials and methods: Pancreatic samples were obtained from the glands of 8 T2D and 5 ND organ donors, with similar clinical features, and processed by standard electron microscopy techniques. Morphometric analyses were performed on micrographs obtained at 10,000x and assessed by overlay with a 11x11 cm graticule composed of 169 points. Volume density was calculated by the formula: VD = Pi/Pt, where Pi is the number of points within the subcellular component and Pt is the total number of points, and expressed as ml/100ml of tissue (ml%). The total number of islet cells examined was 1405 in T2D and 2446 in ND.

Results: A lower amount of beta cells was found in T2D than in ND islets (62±2 vs. 71±3%, p<0.01), whereas no difference was observed for alpha (21±2 vs. 20±3%) and delta (5±1 vs. 4±1%) cells. More beta cells of T2D showed signs of apoptosis (7±1.6 vs. 2±1.3%, p<0.01). Insulin granules were less represented in T2D (3.8±0.4 vs. 5.9±0.6 ml%, p<0.01), and the amount of docked granules, although similar in diabetic (0.34±0.07 ml%) and non-diabetic (0.36±0.05 ml%) beta cells, showed a lower proportion of mature granules in the former (0.21±0.05 vs. 0.30±0.03 ml%, p<0.01). Volume density of the endoplasmic reticulum was increased in T2D samples (1.7±0.08 vs. 0.9±0.06 ml%, p<0.01), and mitochondria number (1.7±0.1 vs. 1.3±0.1 per 10 μm²) and volume (5.3±0.8 vs. 3.8±0.4 ml%) were also higher (both p<0.01) in diabetic than in non-diabetic beta cells.

Conclusion: These results show that in human T2D, beta cells have several ultrastructural alterations, as cause or consequence of functional and survival defects; targeting the deranged organelles might improve the outcome of therapeutic interventions.

Direct evidence of adaptive changes of human islets to an obese murine environment

S.A. Gargani, J.R. Thévenet, J.E. Yuan, B. Lefebvre, V. Gmyr, F. Pattou, J. Kerr-Conte; Biotherapy for Diabetes, University Lille Nord de France, France.

Background and aims: Islet adaptation to obesity in rodents is well established yet no direct evidence exists proving human islet mass adapts to obesity. Indeed most obese people with insulin resistance do not develop diabetes because islets compensate by increasing insulin secretion to maintain normal blood sugar levels. Transplantation of human islets to immune-compromised mice is a validated technique to study human beta cells in an in vivo environment. The aim of this study is to show the adaptive changes of human islets to an obese murine environment.

Materials and methods: Twenty nine adult male C57Bl6 RAG 2 immunodeficient nondiabetic mice were transplanted under the kidney capsule with a suboptimal number of human islets (300 islet equivalents -IEQ) from four organ donors. Islets from one donor were transplanted into at least nine mice per condition. Animals were fed 12 weeks with Control or HFD (Research Diets USA). All mice were followed up for weight, 6 hour fasting glycemia and human c-peptide over 12 weeks. After the sacrifice, both endogenous murine pancreas and human grafts were fixed and paraffin embedded for morphometric analysis (endocrine mass, distribution of a,b cells, proliferation) or snap frozen for RNA extraction and gene expression analysis. Oral glucose tolerance tests (2g/kg body weight) were performed at 6 and 12 weeks. **Results:** HFD mice had increased body weights after 4-12 weeks versus controls (p<0.005), and higher serum triglycerides at 12 weeks. Fasting glycemia was higher in HFD mice from 6 weeks on (vs controls 6wk, 12wk, p<0.05). Human c-peptide levels (12wks: controls 1.606±0.54 vs HFD 3.69±0.69 ng/ml cpeptide p<0.005) or human cpeptide/ glycemia (12wks: controls 1.97±0.55 vs HFD 3.87±0.95 hu cpeptide/glycemia, p=NS) was consistently higher in HFD mice. Morphometric analysis of endogenous mouse pancreas re-

vealed doubling of islet mass in HFD mice vs controls. Planimetry confirmed the near doubling of human endocrine graft volume ($0.05\text{mm}^3 \pm 0.009$ vs $0.113\text{mm}^3 \pm 0.02$) and the increase of beta cells (%Beta cell surface/total endocrine surface: control $45.31\% \pm 2.004$ vs HFD $53.52\% \pm 0.1861$; $p=0.01$). Insulin gene expression was increased in grafts transplanted in mice on HFD. Total proliferation (BrdU positive/ total graft surface) was 4 times greater in HFD grafts (12wks) but endocrine and beta cell proliferation were not significantly different.

Conclusion: We exploited an immunodeficient mouse strain sensitive to hifad diet- induced obesity and show for the first time direct evidence that human islets adapt both endocrine and beta cell mass, function, and gene expression to obesity in vivo. This novel model allows for the first time a longitudinal study of human islet compensation to an obese murine environment and may be instrumental in deciphering pathways leading towards human islet expansion.

Developmental programming of pancreatic tissue by maternal high fat feeding

J. Rkhezay Jaf, M.A. Kepczynska, E.T. Wargent, D.C. Hislop, M.A. Cawthorne, J.R.S. Arch, K. Langlands, J.F. O'Dowd, C.J. Stocker; Clore Laboratory, University of Buckingham, UK.

Background and aims: Overnutrition of pregnant rodents affects the development of the pancreas and susceptibility to diabetes in their offspring. We measured β - and α -cell mass in islets of Langerhans and pancreatic insulin content to obtain a deeper understanding of how pancreatic development is altered in offspring of over-nourished mice.

Materials and methods: Female C57BL/6 mice were fed either standard laboratory chow (C; fat 10% by energy) or an isocaloric high fat diet (HF; fat 42%) or for 8 weeks prior to mating. Offspring (referred to as C or HF according to their mother's diet) were all weaned onto chow. At 6 weeks of age the pancreata were harvested from male and female offspring from each maternal dietary group and processed for immunohistochemical analysis and total pancreatic insulin content. Immunohistochemistry was performed using the Aperio Genie™ for insulin and glucagon. Total pancreatic insulin was measured by radioimmunoassay. Data are expressed as mean \pm SEM.

Results: At conception the dams fed the high fat diet were heavier than the chow-fed dams (body weight: HF 31.4 ± 0.6 ; C 25.1 ± 0.4 g; $p<0.0001$) and fatter as measured by DEXA analysis (fat mass: HF 7.8 ± 0.4 ; C 2.5 ± 0.1 g; $p<0.0001$). At 6 weeks of age the body weights of male offspring from high fat-fed mothers were no different from those of chow-fed mothers (HF 25.6 ± 0.6 ; C 25.6 ± 0.3 g) but female HF offspring were surprisingly lighter than C offspring (HF 16.8 ± 0.5 ; C 18.8 ± 0.1 g; $p<0.0017$). Pancreatic weight expressed relative to body weight was higher ($p<0.05$) in HF offspring (HF female 0.95 ± 0.03 ; C female 0.62 ± 0.07 ; HF male 0.83 ± 0.14 ; C male 0.58 ± 0.02). In both male and female HF offspring, the number of islets, but not the average islet size, was increased (HF female 85.6 ± 10.1 ; C female 40.3 ± 8.7 ; HF 70.7 ± 6.3 , C 55.5 ± 9.3). HF offspring had an increased β -cell mass (HF female 0.38 ± 0.05 ; C female 0.27 ± 0.06 ; HF male 0.49 ± 0.07 ; C male 0.35 ± 0.08 mg) and an increased insulin area (HF female 0.32 ± 0.05 , C female 0.14 ± 0.03 ; HF male 0.32 ± 0.04 , C male 0.26 ± 0.06 mm²). α -cell mass was higher ($p<0.05$) in HF than in C female offspring (HF female 0.55 ± 0.12 , C female 0.19 ± 0.05 mg) with a larger glucagon area (HF female 0.32 ± 0.07 , C female 0.16 ± 0.04 mm²). Total pancreatic insulin was higher in HF than C offspring (HF female 9.05 ± 1.53 , C female 7.24 ± 0.37 ; HF male 10.5 ± 1.16 , C male 8.92 ± 0.66 microgram). By 27 weeks of age, despite no difference in pancreas weight, total pancreatic insulin content was increased ($p<0.05$) in HF female offspring when expressed relative to pancreas weight (HF female 119.35 ± 9.36 , C female 97.53 ± 5.11 microgram/g) or relative to body weight (HF female 0.8 ± 0.06 , C female 0.57 ± 0.06 microgram/g).

Conclusion: Maternal overnutrition remodels the endocrine pancreas, causing increased, islet number and α - and β -cell mass.

491

Effect of intrauterine undernutrition during late gestation on pancreatic beta cell mass

M. Fuchita¹, M. Koyanagi², S.-I. Asahara², T. Inoue², Y. Yoshida¹, M. Kasuga³, S. Seino², Y. Kido^{1,2};

¹Department of Biophysics, Division of Medical Chemistry, Kobe University Graduate School of Health Sciences, ²Department of Internal Medicine, Division of Diabetes and Endocrinology, Kobe University Graduate School of Medicine, ³Research Institute, International Medical Center of Japan, Tokyo, Japan.

Background and aims: Impairment of insulin secretion in type 2 diabetes is accompanied by a decrease in the number of pancreatic β cells. A recent study reported that children with low birth weight are likely to have high risk of developing obesity, diabetes, hyperlipidemia, and hypertension in the future. Further, postnatal body weight gain, known as "catch-up growth," occurs in mammals (including humans) with low birth weight. Studies have shown that low-birth-weight rats whose mothers were maintained under poor nutritional conditions during late gestation have lesser number of pancreatic β cells than their normal counterparts. However, the longitudinal effect of undernutrition during the prenatal period on pancreatic β cell mass has not yet been elucidated. In this study, we developed a mouse model with low birth weight induced by starvation of pregnant mice.

Materials and methods: Pregnant C57BL/6J mice were subjected to 70% dietary restriction from late pregnancy (10.5 days postcoitum [dpc]) until delivery. The offspring were divided into 2 groups (food restriction group [RG] and control group [CG]) and were fostered to female ICR mice. At 4 weeks of age, both groups were provided high-fat diets. We examined the blood glucose and serum insulin levels and the pancreatic β cell mass to determine the effect of undernutrition on pancreatic β cells of the mice.

Results: The birth weight of RG offspring was significantly lower than that of CG offspring. Subsequently, RG offspring gained considerable body weight, and their body weight became equivalent to that of CG offspring about 7 days after birth. Pancreatic β cell mass in RG offspring at birth was about 30% less than that in CG offspring. At 8 weeks of age, a high-fat diet increased the pancreatic β cell mass in RG offspring compared to that in CG offspring, but the difference was not statistically significant. However, at 20 weeks of age, the β cell mass in RG offspring decreased and again became comparable to that in CG offspring. Blood glucose levels in RG offspring were higher than those of CG offspring at ≥ 8 weeks of age. However, blood glucose levels between 18-week-old RG and CG offspring did not differ significantly. Serum insulin levels in RG offspring were higher than those in CG offspring up to 20 weeks of age but tended to be lower at ≥ 24 weeks of age. The higher blood glucose and serum insulin levels and increased pancreatic β cell mass in RG offspring during the initial weeks after birth suggested that the offspring had impaired glucose tolerance.

Conclusion: These findings indicate that the growth of pancreatic β cells in mice with fetal undernutrition is insufficient, and pancreatic β cell failure can easily develop as a consequence of insulin resistance in these mice.

492

Alterations in microRNA expression are potentially involved in the decline of function and mass of pancreatic beta cells in type 2 diabetes

V. Nesca¹, R. Laybutt², R. Regazzi¹;

¹Department of Cell Biology and Morphology, Université de Lausanne, Switzerland, ²Department of Cell Biology and Morphology, Garvan Institute of Medical Research, Darlinghurst Australia.

Background and aims: The mechanisms underlying the development of type 2 diabetes are diverse, all leading to the decline of function and/or mass of pancreatic beta-cells. MicroRNAs, a recently discovered class of non-coding RNAs, are potent regulators of key cellular processes, such as proliferation, differentiation and apoptosis. They are able to regulate gene expression by inhibiting the translation of target mRNAs through sequence-specific binding to the 3' untranslated region (3'UTR). In this study we evaluated the possible contribution of microRNAs to the decline of function and mass of pancreatic beta-cells in db/db mice, a well known type 2 diabetes model.

Materials and methods: Microarray analysis was employed to profile the expression of all known microRNAs in pancreatic islets of wild type and diabetic db/db mice. Two microRNAs showing a strong upregulation in the islets of diabetic mice were overexpressed in the mouse insulin-secreting beta-cell line MIN6B1 to test for their impact on insulin secretion and cell survival.

Bioinformatic tools were used to search for putative targets of these microRNAs and computational predictions were validated by western blotting upon overexpression of the microRNAs.

Results: We found that about 60 microRNAs display altered expression in the islets of diabetic db/db mice. In this study, we focused on miR-199a-5p and miR-199a-3p that are increased 12- and 9-fold, respectively, in the islets of diabetic db/db mice. Overexpression of miR-199a-5p in the beta-cell line MIN6B1 led to defective glucose-induced insulin secretion, while a rise in miR-199a-3p caused an increase in apoptosis. Western blot analysis revealed that overexpression of miR-199a-5p results in the upregulation of granuphilin a potent inhibitor of insulin secretion, and of Sirt 1 an NAD-dependent protein deacetylase that modulates cellular response to stress and altered metabolic flux. On the other side, overexpression of miR-199a-3p reduced the level of mTOR, a serine/threonine kinase playing a key role in beta-cell survival.

Conclusion: Our data suggest that miR-199a-5p and miR-199a-3p, two microRNAs issued from the same precursor, may contribute to beta-cell failure during instauration of type 2 diabetes: with miR-199a-5p causing defective insulin secretion, and miR-199a-3p having a negative effect on pancreatic beta-cell survival.

Activation of free fatty acid receptor FFA1/GPR40 by small agonists exerts beneficial effects on beta cell function and survival

S. Ullrich¹, K. Noack², M. Pfeleiderer¹, K. Liebscher¹, F. Ranta¹, G. Drews², E. Christiansen³, T. Ulven³, H.-U. Häring¹;

¹Internal Medicine and Clinical Chemistry, University of Tübingen,

Germany, ²Pharmacology and Toxicology, University of Tübingen, Germany,

³Physics and Chemistry, University of Southern Denmark, Odense, Denmark.

Background and aims: The insulinotropic effects of long chain free fatty acids (FFAs) including palmitate and oleate depend on the activation of free fatty acid receptor 1 (FFA1/GPR40) whereas adverse effects of FFAs rather depend on cellular accumulation and action of FFA metabolites. The G-protein coupled receptor FFA1/GPR40 couples to G_q and activates PLC and Ca^{2+} release from internal Ca^{2+} -stores. This study examined the effects of a small receptor agonist of FFA1 on insulin secretion and beta-cell survival and analysed the underlying mechanisms.

Materials and methods: The compound TUG-469 which contains a para-substituted dihydrocinnamic acid moiety and binds specifically to FFA1 was chosen to activate FFA1 in insulin secreting cells. Insulin secretion in response to TUG-469 was tested in static incubations of INS-1E cells, of isolated human islets and of WT and FFA1 knockout mouse islets. The release of Ca^{2+} from intracellular IP_3 -sensitive stores was inhibited by xestospongine, from ryanodine-sensitive stores by ryanodine. $[Ca^{2+}]_i$ was measured with the fluorescence dye fura-2. Apoptotic cell death was assessed by TUNEL and cleaved caspase-3 staining.

Results: In INS-1E cell, the FFA1 agonist TUG-469 (10 μ M) enhanced glucose (12 mM)-stimulated but not basal (2.8 mM glucose) insulin secretion. In aged, glucose-insensitive INS-1E cells TUG-469 still significantly augmented insulin release at high but not at low glucose. In parallel, TUG-469 increased $[Ca^{2+}]_i$ only at 12 mM but not at 2.8 mM glucose. Surprisingly, stimulation of secretion by TUG-469 was neither inhibited by ryanodine (1 and 100 μ M) nor by xestospongine (1 and 10 μ M). When INS-1E cells were cultured for prolonged time with TUG-469 (10 μ M for 2 d) no increase in apoptotic cell death was measured by TUNEL or cleaved caspase-3 staining. In contrast, palmitate significantly augmented apoptotic cell death of INS-1E cells and mouse islet cells. In islet cells from FFA1 KO mice palmitate induced apoptosis already at lower concentrations than in WT islet cells suggesting that FFA1 activation does not augment but even protects from apoptosis. In isolated human islets which express FFA1 TUG-469 (10 μ M) enhanced insulin secretion by 60 % and was, thus, as potent as palmitate.

Conclusion: These results suggest that the specific FFA1 agonist TUG-469 represents an attractive therapeutic tool to augment insulin secretion in a glucose-dependent manner.

Mechanisms of autophagy activation in pancreatic beta cells

L. Martino¹, M. Masini¹, M. Novelli¹, P. Beffy², M. Bugliani³, L. Marselli³, A. Pippa¹, V. De Tata¹, P. Marchetti³, P. Masiello¹;

¹Dip. Patologia Sperimentale B.M.I.E., University of Pisa, ²Istituto di Fisiologia Clinica, CNR, ³Dip. Endocrinologia e Metabolismo, University of Pisa, Italy.

Background and aims: In type 2 diabetes (T2D) a progressive decrease of beta-cell function and mass represent a common feature of the disease development. Beta cells, because of their continuous and sustained secretory activity, are constantly exposed to various kinds of stress from misfolded proteins, endoplasmic reticulum (ER) overload and mitochondrial damage. We have recently observed an autophagic vacuole accumulation in beta cells of T2D patients, associated with irreversible cell damage. This suggests that autophagy, a self-digesting mechanism normally responsible for removal of altered organelles and proteins, when exuberant or dysfunctional, might trigger non-apoptotic beta-cell death in diabetic patients. The aim of this study was to investigate the *in vitro* effects of increased levels of glucose and free fatty acids on autophagy activation in pancreatic beta cells.

Materials and methods: A well-differentiated beta-cell line (INS-1E) and isolated rat and human pancreatic islets were incubated for various time pe-

riods (from 0 to 24 h) at different concentrations of glucose (5, 11, 16.7 and 25 mM) and/or palmitic acid (0.1, 0.5 and 1.0 mM). Then, cell survival was evaluated and autophagy activation was explored by a) monodansyl cadaverine (MDC) and cathepsin D fluorescence; b) activation of LC3 protein; c) ultrastructural observation and morphometric analysis of autophagic vacuoles.

Results: In INS-1E cells and rat and human islets, autophagy was markedly activated in beta cells upon exposure to 0.5 and 1.0 mM palmitate (PA), but was not further enhanced by the concomitant presence of high glucose. High glucose alone was ineffective. In particular, the proportion of cells containing MDC-stained dots and the expression of the activated LC3-II band in Western blots considerably increased after 6 h of palmitate incubation. Moreover, LC3-II immunofluorescence co-localized with that of cathepsin D, a lysosomal marker, indicating that the autophagic flux was not impaired in PA-treated cells. Most of these effects were maintained up to 18–24 h incubation and were associated with a significant decline of cell survival, which was correlated with both palmitate concentration and incubation time. Ultrastructural analysis showed the presence of abundant autophagic vacuoles in PA-exposed beta cells, associated with a diffuse and remarkable swelling of the endoplasmic reticulum.

Conclusion: Our results clearly indicate that among the metabolic alterations occurring in T2D, high free fatty acids levels might play a major role in the activation of autophagy in beta cells, possibly leading to irreversible cell damage, through a mechanism that might involve the induction of ER stress.

Apoptotic beta cell death independent of activation of transcription factor FOXO1: effects of glucocorticoids and the role of PKB/AKT isoforms

G. Schulz-Raffelt¹, F. Ranta¹, F. Lang², H.-U. Häring¹, S. Ullrich¹;

¹Internal Medicine IV, ²Institute of Physiology, University of Tübingen, Germany.

Background and aims: Insulin receptor signalling pathways play an important role in maintenance of beta-cell function. The protective effects include the PKB/AKT-dependent phosphorylation of the proapoptotic transcription factor FOXO1. The phosphorylated form of FOXO1 is inactive due to its cytosolic retention. Our previous results suggest that the synthetic glucocorticoid dexamethasone (dexa) increased apoptotic beta-cell death, reduced PKB phosphorylation and increased the protein amount of FOXO1 which, unexpectedly, remained phosphorylated and cytosolic. We now performed experiments to determine the isoforms of PKB/AKT which phosphorylate FOXO1 and examined the role of FOXO1 during glucocorticoid-dependent apoptosis of insulin secreting cells.

Materials and methods: Expression levels of FOXO1 and of AKT1, AKT2 and AKT3 were analyzed by RT-PCR in insulin secreting INS-1E cells under control culture conditions and after treatment with dexa (100 nM) in the absence and presence of the glucocorticoid receptor (GR) inhibitor RU486 (1 µM). Protein levels and phosphorylations were examined by Western blotting. Knockdown of specific PKB/AKT isoforms was achieved by transfection with specific siRNA. Subcellular distribution of FOXO1 was examined after immunohistochemical staining using confocal microscopy. Apoptotic cell death was quantified by TUNEL and cleaved caspase-3 staining.

Results: INS-1E cells contain mRNA of PKB/AKT isoforms with the following order of expression levels: AKT1 (17.4 copies/GAPDHx1000) > AKT3 (3.8 copies/GAPDHx1000) > AKT2 (2.1 copies/GAPDHx1000). Dexa treatment did not change the expression levels of AKT isoforms but increased GR-dependent the expression of FOXO1 2.5-fold. Surprisingly, knockdown of AKT1 and AKT2 expression, either individually or in combination, neither affected phosphorylation nor protein amount of FOXO1 in control and dexa-treated cells. Consistently, FOXO1 remained cytosolic. The assumption that AKT3 may be sufficient to maintain FOXO1 phosphorylated and inhibited is supported by the finding that the unspecific PKB/AKT inhibitor Akti-1/2 abolished phosphorylation and induced nuclear accumulation of FOXO1. Simultaneous staining of cells for FOXO1 and cleaved caspase-3 confirmed apoptotic cell death without nuclear accumulation of FOXO1. However, Akti-1/2 accelerated dexa-induced apoptosis.

Conclusion: These data suggest that phosphorylation of FOXO1 is maintained in insulin secreting cells even when AKT1 and AKT2 expression are inhibited up to 90 %. Dexa-induced apoptosis does not depend on but is aggravated by activation of FOXO1.

L-arginine is essential for pancreatic beta cell functional integrity, metabolism and defence from inflammatory challenge

M. Krause^{1,2}, N.H. McClenaghan³, P.R. Flatt³, J. Rodrigues Krause¹, C. Murphy¹, P. Newsholme²;

¹Department of Science, Institute of Technology Tallaght, Ireland, ²School of Biomolecular and Biomedical Science, University College Dublin, Ireland,

³School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: Glucose is known to stimulate insulin secretion via rapid metabolism and generation of key stimulus-secretion coupling factors including ATP. Specific amino acids are also known to be insulinotropic, utilizing various mechanisms of action. The aim of this study was to determine whether L-arginine (a known insulinotropic amino acid) could promote a shift of β-cell intermediary metabolism favoring glutathione (GSH+GSSG) anti-oxidant responses, stimulus-secretion coupling, and functional integrity. **Materials and methods:** Clonal BRIN-BD11 β-cells and mouse islets were cultured for 24h at various L-arginine concentrations (0 to 1.15mmol L⁻¹) in the absence or presence of a sub-lethal pro-inflammatory cytokine cocktail (IL-1β, TNFα, IFNγ). Cells and Islets were assessed for viability, insulin secretion, GSH, GSSG, glutamate, NO•, superoxide, urea, lactate, and for the consumption of glucose and glutamine. Protein levels of NO synthase (NOS-2), AMPK and the HSP72 were also evaluated.

Results: L-arginine at 1.15 mmol L⁻¹ attenuated the loss of β-cell viability observed in the presence of pro-inflammatory cytokines. L-arginine increased cellular levels of reduced glutathione [from 0.13±0.01 (without arginine) to 0.91±0.14µg/mg protein, in the presence of 1.15mM L-arginine] and glutamate [from 6.42±0.5 (without arginine) to 12.8±0.7µg/mg protein, in the presence of 1.15mM L-arginine] but reduced the GSSG/GSH ratio and glutamate release [from 4.15±0.4 (without arginine) to 2.46±0.4µg/mg protein in the presence of 1.15mM L-arginine]. L-Arginine stimulated glucose consumption in the presence of cytokines [from 15.57±2.35 (without arginine) to 27.6±2µg/mg protein, in the presence of 1.15mM L-arginine] while also stimulating AMPK phosphorylation and HSP72 expression. Pro-inflammatory cytokines reduced, by at least 50%, chronic (24h) insulin secretion, an effect partially attenuated by L-arginine [from 928.3±44.6 (without cytokines) to 425.3±108µg/mg protein/24h, in the presence of cytokine cocktail]. Acute (20min static incubation) insulin secretion was robustly stimulated by L-arginine [from 0.06±0.004 (without arginine) to 0.832±0.03µg/mg protein/20min, in the presence of 1.15mM L-arginine] but this effect was abolished in the presence of cytokines.

Conclusion: L-arginine stimulated β-cell insulin secretion, anti-oxidant and protective responses, with increased functional integrity of β-cells and islets in the presence of pro-inflammatory cytokines. Glucose consumption and intermediary metabolism were increased by L-arginine. These results highlight the importance of L-arginine availability for beta-cells during inflammatory challenge which may be associated with both type 1 and type 2 diabetes.

Antioxidant and antiapoptotic effects of ZnCl₂ in rat pancreatic islets cultured in low and high glucose concentrations

J. Duprez, L.P. Roma, A.-F. Close, J.-C. Jonas;

Pole of endocrinology, diabetes and nutrition, Université catholique de Louvain, Brussels, Belgium.

Background and aims: During prolonged culture of rat islets, glucose markedly decreases cell apoptosis from 5 to 10 mM and increases it moderately from 10 to 30 mM. A similar asymmetric V-shaped profile was observed for glucose-induced changes in the mRNA levels of oxidative stress response genes such as Metallothionein 1a (Mt1a), a metal-detoxifying protein that also exert antioxidant effects in various cell types. This suggests a possible link between oxidative stress and apoptosis under these conditions. In this study, we tested the effect of ZnCl₂, a potent inducer of metallothionein expression, on oxidative stress and islet cell apoptosis induced by low and high glucose concentrations.

Materials and methods: Male Wistar rat islets were cultured for up to 1 week in serum-free RPMI medium containing 5 g/l BSA and 5, 10, or 30 mM glucose (G5, G10, G30) ± 100 µM ZnCl₂. Islet gene mRNA levels were measured by RTq-PCR. Apoptosis was quantified by measuring islet cell histone-associated DNA fragments (commercial ELISA) and by the percentage of TUNEL-positive beta cells. Thiol/disulfide equilibrium was measured as an indica-

tor of mitochondrial oxidative stress in rat islet cell clusters infected with an adenovirus coding “redox sensitive GFP” targeted to the mitochondria (mt-roGFP). Briefly, cells were cultured overnight in the presence of 10% FBS and G5, G10 or G30 \pm 50 μ M ZnCl₂. After culture, mt-roGFP fluorescence ratio (exc: 400/480 nm, em: 535 nm) was measured for 20 min at the same glucose concentration and normalized to the ratio measured after addition of 10 mM dithiothreitol (full reduction, 0%) followed by 1 mM H₂O₂ (full oxidation, 100%). Results are means \pm SEM for at least 3 experiments. Statistical significance of differences between groups was assessed by 1-way ANOVA followed by a test of Newman-Keuls.

Results: In comparison with G10, culture of islets in G5 or G30 significantly increased Mt1a to Tbp mRNA ratio (~50-fold in G5 and ~15-fold in G30) and apoptosis (~12-fold in G5 and ~2 to 4-fold in G30). Culture of dispersed islet cells in G5 and G30 vs. G10 also significantly increased mt-roGFP oxidation (normalized ratios: from 28 \pm 2% in G10 to 44 \pm 2% in G5; from 24 \pm 2% in G10 to 35 \pm 3% in G30). Treatment of islets with 100 μ M ZnCl₂ strongly increased the expression of Mt1a mRNA and protein levels at all glucose concentrations. These effects were accompanied by parallel reductions in early mt-roGFP oxidation and late beta cell apoptosis. Thus, in islet cell clusters, addition of 50 μ M ZnCl₂ to the culture medium significantly reduced by ~40% the increase in mt-roGFP oxidation induced by G5 (normalized ratio: from 44 \pm 2 to 37 \pm 2%), and by ~23% that induced by G30 (normalized ratio: 35 \pm 3 to 32.5 \pm 2). In whole rat islets cultured for 3 to 7 days, addition of 100 μ M ZnCl₂ significantly reduced by at least 27% the stimulation of beta cell apoptosis induced by G5, and by 40–65% the stimulation of apoptosis by G30.

Conclusion: ZnCl₂ protects beta cells from apoptosis during prolonged culture of rat islets in low and high vs. intermediate glucose concentrations. The mechanism involved might depend on metallothionein expression and reduction of mitochondrial oxidative stress.

Impact on beta cells of myokines secreted by skeletal muscle of differing insulin sensitivity and fibre type

K. Bouzakri¹, P. Plomgaard², B.K. Pedersen², P.A. Halban¹;

¹Department of Genetic Medicine and Development, CMU, Geneva, Switzerland, ²Department of Infectious Diseases and CMRC, Centre of Inflammation and Metabolism, Copenhagen, Denmark.

Background and aims: Decreased beta-cell functional mass and insulin resistance are hallmarks of type 2 diabetes (T2DM). We have shown crosstalk between skeletal muscle of different insulin sensitivity and beta-cells, suggesting that myokines secreted by insulin-resistant skeletal muscle could contribute towards decreased beta-cell function/mass in T2DM. In obese and T2DM individuals, the distribution of muscle fiber types is shifted toward faster, more glycolytic fibers. Therefore, we explored the potential communication of human skeletal muscle cells of different fiber type with different insulin sensitivity and pancreatic beta-cells.

Materials and methods: Human skeletal muscle biopsies were collected from vastus lateralis (V), soleus (S) and triceps (T) and cells with different fiber type were cultured. mRNA expression of genes involved in carbohydrate or lipid metabolism and mitochondrial factors were measured by quantitative RT-PCR. Human myotubes where treated for 24h with or without (control) 20 ng/ml TNF- α to induce insulin resistance. Conditioned media from the fiber types (test: TNF- α -CM-S, V, T; control: C-CM-S, V, T) were collected. Sorted rat primary beta-cells were used to test effects of conditioned media for 24h on death (TUNEL), proliferation (BrdU incorporation) and glucose-stimulated insulin secretion. Data are mean \pm SE with statistical significance ($p < .05$) for all indicated differences.

Results: Muscle cells (n=8) isolated from triceps showed higher expression of phosphofructokinase and lactate dehydrogenase (LDH) A whereas LDH B and hexokinase II were highly expressed in soleus and vastus cells. Lipoprotein lipase CD36 and hormone sensitive lipase were predominantly expressed in soleus and vastus muscle cells. Mitochondrial factors were similarly expressed in V, S and T myotubes, with only PPAR gamma more highly expressed in T. CM-S, -V, -T increased GSIS, whereas TNF- α -CM-S, and -V decreased GSIS to a similar extent. Interestingly, TNF- α -CM-T had no impact on GSIS. Beta-cells treated with either TNF- α -CM-S or -V showed increased death (11 \pm 2 and 13 \pm 3.5 fold increased TUNEL⁺ respectively), and decreased proliferation vs. control conditioned media (7.3 \pm 1.7 vs. 1.1 \pm 0.4 and 6.9 \pm 1.2 vs. 0.9 \pm 0.1 % BrdU positive cells, C-CM-S,V vs. TNF- α -CM-S,V). Again, TNF- α -CM-T treatment had no impact on these parameters vs. C-CM-T treatment. Finally, C-CM-S, V, T all increased beta-cell prolifera-

tion (4.7 \pm 0.3 vs 7.3 \pm 0.6 vs. 6.8 \pm 1.2 vs. 8.6 \pm 1.1 % BrdU positive cells respectively).

Conclusion: Taken together these results show that skeletal muscle prepared from biopsies with different fiber composition retain *in-vitro* their *in-vivo* phenotype. Moreover the impact on pancreatic beta cells of human skeletal muscle cells is fiber specific, with both positive and negative effects depending on different insulin sensitivity. The identification of the fiber specific myokines and their molecular targets on beta-cells may lead to new therapeutic strategies for preservation of functional beta-cell mass in T2DM.

499

Aminoacidotoxicity, a potential contributor to beta cell dysfunction in type 2 diabetes: studies *in vitro*

K. Hermansen¹, Z. Liu¹, S. Gregersen¹, L. Bach Larsen^{1,2}, P. Bendix Jeppesen¹;

¹Dept of Endocrinology and Metabolism, Aarhus University Hospital, ²Dept of Food Science, Aarhus University, Tjele, Denmark.

Background and aims: Pancreatic β -cell dysfunction due to elevated glucose and free fatty acids i.e. gluco- and lipotoxicity with increased basal insulin secretion (BIS) and impaired glucose stimulated insulin secretion (GSIS) has been amply demonstrated in type 2 diabetes (T2D). Despite elevated levels of certain amino acids in T2D e.g. leucine, little is known about the chronic effects of amino acids on β -cell function. We investigated the effect of chronically elevated concentrations of leucine on β -cell function, on contents of cholesterol (CH) and triglycerides (TG) in β -cells and on expression of genes related to β -cell metabolism.

Materials and methods: Isolated mouse islets from adult female NMRI mice and clonal β -cell line, INS-1E cells, were incubated with or without addition of 1 - 10 mM leucine. Insulin was analyzed by RIA. ³H-thymidine incorporation was used to monitor INS-1E cell proliferation and DNA synthesis. RT-PCR was performed using an ABI 7500 FAST PCR machine. CH and TG content in INS-1E cells were determined by a CH GHOD-PAP kit and a TG GPO-PAP kit, respectively. Identification of INS-1E cell proteins was performed by MALDI-TOF mass spectrometry.

Results: After 72 h incubation in isolated islets and INS-1E cells, leucine (1-10 mM) significantly increased BIS ($p < 0.05$ -0.01) and decreased GSIS ($p < 0.01$ -0.001) corroborating our hypothesis of the existence of aminoacidotoxicity. The impairment of the β -cell function in INS-1E cells took place concomitantly with alterations in proteins and genes involved in insulin granule transport and trafficking (e.g. CRMP-2 and Ran) and the oxidative phosphorylation pathway (cytochrome c oxidase ($p < 0.001$)). Leucine down-regulated the expression of insulin 1 gene ($p < 0.001$), whereas Pdx1 ($p < 0.001$) and insulin 2 genes ($p < 0.001$) were up-regulated. Leucine (1, 5, and 10 mM) decreased ³H-thymidine incorporation in INS-1E cells ($p < 0.01$ -0.001), indicating a leucine-induced suppression of INS-1E cell proliferation. Proteomic studies showed that leucine (5 mM) increased the autophagy related enzyme, cathepsin D ($p < 0.01$), decreased serine/threonine-protein phosphatase PP1 ($p < 0.05$), which is related to phosphorylation/dephosphorylation states of proteins, and decreased GTP-binding nuclear protein ($p < 0.05$) and increased dihydropyrimidinase related protein-2 ($p < 0.05$), which are related to insulin granule transport/trafficking. Importantly, in INS-1E cells accumulation of CH ($p < 0.05$ -0.01) took place concomitantly with an up-regulation of enzymes involved in CH biosynthesis (e.g. Hmgcs1, Hmgcr, Mvd, Sqle, and Ldlr ($p < 0.001$ for all)), whereas TG content was decreased ($p < 0.001$).

Conclusion: Our findings indicate that chronic exposure to elevated levels of leucine induces β -cell dysfunction (i.e. aminoacidotoxicity) and accumulation of CH, changes in CH metabolism, mitochondrial metabolism and insulin granule transport/trafficking which may contribute to the development of T2D.

500

Beta cell protective effects of using 2-aminobicyclo[2.2.1]heptan-2-carboxylic acid (BCH) as the glutamate dehydrogenase (GDH) activator in db/db mice

S. Han¹, S.-E. Choi¹, S.-A. Yi¹, H. Kim¹, J. Kim¹, K. Lee¹, Y. Kang²;

¹Endocrinology and metabolism, ²Laboratory of Endocrinology, Institute for Medical Sciences, Ajou University School of Medicine, Suwon, Republic of Korea.

Background and aims: Glutamate dehydrogenase (GDH) is mitochondria enzyme that converts glutamate to α -ketoglutarate, and vice versa, playing an

important role in amplification of glucose-stimulated insulin secretion (GSIS). Recently we found that GDH activator, 2-aminobicyclo-heptan-2-carboxylic acid (BCH) had a strong protective effect on the high glucose/palmitate (HG/PA)-induced INS-1 cell death. We initially examined whether BCH restored HG-induced reduction of GSIS, and HG/PA-induced reduction of insulin gene expression. Next, we investigated which death-related signal is affected by BCH. Finally, we studied the effects of BCH on glycemic control and pancreatic β -cell integrity in db/db mice.

Materials and methods: INS-1 cells were incubated with 25 mM glucose and 0.5 mM palmitate in the absence or presence of 10 mM BCH. We evaluated GSIS, insulin gene expression, and DNA fragmentation. An in vivo study was performed, in which seven-week-old diabetic db/db mice were treated with BCH (0.7 g/kg, $n = 10$) and with placebo ($n = 10$) for 6 weeks. After treatment, an intraperitoneal glucose tolerance test and immunohistologic examinations were performed.

Results: Treatment with BCH restored the HG-induced GSIS inhibition and down-regulated insulin gene expression by HG/PA in INS-1 cells. In addition, treatment with BCH significantly decreased HG/PA-induced INS-1 cell death and phosphor-JNK expression. BCH treatment improved glucose tolerance as well as increasing insulin secretion in db/db mice. BCH treatment increased the percentage of insulin-positive β -cell-to-total islet area ($p < 0.05$) and decreased the percentage of β -cell expressing cleaved caspase 3 ($p < 0.05$).

Conclusion: BCH as the activator of GDH improved the glycemic control. This anti-diabetic effect may be associated with improved insulin secretion, and the preservation of islet architecture, and decreased β -cell apoptosis.

Conclusion: Together, we characterized the kinetic progression of beta-cell death under different conditions and highlighted a novel method for the discovery of compounds that can prevent beta-cell death. Since diabetes results from a deficiency in functional beta-cell mass, high-content screening will assist in the discovery of therapeutics for improving beta-cell survival.

Live cell tracking of apoptotic and non-apoptotic beta cell death: multi-parameter high-content screening for compounds that prevent beta cell apoptosis

Y.H.C. Yang, J.D. Johnson;

Department of Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada.

Background and aims: Diabetes is a debilitating disease caused by an absolute or relative deficiency in functional pancreatic beta-cell mass. In type 1 diabetes, the specific autoimmune destruction of pancreatic beta-cells leads to an almost complete ablation of beta-cell mass. Type 2 diabetes is characterized by insulin resistance and a decrease in insulin secretion due in part to increased beta-cell death. Theoretically, the course of the disease could be reversed by preventing beta-cell death due to the ongoing autoimmune attack and promoting beta-cell growth. The aims of the present study were to characterize the mode of beta-cell death under different conditions related to diabetes (hyperglycaemia, cytokine and fatty acid exposure, nutrient deprivation, ER stress) and identify compounds that can prevent beta-cell death through high-content screening.

Materials and methods: Dispersed mouse islet cells and MIN6 cells were infected with lentiviral particles carrying a FRET reporter that allows for simultaneous assessment of caspase-3-dependent apoptosis and insulin promoter activity in live cells (eBFP2-DEVD-eGFP downstream of the insulin promoter), and pdx1 promoter activity (mRFP). Nuclear morphology and cell number were assessed with Hoechst 33342 DNA dye. Propidium iodide and AlexaFluor647-conjugated AnnexinV were used to assess different stages of cell death. Bright field images allowed for detection of plasma membrane morphological changes. Cells were cultured in 5 or 20 mmol/L glucose media and exposed to either a cytokine cocktail (TNF- α , IL-1 β , IFN- γ), palmitate, thapsigargin, or serum free media. High-content imaging was conducted using Molecular Devices ImageXpress^{MICRO} temperature- and CO₂-controlled instrument. This eight-parameter high-content screening was conducted on MIN6 cells exposed to a cytokine cocktail and treated with the Prestwick library of off-patent drugs.

Results: Both apoptotic and non-apoptotic beta-cell death were observed when MIN6 cells were exposed to a cytokine cocktail. Apoptosis was the most prominent form of cell death, as characterized by caspase-3 activation, nuclear condensation, AnnexinV incorporation, and membrane blebbing, prior to propidium iodide incorporation. Non-apoptotic modes of beta-cell death were also observed when cells were exposed to other cell death inducers. Through multi-parameter high-content screening we discovered compounds that can reduce the level of cytokine induced beta-cell death. Eleven different drugs from a library of 1120 were selected for follow-up hit confirmation, including vitamin D2, D3, B5, vitamin E analogs, and other drugs known to have anti-apoptotic effects in different cell types.

PS 028 GLP-1 secretion

Synergism by individual macronutrients explains the marked incretin and islet hormone response to mixed meal: exploration of a novel experimental tool, the oral meal tolerance test in mice

L. Hansson¹, J. Vikman¹, G. Pacini², B. Åhrén¹;

¹Medicine, Clinical Sciences, Lund, Sweden, ²Metabolic Unit, Biomedical Engineering, Padova, Italy.

Background and aims: The glucagon-like peptide-1 (GLP-1) and insulin responses to oral glucose have been well characterised. Fatty acids and proteins also stimulate GLP-1 and islet secretion, however, the relative contribution of the macronutrients to the GLP-1 and insulin response to mixed meal is not known. We therefore explored a novel tool - the oral meal tolerance test (MTT) in mice - to evaluate the differential macronutrient impact on GLP-1 and islet responses to mixed meal.

Materials and methods: Fasted and anesthetized C57BL/6J mice were orally gavaged with 1) a mixed meal consisting of glucose, whey protein and peanut oil with a total caloric load of 0.285 kcal or single macronutrients at same caloric load as mixed meal. For comparison, 2) a test with glucose, whey protein or peanut oil was given in the same quantity as in the mixed meal, i.e., 0.17 kcal glucose, 0.055 kcal whey protein or 0.055 kcal peanut oil. Blood was collected before and 15, 30, 60 and 90 minutes after oral challenge for plasma glucose and insulin analysis and before and 5, 10 and 20 minutes after oral challenge for active GLP-1 determination in plasma.

Results: The early (0–15 min) insulin response to mixed meal was significantly higher (2.8 ± 0.3 nM) when compared to isocaloric loads of glucose (1.7 ± 0.3 nM, $P=0.02$), protein (945 ± 112 pM, $P=0.0002$) and peanut oil (227 ± 28 pM, $P=0.00001$). For comparison, the insulin response (0–15 min) to mixed meal was substantially higher (2.5 ± 0.3 nM) than the response to the single macronutrients in meal quantity (887 ± 140 pM for glucose, 118 ± 45 pM for whey protein and 46 ± 27 pM for peanut oil). Early (0–5 min) increase in active GLP-1 was observed after both mixed meal (2.5 ± 0.2 pg/ml) and glucose (2.5 ± 0.3 pg/ml), however sustained by mixed meal only (3 ± 0.4 pg/ml), whereas no increase in active GLP-1 was observed after glucose and fat alone. No change in plasma glucagon levels was detected between mixed meal and single macronutrients.

Conclusion: This novel approach to explore incretin and insulin secretion in mice revealed that the marked early insulin response to mixed meal emanates from a synergistic, rather than an additive effect of the macronutrients and this is most likely caused by increased GLP-1 secretion. Hence, superior to glucose alone, the MTT offers a physiological tool for exploration of incretin and islet hormone secretion in studies on integrative metabolism and drug development.

In humans, the removal of duodenum increases GLP-1 secretion

G. Muscogiuri¹, G. Sorice¹, T. Mezza¹, A. Priolella¹, J.J. Holst², A. Giaccari¹;

¹Department of Endocrinology, Rome, Italy, ²Diabetes Division, Copenhagen, Denmark.

Background and aims: Obesity has reached epidemic proportions and bariatric surgery has emerged as an acceptable treatment for morbid obesity and, recently, as the most effective therapy for type 2 diabetes. The initial assumption was that the mechanism causing this effect was through weight loss. It is becoming evident that the anti-diabetic effect is not entirely explained by weight loss as there is a consistent observation that the improvement of glucose and insulin levels occurs within days after RYGB, clearly before any clinically relevant weight loss. Instead the 'hindgut' proposes that rapid delivery of partially digested nutrients to the distal bowel up-regulates the secretion of incretins such as glucagon-like peptide-1 (GLP-1).

Materials and methods: To examine the actual role of duodenum in regulating GLP-1 secretion, we studied 11 (6 men, 52.8 ± 2.7 years, body mass index: 28.0 ± 5.5 kg/m²) normal glucose tolerant humans before and after duodenum head pancreatectomy with a 240-min meal test, assaying plasma concentration of GLP-1, GIP, glucagon, insulin, C-peptide and glycaemia.

Results: Post-challenge insulin and C-peptide levels were significantly lower after partial pancreatectomy ($P < 0.01$), although the biphasic physiological insulin secretion after the meal was preserved. When compared with the pre-surgery study, the oral meal ingestion elicited an increase in GLP-1 concen-

trations ($P=0.01$) along with a decrease in GIP secretion ($P<0.01$). Interestingly, the greater the increase in the GLP-1 secretion after surgery, the lower was the reduction in insulin ($r=-0.5$; $p=0.02$) and C-peptide ($r=-0.4$; $p=0.03$). The glucose-induced glucagon suppression did not change after surgery, probably as a consequence of the increase in GLP-1 levels.

Conclusion: The removal of duodenum and the subsequent anastomosis with the ileum caused a significant increase in GLP-1 associated with a significant decrease in GIP. We believe that the removal of duodenum may play an important role in the modulation of GLP-1 secretion and that it may help in explaining some of the data emerging for studies of gastric bypass surgery.

504

Glucose absorption rate and insulin sensitivity assessment during a mixed tube infusion in the duodenum, jejunum and ileum in insulin resistant, normo-tolerant obese subjects

S. Salinari¹, A. Bertuzzi², C. Guidone³, M. Riccioni⁴, A. Manto³, S. Cercone⁵, R.D. Carr⁵, G. Ghirlanda³, G. Mingrone³;

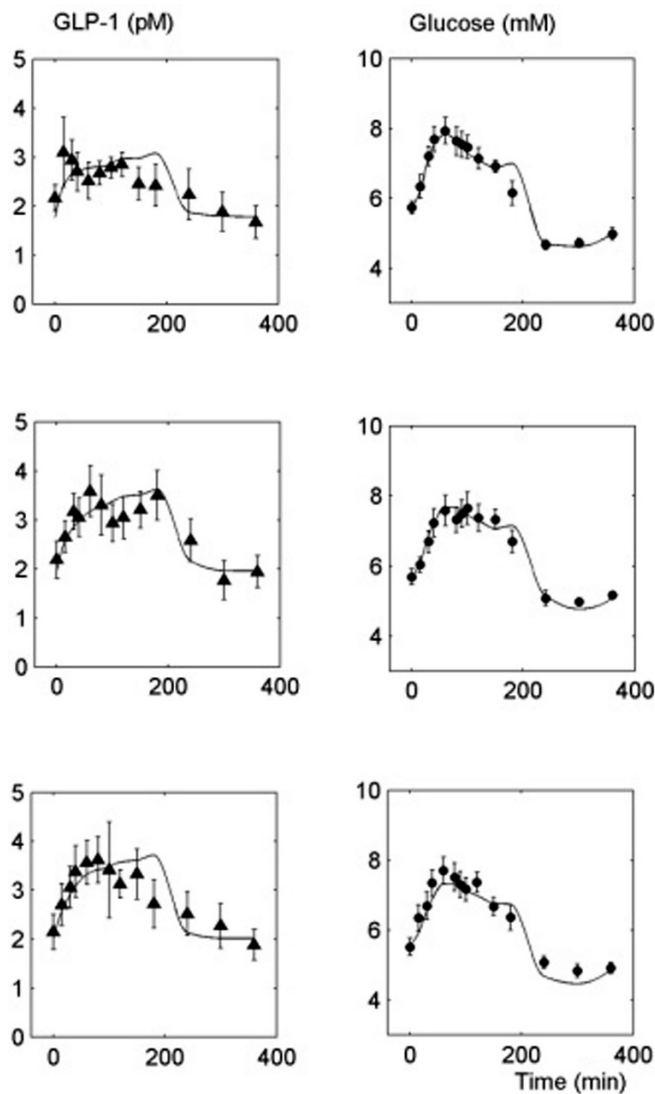

¹Dpt. of System and Computer Sciences, University of Rome, ²Institute of System Science and Informatics, National Research Council (CNR), ³Dpt. of Internal Medicine, Catholic University of Rome, ⁴Dpt. of Surgery, Catholic University of Rome, ⁵Merck Sharp & Dohme Italy and International, Italy.

Background and aims: Duodenal and jejunum bypass as obtained by bariatric surgery results in improvement/resolution of type 2 diabetes (T2D) and improvement of insulin resistance. It has been argued that bypass of the proximal bowel may reduce glucose absorption, which could, at least in theory, improve postprandial glucose homeostasis. Intestinal lipid malabsorption, resulting from the diversion of bilio-pancreatic juices into the terminal ileum, has also been proposed as an alternative hypothesis for the control of diabetes after bilio-pancreatic diversion. However, the mechanisms through which these findings happen are not still elucidated. Aim of the present study is to investigate the differences in insulin sensitivity due to nutrients infusion in different portions of the small intestine, namely duodenum (D), jejunum (J) and ileum (I) in insulin resistant, normo-tolerant (NGT) subjects.

Materials and methods: Ten NGT obese subjects (7 W, 3 M) 45.9 ± 9.1 years old and with a BMI of 39.1 ± 0.7 kg/m² were studied in 3 different occasions. An energy dense tube feed (Nutrison Energy) was infused over 180 minutes in the duodenum, proximal jejunum or ileum and blood drawing was continued over further 180 minutes. Overall, 55.5 g of carbohydrates, 18 g of proteins and 17.4 g of fat were infused. The glucose Ra time course, and the insulin sensitivity were calculated by a validated mathematical model providing an expression for the release of incretin hormones as related to glucose transit into the gut lumen. The model was fitted on the population data (Figure).

Results: The highest glucose absorption rate was observed in the ileum (27.96 ± 5.47 vs 17.60 ± 6.43 D and vs 20.85 J min⁻¹, $P<0.05$). The glucose effectiveness ($SG \times 10^2$) was similar ($P=NS$) in the three intestinal segments (2.80 ± 1.23 D vs 2.73 ± 1.42 J and 3.49 ± 1.22 I). The insulin sensitivity ($SI \times 10^4$) was 40% higher when the test meal was infused in the ileum (0.98 ± 0.42 min⁻¹ pM⁻¹) than in the duodenum (0.55 ± 0.22) and the jejunum (0.68 ± 0.26), $P<0.015$ I vs D.

Conclusion: The delivery of an energy dense tube feed, containing carbohydrates, proteins and lipids, into the ileum enhances glucose absorption simultaneously improving insulin sensitivity.

505

Lipid triggered GLP-1 secretion from primary L-cells

E. Diakogiannaki, F.M. Gribble, F. Reimann;
Clinical Biochemistry, University of Cambridge, UK.

Background and aims: Glucagon-like peptide 1 (GLP-1) is a hormone secreted by enteroendocrine L-cells found scattered along the length of intestinal tract with highest density in the distal ileum and colon. Apart from being a critical regulator of insulin secretion, GLP-1 modulates pancreatic beta-cell proliferation and survival, and mediates satiety. It is not surprising, thus, that GLP-1 based-regimes are already in use in the clinical setting for the treatment of type 2 diabetes. Although GLP-1 is known to be secreted in response to the presence of ingested lipids, the molecular mechanisms involved in the nutrient sensing by L-cells and subsequent secretion of GLP-1 are still unclear. Therefore, understanding these pathways is important for the identification of potentially new therapeutic targets for the treatment of obesity and type 2 diabetes. The aim of this study was to investigate the effects of lipid micelles on GLP-1 secretion by primary L-cells.

Materials and methods: GLP-1 secretion was assayed in primary cultures of murine colonic epithelium. Ratiometric $[Ca^{2+}]_i$ imaging experiments were performed on individual L-cells isolated from transgenic mice expressing the yellow fluorescent protein Venus under the control of the proglucagon promoter. These cells were identified within a mixed colonic culture based on their Venus fluorescence and loading with Fura-2AM. To simulate the conditions epithelial cells experience after a lipid rich meal, "post-prandial micelles",

comprised of oleic acid, 2-monooleoyl glycerol, L- α -lysophosphatidylcholine, cholesterol and taurocholic acid, were applied.

Results: Primary L-cells responded to lipid micelles by secreting enhanced amounts of GLP-1 (24.9 fold stimulation, compared to baseline, $p < 0.001$). The stimulation of GLP-1 secretion by lipid micelles was not attributable to cell lysis, as monitored by lactate dehydrogenase activity released into the supernatant. Fluorescence calcium imaging measurements demonstrated transient elevations in intracellular calcium in response to lipid micelles ($R_{340/380}$ increased 1.23 fold compared to baseline $p < 0.001$ $n=16$). To determine whether these augmented levels of calcium derived from intracellular stores or from extracellular supply, imaging experiments were performed in calcium free saline. It was found that in the absence of extracellular calcium, lipid micelles lack the ability to alter the concentration of intracellular calcium. The modulator of the transient receptor potential (TRP) family, 2-APB, significantly attenuated the secretion of GLP-1, stimulated by lipid micelles (53% attenuation). Similar were the effects of the lanthanides La^{3+} and Gd^{3+} which block calcium-permeable cation channels. Both La^{3+} and Gd^{3+} markedly reduced the secretory responses (51% and 39% respectively, compared to stimulation by micelles).

Conclusion: Lipid micelles stimulate GLP-1 secretion from primary murine cultures. This stimulation of GLP-1 can be blocked by La^{3+} , Gd^{3+} and 2-APB suggesting that activation of non-selective cation/ TRP channels may be involved in the secretory responses by lipid micelles

High fat diet increases enteroendocrine L cell number in the jejunum of mice in conditions of insulin resistance

T. Aranas¹, J. Gilet¹, S. Guilmeau², A. Grosfeld¹, M. Le Gall¹,
E. Brot-Laroche¹, A. Leturque¹, P. Serradas¹;

¹Centre de Recherche des Cordeliers, ²Institut Cochin, Paris, France.

Background and aims: The potent insulinotropic and satiety hormone Glucagon-like Peptide-1 (GLP-1) is released by enteroendocrine L cells which are scattered in the intestinal mucosa. Intriguingly, GLP-1 secretion is diminished in obese patients and in models of obesity in rodents, suggesting that a deficient GLP-1 signal could contribute to the development of obesity. As L cell number can be influenced by nutritional factors such as non-digestible high fructan rich meal, we hypothesized that impaired GLP-1 secretion in obesity could be linked to a decrease in L cell number. The present study aimed to evaluate the number of enteroendocrine L-cells in a diet-induced obesity mouse model.

Materials and methods: 8 week-old mice were fed with either a control diet (4% fat) or a high-fat diet (HFD, 34% fat) for up to 16 weeks. After a diet period, oral glucose tolerance tests (4mg/kg) were performed on 16h-fasted mice. Afterwards, mice were sacrificed and proximal jejunal samples were processed for immunohistochemistry and biochemical investigations. Total enteroendocrine cells and specific L-cells were quantified with chromogranin A and GLP-1 labeling respectively. Two methodological approaches were performed in this study. First, we determined the L cells number (as % of total epithelial cells of tissue) on paraffin-embedded intestinal tissues which were immunostained and quantified by the image J software. A parallel approach was performed on isolated epithelial cells from intestinal tissues, where enteroendocrine cells and specific L-cells were quantified by flow cytometry and results were expressed as % of epithelial cells. In addition, proglucagon mRNA levels were measured in intestinal samples by quantitative PCR.

Results: As expected, mice fed with HFD developed glucose intolerance, hyperinsulinemia and obesity. In jejunum, the number of enteroendocrine cells ($0.22 \pm 0.03\%$) and L-cells ($0.11 \pm 0.01\%$) were identical during all time-course (1 to 12 weeks) analyzed in the study in mice fed with control diet. Surprisingly, HFD doubled the number of enteroendocrine cells ($0.34 \pm 0.02\%$, $p < 0.05$) after 5 weeks of diet and remains high during the 12-week diet period ($0.39 \pm 0.02\%$, $p < 0.01$) when compared to control. In parallel, L cell number increases after 8 weeks of HFD ($0.18 \pm 0.01\%$, $p < 0.01$) when compared to control diet. An increase in L cell number was observed using both methodological approaches. This increase was consistent with enhanced proglucagon expression in proximal and distal intestine.

Conclusion: In this study, we demonstrate that mice fed a HFD have an enhanced enteroendocrine L-cells cell population in the jejunum, which is consistent with a raise in proglucagon expression in the intestine. Therefore, basal impairment of GLP-1 secretion observed in diet-induced obesity cannot be explained by loss of L cells. The nutritional modulation of enteroendocrine cell number could represent an adaptive response to obesity and insulin resistance.

sistance that compensates defective L cell functions downstream hormone synthesis.

COUP-TFII controls mouse postnatal pancreatic beta cell mass through GLP-1 activated beta-catenin signalling pathway

M. Boutant¹, O.H. Pereira Ramos¹, C. Tourrel-Cuzin¹, J. Movassat², F. Schuit³, J. Planchais¹, J.-P. Pégrier¹, P. Bossard¹, P. Petit⁴, A. Grapin-Botton⁵, M. Vasseur-Cognet¹;

¹EMC, Institut Cochin - Inserm U1016, ²Université Paris Diderot - CNRS EAC 4413, France, ³Molecular Cellular Biology, K.U.Leuven, Belgium, ⁴Institut Cochin - Inserm U1016, Paris, France, ⁵Ecole Polytechnique Fédérale de Lausanne, Switzerland.

Background and aims: The nuclear receptor COUP-TFII (Chicken Ovalbumin Upstream Promotor Transcription Factor, also called NR2F2) has a regulatory role in glucose metabolism. Here, our objective is to identify the role of this transcription factor in pancreatic beta-cell homeostasis.

Materials and methods: Our results are based on transgenic mouse models in which pancreatic beta-cells are made totally deficient in COUP-TFII using the Cre-lox system, on isolated mouse pancreatic islets, and on the INS-1 832-13 beta-cell line with loss of function of COUP-TFII (siRNA) and gain of function of COUP-TFII (overexpression using hCOUP-TFII adenovirus).

Results: Total ablation of the COUP-TFII gene in pancreatic beta-cells of mice results in glucose intolerance and impaired glucose-induced insulin secretion compared to wild type. It also leads to a significant 50% reduction in beta-cell number during the suckling period, when apoptosis and proliferation are essential in establishing the final beta-cell mass. Molecular analysis of pancreatic islets isolated from these mice and of 832/13 INS-1 beta-cells reveal that COUP-TFII up-regulates beta-catenin target genes, such as cyclin D1 and axin-2, by activating beta-catenin gene expression. This suggests that COUP-TFII controls Wnt-beta-catenin signalling pathway, which is known to be implicated in controlling early beta-cell mass development. Glucagon-like peptide-1 (GLP-1) is reported to activate the beta-catenin signalling pathway and its target genes such as cyclin D1. We show that in the absence of COUP-TFII, neither induction by GLP-1 nor its stable agonist exendin-4 can fully activate the cyclin D1 gene. These results demonstrate the requirement of COUP-TFII for GLP-1 activation of the beta-catenin signalling pathway and downstream transcription. Our results suggest that GLP-1, COUP-TFII and the beta-catenin pathway regulate beta-cell mass in a coordinate manner. Given the well established roles of the Wnt/beta-catenin pathway and GLP-1 in beta-cell survival and expansion, these findings may explain why pancreatic beta-cell mass is diminished in mice lacking COUP-TFII.

Conclusion: This work documents an important new role for COUP-TFII in beta-cell biology and links the action of insulinotropic hormone GLP-1, Wnt-beta-catenin and nuclear receptor pathways in determining pancreatic beta-cell mass, which is of direct clinical relevance in diabetes. It has been reported previously that GLP-1 receptor expression is high in pancreatic islets and plasma levels of GLP-1 are high during the suckling period, so our results further highlight a possible role for GLP-1 in controlling beta-cell homeostasis during the neonatal period.

Glucagon-like peptide-1 secretion from proximal rat intestine

B. Svendsen, J. Pedersen, J.J. Holst;

Department of Biomedical Sciences, The Panum Institute, University of Copenhagen, Denmark.

Background and aims: Glucagon-like peptide-1 (GLP-1) is an incretin hormone, secreted from intestinal L-cells after intake of nutrients. Classically, L-cells are believed to be located primarily in the distal part of the small intestine and the colon. This led to the hypothesis of a duodenal-ileal loop explaining the very rapid GLP-1 response to a meal. Recently, L-cells were found in the proximal small intestine. This study aimed to compare GLP-1 secretion from the proximal and the distal small intestine using the in situ perfused rat intestine.

Materials and methods: Experiments were performed by perfusing either the proximal or distal half of the small intestine in male Wistar rats. Intestinal secretion was stimulated by infusion with the phosphodiesterase inhibitor

3-isobutyl-1-methylxanthine (IBMX; 1 mmol/L). Effluent concentrations of GLP-1 and peptide YY (PYY) were subsequently measured. Furthermore, expression levels of Glucagon and Pyy in the most proximal small intestine were compared to expression levels in the most distal small intestine.

Results: Infusion of IBMX significantly increased GLP-1 secretion from the proximal small intestine from a basal level of 52.9 ± 7.7 $\mu\text{mol}/\text{min}$ to a peak level of 277.5 ± 54.2 $\mu\text{mol}/\text{min}$ ($n=7$; $p=0.0032$). Comparable GLP-1 peak levels were observed from the distal intestine (peak 345.0 ± 18.2 ; $n=7$). However, the overall IBMX response (AUC) was greater in the distal (3156.6 ± 331) compared to the proximal small intestine (1847.4 ± 202.9 ; $p=0.0073$). In contrast, stimulation with IBMX resulted in a significant increase in PYY secretion from the distal intestine from 37.2 ± 3.9 to 175.7 ± 29.0 $\mu\text{mol}/\text{min}$ ($p=0.0021$), but had no effect on PYY secretion from the proximal intestine. Expression analysis showed that expression of Glucagon was only slightly less in the proximal compared to the distal intestine (7.4 fold (95% CI 4.7;11.5) greater in the distal intestine), whereas Pyy expression was largely restricted to the distal intestine (240 fold (125;460) greater relative to the proximal intestine).

Conclusion: These results show that infusion of IBMX stimulates secretion of GLP-1 from both the proximal and distal small intestine, whereas PYY secretion is only stimulated from the distal small intestine. Consequently, GLP-1 secretion is not limited to the distal part of the gastrointestinal tract and the early GLP-1 response could arise from direct stimulation of L-cells in the proximal small intestine.

Combination of GLP-1 and FGF-21 causes synergistic weight loss in diet-induced obese mice

T. Coskun, A. Kharitonov, M.A. Schneider, W. Glaesner, P. Larsen; Endocrine, Eli Lilly and Company, Indianapolis, USA.

Background and aims: GLP-1 agonism is well-established mono-therapy for diabetes (as an incretin factor causing insulin secretion) and even weight management (as a promoter of satiety). However, nausea is a well known dose limiting side effect associated with GLP-1 agonist therapy. Preclinical data suggests that FGF-21 has potential as a therapeutic agent for diabetes and obesity via promoting insulin sensitization and increasing energy expenditure. In this study, we aimed to understand combination treatment of GLP-1 and FGF-21 in diet-induced obesity by targeting two distinct mechanisms (food intake and energy expenditure) that offers superior glucose and body weight control.

Materials and methods: In DIO mice; 1. To test GLP-1 as a dose response as a continuous subcutaneous infusion at doses of 1, 3, and 10 nmol/kg/day, 2. To test dose response of FGF21 therapy provided as once daily subcutaneous injection (50, 150, and 500 nmol/kg), 3. To test the combination treatment at doses of 3 nmol/kg/day of GLP1 + 50 nmol/kg FGF21.

Results: 1. GLP-1 alone dose dependently caused weight loss resulting in approximately 10% weight loss at highest dose tested. 2. FGF-21 dose dependently lowered body weight reaching 14% weight loss at the highest dose tested. 3. Combination treatment caused 20% weight loss compared to 8% weight loss with GLP-1 at 3 nmol/kg/day or 6% with FGF-21 at 50 nmol/kg.

Conclusion: Combination of GLP-1 with FGF-21 caused synergistic body weight loss in diet-induced obesity.

Effects of glucagon-like peptide-1 (GLP-1) analogue on fibroblast growth factor-21 signalling pathway in ApoE^{-/-} mice with hypoadiponectinaemia *in vivo*

C. Lu¹, L. Li¹, G. Yang²;

¹Department of Clinical Biochemistry, Division of Laboratory Medicine,

²Department of Endocrinology, the Second Affiliated Hospital, Chongqing Medical University, China.

Background and aims: Liraglutide is a glucagon-like peptide-1 (GLP-1) analogue that stimulates pancreatic insulin secretion and improves β-cell function. However, it is not clear whether liraglutide achieves its glucose lowering effect only by its known effects or whether other as yet unknown mechanisms are involved. Fibroblast growth factor-21 (FGF-21) is a regulator of insulin action on glucose and lipid metabolism. It is produced predominantly by the liver and, to a lesser extent, by adipose tissue. In this study, we have tested the hypothesis that 1) FGF-21 decreases insulin resistance (IR) and 2) that the glucose lowering effects of liraglutide was, at least in part, due to increased FGF-21 in a new insulin resistant mouse model.

Materials and methods: Sixty four male ApoE^{-/-} mice were randomly divided into two groups for intravenous glucose tolerance tests (IVGTT, n=28) and a hyperinsulinemic-euglycemic clamp study (n=36). Thirty six HFD-fed

ApoE^{-/-} mice were subdivided into four groups. One group was given 100µl (1×10⁹PFU) of adenoviral control vectors (Ad-shGFP, GF group, n= 6). The second group received 100µl of adiponectin RNAi adenovirus (Ad-shAcrp30, ADI group, n= 10). The third group was given 100µl of Ad-shAcrp30 and liraglutide (HEA group, n=10) and the fourth group was given 100µl sterile saline (HF group, n=10). Insulin sensitivity and gene expression were examined by euglycaemic-hyperinsulinaemic clamp and Quantitative real-time PCR, respectively. Plasma insulin, glucose, TG, TC, HDL-C, and LDL-C concentrations were measured.

Results: Hypoadiponectinemia significantly increased FGF-21 mRNA expressions in both liver and adipose tissues and decreased FGF-21 receptor 1 (FGFR-1) and β-Klotho mRNA levels in adipose tissues, as well as FGFR-1-3 and β-Klotho mRNA levels in liver. Treatment with liraglutide markedly increased FGF-21 mRNA expression in liver and FGFR-3 in adipose tissues and restored glucose and lipid metabolism and β-Klotho mRNA expression in adipose tissue as well as FGFR-1, FGFR-2, FGFR-3 and β-Klotho mRNA levels in liver up to the levels observed in ApoE^{-/-} mice fed HFD. Dot blot analyses revealed a marked increase in FGF-21 protein levels in liver, adipose tissue, and plasma of ApoE^{-/-} mice with hypoadiponectinemia. Treatment with liraglutide further increased these proteins in liver and plasma.

Conclusion: We investigated the impact of liraglutide on hypoadiponectinemia induced IR. These data suggested that 1) liraglutide might tissue specifically activate FGF21 signaling in adipose tissue through the β-Klotho-FGFR3 complex while in liver through βKlotho-FGFR1-3 complex, 2) hypoadiponectinemia in ApoE^{-/-} mice fed HFD, exacerbated insulin resistance and resulted in FGF-21 resistance, and 3) Liraglutide completely reversed the insulin and FGF-21 resistance induced by hypoadiponectinemia.

The effects of acute exercise on insulin secretion in type 2 diabetes

S.H. Knudsen, K. Karstoft, K. Winding, B.K. Pedersen, T.P.J. Solomon; Centre of Inflammation and Metabolism, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Type 2 diabetes mellitus (T2DM) is an increasing public health problem and so understanding its pathogenesis is crucial. Recent studies have demonstrated that exercise and diet interventions may improve β-cell function in patients with T2DM, possibly by a mechanism related to incretin hormones. This suggests that pancreatic β-cell dysfunction is potentially treatable with a lifestyle-intervention, however the exercise effect on β-cell sensitivity to different insulin secretagogues has not been studied. The aim of the present study was to investigate whether a single bout of exercise can affect β-cell insulin secretion capacity, in response to glucose, the incretin hormone GLP-1, and arginine.

Materials and methods: Individuals with T2DM were screened and underwent measures of body composition and maximal aerobic capacity (VO₂max). Subjects withheld their oral antidiabetic medication for 7 days prior to testing. No subject was being treated with insulin. The final study population included 8 elder, overweight, T2DM subjects (age 60±6 y, BMI 30.2±5.2 kg/m², VO₂max 24.6±4.3 mL/kg/min, fasting glucose levels 7.06±1.9 mmol/l, 2h OGTT glucose value 15.1±4.5 mmol/l, HbA_{1c} 6.5±0.3%). Before and the morning following a one-hour treadmill walk at 65% of maximum heart rate, a hyperglycemic (5.4 mM above basal) clamp was performed combined with a sequential 0.5 pmol/kg/min primed infusion of GLP-1⁷⁻³⁶ amide and a 5 g bolus injection of arginine hydrochloride. Arterialised blood glucose was measured every 5 min throughout and corrections to the glucose infusion rates (GIR; mg/kg/min) were based on a computational algorithm. Insulin secretion rates (ISR; pmol/min) in response to glucose, GLP-1 and arginine were deconvoluted from peripheral blood C-peptide concentrations using standard parameters for C-peptide clearance. Paired T-tests were used to compare pre/post exercise variables. All data are presented as mean±SD.

Results: Exercise did not alter fasting glucose levels (7.7±1.8 vs. 7.9±2.2 mmol/l, P>0.05). Steady state clamp glucose levels were 12.6±0.2 mmol/l before and after exercise, with a CV% of 2.96±1.4 and 4.3±2.8 respectively. The GIR required to maintain hyperglycemia did not differ between trials (P>0.05). However, glucose-stimulated ISR was reduced after exercise (650.3±113.3 vs 593.0±87.6 pmol/min, P=0.05), while GLP-1 (1380±249 vs. 1493±255, P=0.16) and arginine-stimulated ISR (2371±553 vs 2578±673, P=0.01) were increased after exercise.

Conclusion: The exercise effect on insulin secretion from pancreatic β-cells differed between the stimulus from glucose, GLP-1 and arginine. The exercise

related improvement in insulin secretion in response to GLP-1 and arginine could indicate an enhanced insulin secretion capacity of the β -cells. However, further studies are needed to clarify the mechanisms behind this exercise-induced improvement in β -cell function related to insulin secretagogues.

Background and aims: Exendin-4 (Ex-4) is a GLP-1 receptor agonist approved for the treatment of Type 2 Diabetes (T2DM). The aim of the study was to characterize the effects of Ex-4 expressed continuously from salivary glands (SG), following adeno-associated virus-mediated (AAV) gene therapy in two different model of obesity and T2DM. Several trials support an AAV good safety and little toxicity profile. Serotype 5 (AAV5) presented enhanced gene transfer activity in SG. SG exhibit efficient protein secretion into the bloodstream.

Materials and methods: A recombinant AAV vector was produced using a four-plasmid procedure. In accordance with the European Directive (86/609/EEC) and Italian National Health Institute approval, following 5x10¹² DRP/ml vector (encoding Ex-4 or empty) administration, efficacy and metabolic effects in high fat diet (HFD) fed mice (n=20) and Zucker fa/fa rats (n=10) were evaluated.

Results: Ex-4 levels averaged 138.9 \pm 42.3 pmol/L at day 42 in treated mice and 238.2 \pm 72 pmol/L at day 30 increasing to 3 nmol/L at day 60 in treated rats. Transduction specificity was confirmed through a qPCR amplification using specific primer in SG, liver, spleen and pancreas. Treated animals reached a significantly lower weight gain in comparison to controls at day 42 in mice (16.5 \pm 2.7 vs 19.5 \pm 1.9 g; p<0.05) and by day 35 in rats (156.8 \pm 17.5 vs 186.2 \pm 18.6 g, p<0.05) through the study. Transient reduction on food intake was reported. Furthermore, treated mice presented: significant lower leptin circulating levels (2.24 \pm 0.39 vs 5.89 \pm 1.07 ng/ml; p<0.01) and visceral adipose mRNA expression (3.43 \pm 0.48 vs 8.28 \pm 0.72 Arbitrary Unit; p<0.01) and at day 41, a greater insulin-induced reduction in glycaemia during an intraperitoneal insulin tolerance test (Figure 1). A significant reduction in HbA1c (4.7 \pm 0.1 vs 4.9 \pm 0.1 %; p<0.05) and glycosuria (4 cases vs 0) was reported in treated rats.

Conclusion: This study suggests an alternative approach delivering Ex-4 in the treatment of T2DM.

Figure 1. ITT test at day 41, in High Fat-Diet mice (n=20). The graphs represent the average glycaemic values (mmol/L) \pm Standard Error (SE). * = p<0.05.

Differential effect of pioglitazone, exenatide and combination of pioglitazone and exenatide on adipocyte insulin resistance in type 2 diabetes

A.O. Chavez, R. Guardado-Mendoza, J.W. King, J. Kincade, F. Folli, R.A. DeFronzo, D. Tripathy;

Diabetes, Medicine, University of Texas Health Science Center, San Antonio, USA.

Background and aims: Adipose tissue insulin resistance is characterized by an increased rate of lipolysis and elevated circulating non-esterified fatty acid (NEFA) levels in obesity and type 2 diabetes (T2DM). Pioglitazone improves glycemic control by increasing insulin sensitivity in target organs. Exenatide lowers glucose levels by enhancement of incretin effect. We sought to examine the effect of Pioglitazone (PIO) and combined therapy with PIO and Exenatide (EXE) on adipocyte insulin resistance in T2DM and its association with changes in peripheral insulin sensitivity and beta cell function.

Materials and methods: We studied 30 T2DM subjects (age=55 \pm 37 yrs; BMI=34 \pm 5; FPG=175 \pm 40 mg/dl; HbA1c= 8.3 \pm 1%) who were randomized to receive: (i) EXE (10ug bid, n=11), (ii) PIO (45 mg/d, n=10), or (iii) PIO+EXE (n=9) for 24 weeks. Before and 24 weeks after treatment subjects received an OGTT and two-step hyperglycemic (+125 and +400mg/dl) clamp followed by IV arginine (5g) bolus. The Matsuda Index (MI) of insulin sensitivity and Disposition Index ($\Delta I/\Delta G_{0-120} \times MI$) was calculated from OGTT. Adipocyte insulin resistance index (AdipoIRI) was calculated as the fasting NEFA \times fasting plasma insulin.

Results: PIO + EXE caused a greater reduction in FPG, 2-h glucose and HbA1c compared to PIO alone or EXE alone (all p<0.05). In all groups, change (Δ) in AdipoIRI correlated significantly with Δ HbA1c (r=0.419, p=0.02), Δ MI (r=-0.380, p=0.039) and Δ NEFA (r=0.477, p=0.008) with PIO improved MI of insulin sensitivity from 4.4 \pm 1 to 7.7 \pm 0.9 (p<0.05). Combined PIO + EXE therapy increased MI from 3.2 \pm 0.7 to 6.4 \pm 0.8 (p<0.05) and Disposition Index (DI= $\Delta I/\Delta G_{0-120} \times MI$) from 0.29 \pm 0.06 to 1.1 \pm 0.33 (p<0.05). PIO decreased fasting NEFA (0.648 \pm 0.05 to 0.376 \pm 0.06 μ M, p=0.001), 2-hour NEFA (0.252 \pm 0.09 to 0.09 \pm 0.01 μ M, p=0.009) and the basal adipocyte insulin resistance index (7.35 \pm 2.1 to 1.6 \pm 0.3, p<0.05). No significant changes in plasma FFA concentrations or were observed in patients treated with EXE or a PIO+EXE. The change in MI correlated strongly with Δ AdipoIRI (r=-0.380, p<0.05). Δ DI also correlated with both AdipoIRI (r=0.573, p=0.02) and Δ AdipoIRI (r=0.726, p<0.001). In all groups, changes in insulin secretion in every step during the hyperglycemic clamp were inversely correlated with AdipoIRI at study end (AIR₀₋₁₀₇ r=-0.377 p=0.04, AUC_{INS12-160} r=-0.615, p<0.0001, AUC_{ARG160-190} r=-0.410 p=0.02). At study end, degree of glucagon suppression correlated with AdipoIRI.

Conclusion: PIO alone improved AdipoIRI. Improvement in adipocyte insulin sensitivity could represent a fundamental mechanism by which PIO improves insulin sensitivity. EXE had no effect on adipocyte insulin resistance and attenuated the effect of PIO on AdipoIRI.

Continuous exenatide infusion markedly improves insulin sensitivity and disposition index in partially pancreatectomised baboons

F. Casiraghi¹, A.O. Chavez¹, A.M. Davalli^{1,2}, G.A. Abrahamian³, A. Gastaldelli^{1,4}, R.A. Bastarrachea⁵, S. Kamath¹, R. Petz⁶, P. Zuo¹, A. Ricotti^{1,4}, P.B. Higgins⁵, A. Comuzzie⁵, G.A. Half³, R.A. DeFronzo¹, F. Folli¹;

¹Medicine/Diabetes, UTHSCSA, San Antonio, USA, ²Medicine, HS Raffaele, Milan, Italy, ³Transplant Center, UTHSCSA, San Antonio, USA, ⁴Institute of Clinical Physiology, CNR, Pisa, Italy, ⁵Texas Biomedical Research Institute, San Antonio, USA, ⁶CNR, Pisa, Italy.

Background and aims: Hyperglycemia in Type 2 diabetes (T2DM) is determined by β -cell failure to compensate for insulin resistance. The GLP-1 analogue, Exenatide (EXE) improves glycemic control in T2DM by enhancing insulin secretion. However, the effect of continuous chronic EXE infusion on α and β -cell function has not been well studied previously.

Materials and methods: We examined the effect of a continuous IV infusion (via tether system) of: i) EXE (0.014 μ g/kg.h, n=12) or ii) saline (SAL, n=12) on α and β -cell function in non-diabetic baboons (NDB). At baseline, baboons received a two-step Hyperglycemic (+125 and +225 mg/dl) Clamp followed by an IV Arginine bolus (0.15 g/kg) (HC+A), with a total duration

of 210 minutes. Immediately after HC+A baboons underwent a partial pancreatectomy (~30% total mass) and started EXE or SAL infusion for 13 weeks. At the end of treatment, EXE infusion was stopped for 72 hours before HC+A was repeated and remnant pancreas was collected. In these experimental conditions, the chronic *in vivo* effects of EXE on insulin secretion and insulin action can be evaluated, because of the extensive wash-out period.

Results: Insulin sensitivity (IS) was measured as the glucose infusion rate per unit of insulin (M/I) during steady state conditions, and insulin secretory rate (ISR) was calculated by deconvoluting C-Peptide during the clamp. β -cell function (Disposition Index=DI) was calculated as $ISR \times M/I$, α -cell function as % suppression of glucagon secretion from baseline. Body composition was evaluated by DXA. There was no significant change in food consumption (EXE 55.2 ± 4 , SAL 53.6 ± 2.6 kcal/kg body weight/day). A significantly decrease in body weight (EXE 18.24 ± 0.81 to 17.23 ± 0.65 p=0.034, SAL 18.49 ± 0.62 to 16.67 ± 0.7 kg p=0.006), fat mass (EXE 1.54 ± 0.5 to 0.93 ± 0.2 p=0.044, SAL 1.29 ± 0.2 to 0.86 ± 0.2 kg p=0.035), and lean mass (EXE 15.65 ± 0.4 to 15.22 ± 0.5 p=ns, SAL 16 ± 0.5 to 15 ± 0.6 kg p=0.033) were observed. M/I increased by ~68% after EXE (17.08 ± 3.1 to 28.87 ± 4.2 , p<0.0093) and decreased by 19% in SAL (33.24 ± 9.16 to 26.81 ± 4.41). ISR increased significantly in SAL group (Basal-ISR 2.0 ± 0.3 [Pre] to 4.3 ± 1.0 [Post] pmol/min/g pancreas, p<0.04, Total-ISR 5.6 ± 0.4 to 7.7 ± 1.1 nmol/g pancreas, p=0.08) but not in EXE (Basal-ISR 3.0 ± 0.7 to 4.5 ± 1.1 pmol/min/g pancreas; Total-ISR 7.2 ± 1.0 to 8.0 ± 1.6 nmol/g pancreas, p=ns). DI increased significantly after EXE (1.0 ± 0.1 to 2.2 ± 0.3 , p<0.01), but not after SAL (1.5 ± 0.2 to 1.7 ± 0.3 , p=ns). No differences were found in glucagon suppression or insulin/glucagon ratio between groups (EXE 26.5 ± 3.3 to 22.1 ± 5.2 vs. SAL 25.0 ± 5.5 to 20.2 ± 2.4 mU/l/(ng/ml)⁻¹).

Conclusion: Continuous IV treatment with EXE increased IS and DI, whereas SAL treated NDB had a compensatory increase in ISR, after partial pancreatectomy. In conclusion, chronic Exenatide treatment causes an unexpected marked improvement of IS, with no significant change in insulin secretion, thereby possibly inducing β -cell “rest”.

Liraglutide attenuated hypoadiponectinaemia-induced deterioration in peripheral and hepatic insulin sensitivity and alterations of gene expression in glucose and lipid metabolism

Z. Miao¹, L. Li¹, G. Yang²

¹Department of Clinical Biochemistry, ²Department of Endocrinology, the Second Affiliated Hospital, Chongqing Medical University, China.

Background and aims: Liraglutide is a glucagon-like peptide-1 (GLP-1) analogue that reduces blood glucose levels, increases insulin secretion, and improves insulin sensitivity through mechanisms have not been completely understood. However, the physiological role of liraglutide in glucose and lipid metabolism and relevant signal transduction pathways still need to be determined. We aimed to evaluate the metabolic impact and underlying mechanisms of liraglutide in a hypoadiponectinemia and high fat diet (HFD)-induced insulin resistance (IR) model.

Materials and methods: Sixty four male ApoE^{-/-} mice were randomly divided into two groups for intravenous glucose tolerance tests (IVGTT) and a hyperinsulinemic-euglycemic clamp study. Thirty six HFD-fed ApoE^{-/-} mice were subdivided into four groups: GF group (100 μ l (1 \times 10⁹ PFU) of adenoviral control vectors), ADI group (100 μ l of adiponectin RNAi adenovirus), HEA group (100 μ l of Ad-shAcrp30 and liraglutide) and HF group (100 μ l sterile saline). Insulin sensitivity and gene expression were examined and Quantitative real-time PCR, respectively.

Results: Treatment with Ad-shAcrp30 achieved a 76% reduction of Acrp30 expression in adipose tissues and a 35% reduction of plasma Acrp30 level in the ADI group than in HEA, HF or GF groups. Fasting plasma insulin, FFA, TG and TC were significantly increased in the ADI group. Liraglutide treatment significantly decreased body weight and fasting blood glucose compared with the other three groups. Plasma FFA, TC and TG were significantly suppressed during the clamp procedures in four groups, but remained higher in the ADI group than in the other three groups. The ADI group required a much lower glucose infusion rate (GIR) than the HF and GF mice did during the clamp procedure. The liraglutide treatment markedly increased the GIR in the HEA mice to levels similar to those observed in HF and GF mice. Hepatic PEPCK mRNA expression was significantly up-regulated, while GLUT-1 mRNA expression was significantly down-regulated in ADI group oppose to those three groups. The mRNA expressions of HSL and PPAR γ in adipose tissues were significantly down-regulated in ADI group. The administration

of the Acrp30 siRNA-expressing vector significantly up-regulated the FAS mRNA expression of adipose tissue. However, treatment of liraglutide restored it, and down-regulated ACC and SCD1 mRNA expressions.

Conclusion: This study is the first to reveal the profound anti-insulin resistance effect of liraglutide when administered systemically in murine models of hypoadiponectinemia and HFD. Our data clearly indicate that liraglutide's effects are, at least in part, likely to be mediated by the alterations of gene expressions involved in glucose and lipid metabolism. However, it will be important in future studies to determine the role of liraglutide in the metabolic regulatory pathways of these genes.

Early DPP-4 inhibition suppresses the progression of diabetes in low-dose STZ mice via alleviation of beta cell death and alpha cell proliferation

Y. Takeda, Y. Fujita, J. Honjo, T. Yanagimachi, H. Kitsunai, Y. Takiyama, Y. Makino, A. Abiko, M. Haneda;

Division of Metabolism and Biosystemic Science, Department of Internal Medicine, Asahikawa Medical University, Japan.

Background and aims: Incretins such as glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) not only stimulate insulin secretion in glucose-dependent manner but also promote β -cell proliferation and survival, and inhibit β -cell apoptosis. Dipeptidyl peptidase-4 (DPP-4) inhibitor is a new anti-diabetic treatment via blocking incretin inactivation by DPP-4. DPP-4 inhibitors have been reported to be able to delay or suppress the progression of diabetes in some spontaneous animal models, but the mechanism is not well elucidated. First, we confirmed whether DPP-4 inhibition suppresses the progression of diabetes in low-dose streptozotocin (STZ) induced diabetic mice, and then investigated how DPP-4 inhibition affects islet function and morphology.

Materials and methods: Des-F-sitagliptin (Sita), an analog of sitagliptin was administered orally to mice before and after STZ treatment (50 mg/kg/day, 5 consecutive days). We observed for additional 20 days after STZ treatment with continuous administration of Sita. We measured metabolic variables, examined immunohistochemical analysis, and quantified pancreatic hormone contents.

Results: Glycated haemoglobin levels were significantly lower in Sita-treated STZ mice compared to non-treated STZ mice (non-treated: $5.6 \pm 0.2\%$, Sita-treated: $3.9 \pm 0.2\%$, control: $3.7 \pm 0.1\%$). Glucose-stimulated insulin secretion was also significantly higher in Sita-treated mice compared to non-treated mice. In non-treated STZ mice, we observed marked reduction of β -cells with reduction of pancreatic insulin content and huge expansion of α -cells with increase of glucagon content. While in Sita-treated mice, these morphological changes were mild and the islet architecture was preserved better, and reduction of insulin content was not remarkable and increase of glucagon content was not observed. These findings were more striking in mice with administered Sita earlier and longer. To elucidate the effect of Sita on islets, we examined immunohistochemical analysis 24 hr after final STZ injection. TUNEL positive β -cells and caspase-3 positive β -cells were increased in non-treated mice, whereas these apoptotic cells were significantly reduced in Sita-treated mice, equivalently to GLP-1 mimetic exendin-4 treated mice. These findings suggested that Sita suppresses β -cell apoptosis in STZ mice. Interestingly, PCNA positive α -cells were observed in non-treated mice immediately after STZ injection, but the α -cell proliferation was not observed in Sita-treated mice. It is suggested that DPP-4 inhibition can suppress absolute α -cell proliferation observed in non-treated STZ mice. To confirm incretin effects on β -cell protection *in vivo*, we further examined *in vitro* studies using MIN6 β -cell line. STZ induced apoptosis in MIN6 cell dose-dependently. GIP and GLP-1 equivalently suppressed MIN6 cell apoptosis induced by STZ. Intriguingly, GIP and GLP-1 suppressed synergistically MIN6 cell apoptosis by high-dose STZ treatment.

Conclusion: Our present study indicates that early DPP-4 inhibition can significantly suppress the progression of diabetes via alleviation of not only β -cell death but also α -cell proliferation in STZ mice.

517

Mechanism of the preventive effect of sitagliptin upon changes induced by short-term fructose administration in liver glucokinase activity

L.M. Massa, F. Francini, M.C. Castro, J.J. Gagliardino;
CENEXA Center of Experimental and Applied Endocrinology, La Plata, Argentina.

Background and aims: While the effect of exendin-4 (GLP-1R agonist) and DPP-IV inhibitors upon islet hormones secretion, β -cell mass, appetite and gastric emptying delay has been widely reported, little is known about their effect upon liver glucokinase (GK-I) activity and their physiologic modulators. The aim of this study was to evaluate the effect of exendin-4 and sitagliptin upon fructose (Fr)-induced changes in GK-I activity and the regulatory mechanism of such activity (genic and protein level, cellular compartmentation and interaction with PFK2).

Materials and methods: Adult male Wistar rats received (3 weeks) a standard commercial diet, without (C) or with 10% Fr (w/v) in the drinking water (F). C and F were daily treated either with sitagliptin (115 mg/day per rat) (CS and FS) or exendin-4 (0.35 nmol/kg of body weight) (CE and FE). After such treatment, we measured: 1) Serum glucose (G) (enzymatic method), insulin (I) (RIA) and triglyceride (TG) (enzymatic method) levels; 2) GK-I activity in both cytosolic (CF) and nuclear (DNF) fractions (enzyme-coupled photometric assay), 3) GK-I and PFK2 mRNA (qPCR) and 4) protein GK-I and PFK2 concentration (Western blot [Wb]).

Results:

	C	CE	CS	F	FE	FS
G (mM)	4.5 \pm 0.1	4.2 \pm 0.1	4.5 \pm 0.2	4.9 \pm 0.2	4.2 \pm 0.2	4.7 \pm 0.3
TG (mM)	0.47 \pm 0.01	0.48 \pm 0.06	0.63 \pm 0.09	1.14 \pm 0.12 $\dagger\dagger$	0.72 \pm 0.09*	0.67 \pm 0.05**
I (ng/ml)	0.30 \pm 0.02	0.25 \pm 0.03	0.27 \pm 0.03	1.09 \pm 0.28 \dagger	0.30 \pm 0.05*	0.31 \pm 0.05*

Values are means \pm SEM (n = 20). TG: $\dagger\dagger$ F vs. C, $P < 0.0001$; * FE vs. F, $P < 0.003$; ** FS vs. F, $P < 0.001$. I: \dagger F vs. C, $P < 0.02$; * FE or FS vs. F, $P < 0.03$.

F induced a significant increase of total GK-I activity that was prevented by administration of either exendin-4 or sitagliptin. Most of the GK-I activity was measured in the DNF in C rats but in the CF in F rats. Exendin-4 and sitagliptin administration to F rats prevented such compartmentation changes. GK-I mRNA concentration was significantly higher in F rats and both exendin-4 and sitagliptin administration turn down these increase to values comparable to those measured in C rats. PFK2 mRNA concentration undergo similar changes. GK-I and PFK2 protein expression (Wb) were significantly higher in F rats. While exendin-4 and sitagliptin administration to F did not modify GK-I protein concentration, it induced a significant decrease in PFK2 concentration, suggesting that their effect on GK-I activity would be associated to the latter action.

Conclusion: F administration to normal rats induced a) significant increase of serum TG and I levels but not of fasting blood G; administration of either exendin-4 or sitagliptin to F prevented the development of such changes; b) the significant increase in GK-I activity measured in F would result from a combination of an increased protein synthesis, a switch in its cellular compartmentation towards the cytosol, and an increase in PFK2 protein level. Exendin-4/sitagliptin administration prevented the F-induced changes in GK-I activity by affecting PFK2 concentration and GK-I compartmentation rather than GK-I protein level.

Effects of inhibited GIP secretion on high fat diet-induced obesity and insulin secretion

D. Nasteska, N. Harada, A. Hamasaki, K. Suzuki, S. Yamane, E. Joo, A. Muraoka, M. Hishizawa, Y. Kondo, X. Liu, N. Inagaki;
Department of Diabetes and Clinical Nutrition, Kyoto University, Japan.

Background and aims: Gastric inhibitory polypeptide (GIP) is an incretin hormone which is produced by enteroendocrine K cells following nutrient uptake. In conditions of obesity, except for increasing blood glucose concentrations, GIP has a role in compensatory insulin secretion and fat storage in adipocytes, as well as in pancreatic β -cell signaling. However, the extent of GIP effects on insulin secretion on an obese background remains unclear. For that purpose, we have designed GIP-deficient mice and evaluated its effects on insulin secretory capacity and high fat diet-induced obesity.

Materials and methods: We generated knocked-in mice with truncated GIP gene (GIP KI mice). Using immunohistochemistry the intestine of wild type (WT), GIP-deficient heterozygous (GIP^{+/-}) and homozygous (GIP^{-/-}) mice was evaluated. Then, wild type mice (WT), GIP-deficient heterozygous (GIP^{+/-}) and homozygous (GIP^{-/-}) mice underwent oral glucose tolerance test (OGTT) in which blood glucose levels, plasma insulin and total GIP levels were measured. Subsequently, all groups of mice were kept on control fat diet (containing 10% fat) and high fat diet (containing 60% fat) for 8 weeks during which body weight changes were continuously monitored.

Results: Immunohistochemical staining of the small intestine of GIP^{+/-} mice and WT mice revealed GIP-positive cells. In GIP^{-/-} mice GIP-positive cells were not confirmed. During OGTT, GIP^{+/-} mice showed significantly decreased GIP levels compared to WT mice; the total reduction of GIP secretion (AUC-GIP) was 41.7%. In the case of GIP^{-/-} mice, GIP levels were below detectable range. Blood glucose levels in GIP^{+/-} mice and GIP^{-/-} mice showed significant increase compared to WT mice (30 and 60 min after oral glucose load). Insulin levels in the acute phase of OGTT were significantly decreased in GIP^{+/-} and GIP^{-/-} mice compared to WT mice. In conditions of high fat diet, WT mice showed increased weight gain compared to GIP^{+/-} mice and GIP^{-/-} mice; the latter had lowest weight gain among all three groups.

Conclusion: Our mice model of impaired GIP secretion, in which GIP^{+/-} heterozygous mice show reduced GIP secretion while GIP^{-/-} homozygous mice exhibit total lack of GIP secretion, suggests that inhibition of GIP secretion may suppress fat accumulation and insulin secretion in conditions of high fat diet.

Pasta consumption elicits similar postprandial glucose, but lower GIP and insulin response compared to bread

M.G. Pribe^{1,2}, C. Elderink^{1,2}, M. Schepers¹, T. Preston³, L.A.C. Oudhuis^{4,2}, R.J. Vonk¹;

¹Medical Biomics, University Medical Center Groningen, Netherlands,

²Top Institute Food and Nutrition, Wageningen, Netherlands, ³Scottish Universities Environmental Research Center, University of Glasgow,

UK, ⁴Food and Biotechnology Innovations, TNO Quality of Life, Zeist, Netherlands.

Background and aims: Consumption of slowly digestible starch is implicated with a decreased risk for the development of obesity, insulin resistance and type 2 diabetes. Underlying mechanisms of this beneficial effect are not yet elucidated. We aimed to investigate the difference in metabolic response after the consumption of products with slowly and rapidly digestible starch in human subjects.

Materials and methods: Ten healthy male volunteers (age 21.4 \pm 0.5 y, BMI 22.5 \pm 0.6 kg/m² [mean \pm SEM]) participated in a cross-over study, receiving two different meals on separate days. The test meals were fiber-enriched wheat bread and pasta. The products were enriched in ¹³C and the dual isotope technique was applied in order to calculate glucose kinetics: the rate of appearance of exogenous glucose (RaE), endogenous glucose production (EGP), and the glucose clearance rate (GCR), reflecting glucose uptake by tissues. Blood samples were drawn for analysis of total glucose concentration, insulin and incretin concentrations.

Results: The incremental area under the curve (iAUC, 0–2 h) for total glucose concentrations was not significantly different between both meals, however

the iAUC of insulin was significantly lower after pasta ($p < 0.01$). Glucose appearance from pasta was slower compared to bread, resulting in a lower iAUC of RAe compared to bread ($p < 0.0001$) and correlated with low postprandial concentrations of the incretin hormone glucose-dependent insulinotropic polypeptide (GIP). In accordance with the lower insulin concentrations the GCR was lower after pasta, but paradoxically, EGP was more suppressed.

Conclusion: Slower intestinal uptake of glucose from a starchy food product results in lower postprandial GIP and insulin concentrations, but not necessarily in lower glucose concentrations. In view of the proposed effects of GIP on fat storage and resting energy expenditure these results might explain the role of slowly digestible carbohydrates in the prevention of obesity.

The influence of metabolic syndrome and glucose tolerance on the incretin effect

S. Calanna, F. Urbano, T. Tomaselli, G. Privitera, A. Di Pino, S. Piro, F. Purrello, A.M. Rabuazzo;
Clinical and Molecular Biomedicine, University of Catania, Italy.

Background and aims: Metabolic syndrome (MS) and impaired glucose tolerance (IGT) are high risk conditions for type 2 diabetes, a disease where the incretin plasma levels or biological activity have been shown to be reduced. Previous data indicate that normotolerant (NGT) subjects with the MS have an increased early phase insulin secretion during OGTT, as measured by insulinogenic index (IG30), in comparison to individuals without the metabolic syndrome, independently from insulin resistance. The present study was undertaken to further investigate the alpha and beta cell function and entero-insular axis in these pre-diabetic conditions.

Materials and methods: Using oral (OGTT) and intravenous (IVGTT) glucose tolerance test we studied alpha and beta cell function, insulin resistance, incretin levels and their relationship to impaired glucose tolerance state in 139 subjects with normal fasting glucose, with (59) and without MS (80).

Results: Among normotolerant subjects, MS+ individuals showed in comparison with MS-: higher AUC (0-10) for glucose ($p < 0.05$) but similar first phase insulin secretion ($p = ns$) as measured by Δ AIRG and AUC (0-10) for insulin during the IVGTT; increased ($p = 0.04$) AUC (0-60) for insulin during the IVGTT, although this difference disappeared when HOMA-IR was used as covariate; similar AUC (0-120) for GLP-1 and GIP ($p = ns$) during the OGTT; higher glucagon suppression relative to the increase of glucose ($p = 0.002$) but similar glucagon levels ($p = ns$). Among impaired glucose tolerance subjects, MS+ individuals showed no statistically significant differences in the above parameters. When taken together IGT subjects showed in comparison to NGT individuals: decreased Δ AIRG ($p < 0.01$) and AUC (0-10) for insulin during IVGTT, and these differences remained when HOMA-IR was used as covariate; similar ($p = ns$) AUC (0-60) for insulin during the IVGTT; higher GIP plasma levels and AUC (0-120) for GIP ($p < 0.05$) during the OGTT; similar ($p = ns$) AUC (0-120) for GLP-1 and glucagon levels; lower glucagon suppression relative to the increase of glucose ($p = 0.04$).

Conclusion: In contrast to the data obtained with OGTT, NGT subjects with metabolic syndrome did not show at the IVGTT an increase of early phase insulin secretion. This difference might be due to an increased incretin effect as suggested also by the higher glucagon suppression in relation to the increase of glucose observed in these subjects. IGT subjects try to compensate the impaired beta-cell secretory capacity by a hyper activation of incretin axis as suggested by the increased GIP levels but they fail to restore an adequate insulin secretion and glucagon suppression relative to the glucose rise. Alike we observed the failure of these compensatory mechanisms when the two defects, metabolic syndrome and impaired glucose tolerance, are associated.

521

Glucose dependent insulinotropic polypeptide in impaired glucose tolerance and its association with insulin secretion and sensitivity

Z. Zeba¹, M. Akhter¹, S. Akter¹, R. Zinnat¹, L. Ali²;

¹Biochemistry and Cell Biology, BIRDEM, ²Biochemistry and Cell Biology, Bangladesh Institute of Health Science, Dhaka, Bangladesh.

Background and aims: Both insulin secretory defect and insulin resistance are present in Bangladeshi T2DM subjects, but the secretory defect seems to have a predominant role. In case of prediabetes, IFG and IGT seem to be

separate disorders where β -cell dysfunction is predominant in IFG and insulin resistance has a major role in IGT. A combined IFG-IGT group has both the defects. Although abnormalities of incretin effects have been established as major determinants of insulin secretion and sensitivity, these have not yet been studied in any Bangladeshi population. As study in prediabetic subjects can give substantial insight on the natural history of the disorders, the present study was undertaken to investigate the association of GIP with glycemic and insulinemic status in IGT subjects.

Materials and methods: The analytic observational study was conducted under a case-control design with age- and BMI-matched IGT subjects ($n = 51$, age 40 ± 6 yrs, BMI 24 ± 2.9) and Controls ($n = 47$, age 41 ± 5 yrs, BMI 29.0 ± 3.5). IGT was diagnosed following the WHO Study Group Criteria. Serum C-peptide and serum glucose dependent insulinotropic hormone (GIP) were measured by ELISA method. Insulin secretory capacity (HOMA%B) and insulin sensitivity (HOMA%S) were calculated by homeostasis model assessment.

Results: Fasting C-peptide value of IGT subjects was not significantly different from the value of the Controls [(ng/ml), Median (Range) $0.68(0.21-1.39)$ vs $0.64(0.18-1.62)$, $p = 0.914$]. Insulin sensitivity was significantly lower in IGT subjects [HOMA%S, $65(22-222)$ vs $71(27-247)$, $p = 0.005$]. Fasting GIP was significantly higher in case of IGT subjects compared to controls [pgm/ml, $74.21(10-190)$ and $49.62(6.1-278)$; ($p = 0.001$)], but postprandial GIP value was not significantly different. The ratio of the postprandial and fasting GIP was significantly lower in case of IGT compared to controls [PGIP: FGIP, $3.47(0.98-22.0)$ and $5.14(0.96-19.85)$, ($p < 0.001$)]. Serum fasting C-peptide and fasting GIP ratio was significantly lower in IGT subjects than that of control subjects [FC-pep: FGIP, $0.037(0.009-0.251)$ and $0.045(0.009-0.205)$, ($p = 0.05$)]. Serum fasting GIP and fasting glucose ratio in Control and IGT were $2.26(0.29-11.26)$ and $3.53(0.41-7.96)$, ($p = 0.002$). A significant positive correlation was found between fasting C-peptide and fasting GIP ($p = 0.019$) in the control subjects. In multiple regression analysis a significant positive association was found between fasting C-peptide and fasting GIP ($p < 0.01$). A significant negative association was found between fasting GIP and HOMA%S ($p = 0.05$). No association was found between fasting glucose and fasting GIP both in simple correlation and multiple regression.

Conclusion: The incretin effect of GIP is diminished in IGT and it is associated with insulin resistance in Bangladeshi T2 diabetic population.

Secretion and role of glucose-dependent insulinotropic polypeptide (GIP) in metabolic adaptations during pregnancy and lactation in rats

N. Irwin, J.M.E. Francis, P.R. Flatt;

School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: As well as being a key incretin hormone, glucose-dependent insulinotropic polypeptide (GIP) exerts important regulatory effects on lipid metabolism and energy disposition. Pregnancy and the transition to lactation involve major remodelling of energy homeostasis, yet dynamic changes in intestinal K-cell function are not fully appreciated. The present study investigated changes of GIP synthesis and secretion in the context of metabolic adaptations during pregnancy and lactation in rats.

Materials and methods: Female, virgin, albino Wistar rats (15 weeks old, groups of $n = 6$) were time-mated and caged individually. Pregnancy proceeded without intervention until parturition, at which point litter sizes were standardised to $n = 10$. Food intake, body weight, non-fasting plasma glucose, insulin and GIP concentrations were monitored at 6-8 day intervals during pregnancy and lactation. On day 21 of both pregnancy and lactation an oral glucose (3.2 g/kg b.w. (51.2 kJ/kg)) or oral fat (1.38 g corn oil/kg b.w. (51.2 kJ/kg)) challenge were conducted after an overnight fast, with assessment of plasma glucose, insulin and GIP responses. Small intestines were excised, weighed and processed for measurement of GIP content.

Results: As expected, in pregnant rats body weight increased 1.2-1.5-fold ($p < 0.05$ to $p < 0.001$) from 13 days post coitus, returning to near control levels shortly after parturition. There was also a transient 1.2-fold increase ($p < 0.05$) in body weight on day 12 and 16 of lactation. Energy intake was consistently 1.8-3.4-fold greater in lactating rats compared to controls ($p < 0.01$). Pregnancy also increased energy intake (1.4-fold) on days 14 and 18 post coitus ($p < 0.05$). Pregnant rats exhibited 19.8% decreased circulating glucose levels ($p < 0.01$) accompanied by 1.6-fold elevated insulin concentrations ($p < 0.05$), which rapidly returned to basal levels following parturition. Circulating GIP concentrations (152.3 ± 18.6 pmol/l) were normal during pregnancy but were elevated 1.4-1.9-fold during the lactation period ($p < 0.05$ to $p < 0.01$). In addition, lactating rats exhibited a 58.4% decreased glycaemic excursion after

oral glucose compared to control rats (158.6 ± 14.3 vs. 381.6 ± 38.1 mmol/l.min, respectively; $p < 0.001$). Corresponding glucose-induced plasma insulin and GIP concentrations in lactating rats were not significantly different from controls (72.6 ± 6.3 ng/l.min and 9986.3 ± 1004.2 pmol/l.min, respectively). However, pregnant rats had a similar glycaemic excursion but showed elevated overall insulin levels ($p < 0.001$) accompanied by 32.6% lowered GIP concentrations following the oral glucose challenge ($p < 0.05$). Metabolic responses to an oral fat challenge were similar in control, pregnant and lactating rats. Lactating rats exhibited 1.4-fold elevated intestinal weight compared to pregnant rats ($p < 0.01$), which was also increased by 1.3-fold compared to controls ($p < 0.01$). Assessment of GIP intestinal content revealed pregnant, but not lactating, rats to have 1.5-fold elevated peptide concentrations when compared to controls (654.0 ± 39.2 vs. 167.6 ± 21.4 pmol/g wet weight, respectively, $p < 0.01$).

Conclusion: Metabolic adaptation in pregnancy and lactation are associated with distinct changes of circulating and intestinal GIP concentrations, suggesting a prominent role of intestinal K-cells in partition of energy regulation mediated via extrapancreatic targets.

Not glucose tolerance but obesity impairs the numerical incretin effect in Japanese subjects

A. Hamasaki¹, N. Harada¹, A. Muraoka¹, E. Yamane¹, E. Joo¹, K. Suzuki¹, D. Nasteska¹, Y. Kondo¹, M. Hishizawa¹, T. Takano², Y. Seino³, N. Inagaki¹; ¹Diabetes and Clinical Nutrition, Kyoto University, ²Novo Nordisk Pharma Ltd., Tokyo, ³Kansai Electric Power Hospital, Osaka, Japan.

Background and aims: It is well known that incretin effect contributes to as much as half of insulin secretory response to oral glucose load. Previous studies showed that this effect reduces along with worsening of glucose tolerance and correlates to BMI. These findings are, however, almost based on Caucasian subjects, and little is known on Asian subjects who have different genetic background resulting in much lower insulin secretory capacity. Previously, we have reported for the first time that incretin effect in Asian normal glucose tolerance (NGT) subjects is comparable to that in European subjects. Thus, in this study, we aimed to investigate whether glucose tolerance and BMI influences incretin effect.

Materials and methods: Isoglycemic 3-hour oral (75g oral glucose tolerance test (OGTT)) and intravenous glucose administration was performed in 25 Japanese subjects (age: 38.3 ± 13.6 (23–68) years; body mass index (BMI): 24.0 ± 4.1 (17–33) kg/m² (mean \pm S.D. (range))) who consists of 16 NGT, 4 impaired glucose tolerance (IGT) subjects, and 5 patients with type 2 diabetes (T2DM). In the isoglycemic test, intravenous glucose infusion (20% wt/vol) was performed aiming to reproduce the plasma glucose profile at OGTT using artificial pancreas system STG-22 (Nikkiso, Tokyo, Japan). Plasma or serum levels of glucose, insulin, C-peptide, glucagon, free fatty acids (FFA), gastric inhibitory polypeptide (GIP) and glucagon-like polypeptide-1 (GLP-1) were determined. Incretin effect values were calculated by relating the difference in integrated incremental β -cell secretory responses.

Results: The glucose excursions during OGTT were closely reproduced by intravenous glucose infusion. Plasma concentrations of GIP and GLP-1 increased significantly after oral glucose load but not increased after intravenous glucose load. There was significant negative correlation between the incretin effect and BMI ($r = -0.47$, $P = 0.02$), while there was not significant correlation between the incretin effect and integrated glucose concentration during glucose administration. The numerical incretin effect was not significantly reduced in T2DM (47 ± 12) compared with IGT (47 ± 3) and NGT (51 ± 13). Integrated incremental β -cell secretory responses relative to integrated glucose concentration was remarkably reduced in T2DM. Furthermore, there were significantly negative relationships between β -cell secretory responses and glucose excursions both in oral and intravenous glucose administration similarly ($r = -0.59$, $P < 0.01$ and $r = -0.43$, $P < 0.05$ respectively).

Conclusion: In this study, we show that the numerical incretin effect is impaired in obesity as previously reported, and, however, is not always reduced in T2DM. The severely impaired β -cell response to intravenous glucose administration might be reflected to this finding in Japanese T2DM. Our results suggest that it is necessary to interpret the incretin effect carefully in dealing with the subjects with genetically different β -cell backgrounds.

Enteral supplementation with glutamine, fibre and oligosaccharide modulates incretin secretion

A. Muraoka¹, A. Hamasaki¹, N. Harada¹, H. Tsuji¹, S. Yamane¹, E. Joo¹, K. Suzuki¹, D. Nasteska¹, Y. Kondo¹, M. Hishizawa¹, K. Shide¹, Y. Seino², N. Inagaki¹;

¹Diabetes and Clinical Nutrition, Kyoto University, ²Kansai Electric Power Hospital, Osaka, Japan.

Background and aims: Secretion of incretin hormones, such as glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1, are stimulated by oral loading of various nutrient components. Recently, it is reported that glutamine and dietary fibre intake modify incretin secretory profiles in human. Furthermore, short-chain fatty acid brought by dietary fiber and oligosaccharide is suggested to increase plasma incretin concentration. Currently, enteral supplementation product enriched with glutamine, dietary fiber, and oligosaccharide (GFO) is available as prebiotics in clinical situation. Thus, in the present study, we examined the effects of GFO on incretin secretion.

Materials and methods: We recruited 20 healthy volunteers. Oral GFO (including 9 g glutamine, 15 g fiber, 18 g carbohydrates) and glucose (18 g) were administered on separate days. Plasma or serum levels of glucose, insulin, C-peptide, GIP and GLP-1 were determined over 180 min.

Results: Plasma glucose level is higher in Glucose loading than in GFO loading at 30 min ($p < 0.01$) and area under the curve of (AUC-) glucose in glucose loading was significantly higher than in GFO loading ($p < 0.05$). Plasma GLP-1 level is higher in GFO loading than in Glucose loading at 30 min (GFO 26.5 ± 2.4 vs. Glucose 21.1 ± 1.9 (pg/ml), $p < 0.01$), 60 min (22.1 ± 1.8 vs. 12.1 ± 1.4 (pg/ml), $p < 0.01$), and 120 min (16.1 ± 2.2 vs. 12.1 ± 1.7 (pg/ml), $p < 0.01$). AUC-GLP-1 in GFO loading was significantly higher than in Glucose loading ($p < 0.01$). In contrast, plasma GIP level is higher rather in Glucose loading than in GFO loading at 30min (GFO 89.7 ± 5.8 vs. Glucose 126.7 ± 11.1 (pg/ml), $p < 0.01$) and 60min (66.1 ± 3.2 vs. 84.3 ± 4.9 (pg/ml), $p < 0.01$). AUC-GIP in Glucose loading was significantly higher than in GFO loading ($p < 0.01$). Serum insulin and C-peptide levels showed no significant difference at each time point.

Conclusion: These results showed that GFO loading induce more GLP-1 secretion and less GIP secretion compared to glucose loading which elicit higher blood glucose level. It is suggested that GFO has a potential of dietary supplemental intervention to improve glucose metabolism and may have a favorable influence on metabolic status by modulation of incretin signaling.

525

The effects of glucose and meal ingestion on incretin secretion in Japanese subjects with normal glucose tolerance

S. Yamane¹, N. Harada¹, A. Hamasaki¹, A. Muraoka¹, E. Joo¹, K. Fujita¹, D. Nasteska¹, T. Takano², Y. Seino³, N. Inagaki¹;

¹Department of Diabetes and Clinical Nutrition, Kyoto University Graduate School of Medicine, ²Novo Nordisk Pharma Ltd., Tokyo, ³Department of Medicine, Kansai Electric Power Hospital, Division of Diabetes, Clinical Nutrition and Endocrinology, Osaka, Japan.

Background and aims: Gastric inhibitory polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) are major incretins and their secretion during various nutrient loads are evaluated well in Caucasians. However, little is known about relationship between incretin secretion and kinds or amounts of nutrition load in Japanese subjects. In the present study, we investigated how incretin levels are associated with the different amounts of glucose load or meal ingestion by measuring plasma GLP-1 and GIP levels after the administration of 17g or 75g glucose or mixed meal in Japanese normal glucose tolerance (NGT) subjects.

Materials and methods: We recruited 10 Japanese healthy volunteers. The subjects had no history of hypertension, hyperlipidemia, or kidney and liver diseases and did not take any drugs 2 weeks before the study. They participated in 75g oral glucose tolerance test (OGTT), 17g OGTT and meal tolerance test (MTT). Plasma glucose (PG), serum insulin (IRI), serum C-peptide (CPR), plasma total GIP, and plasma total GLP-1 during OGTTs and MTT were determined.

Results: Judging by the results of 75g OGTT, all the subjects were diagnosed NGT according to WHO criteria with fasting plasma glucose and 2-h glucose levels below 6.1 and 7.8 mmol/l, respectively. Between OGTT studies, AUC-PG, AUC-IRI and AUC-CPR in 75g OGTT were larger than those in

17g OGTT. Regarding incretins, AUC-GIP was significantly larger in 75g OGTT than in 17g OGTT. On the other hand, AUC-GLP-1 was not significantly different between 75g OGTT and 17g OGTT. Between MTT and 75g OGTT, there was no significant difference in AUC-PG, AUC-IRI, AUC-CPR and AUC-GLP-1. However, AUC-GIP was significantly larger in MTT than in 75g OGTT.

Conclusion: By comparing the results of the three loading tests (75g OGTT, 17g OGTT, MTT), we speculate that AUC-GIP was altered by contents of each loading test while AUC-GLP-1 was not. Our results suggest that nutritional composition might have larger effect on GIP secretion than on GLP-1 secretion in Japanese NGT subjects.

Elevated early GLP-1 and increased overall GIP response in type 2 diabetes as compared to the general population

M. Alsema¹, J.M. Rijkkelijkhuizen¹, J.J. Holst², E.M.W. Eekhoff³, L.M. 't Hart⁴, G. Nijpels¹, J.M. Dekker¹;

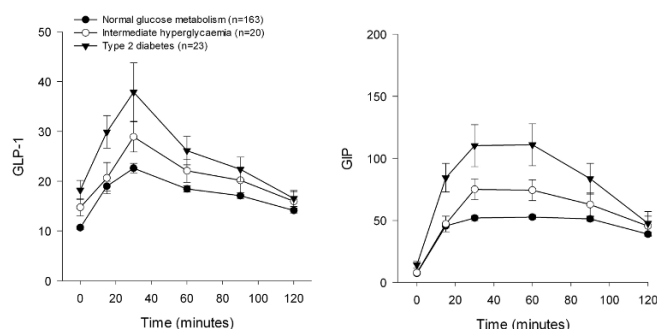

¹EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, Netherlands, ²Faculty of Health Sciences, University of Copenhagen, Denmark, ³Department of Internal Medicine section Endocrinology, VU University Medical Center, Amsterdam, Netherlands, ⁴Department of Molecular Cell Biology, Leiden University Medical Center, Netherlands.

Background and aims: Therapeutic interventions target enhancement of the gut-derived incretin hormones glucagon-like peptide 1 (GLP-1) and glucose-dependent insulintropic polypeptide (GIP) because of the stimulating effects on insulin secretion. Despite this, assessment of the incretin response in type 2 diabetes has led to conflicting results possibly due to selected control groups. We aimed to assess meal-related and oral glucose related GLP-1 and GIP responses among persons with early type 2 diabetes and intermediate hyperglycaemia as compared to a population-based sample of persons with normal glucose metabolism.

Materials and methods: In a population-based study, 163 persons with normal glucose metabolism, 20 with intermediate hyperglycaemia and 23 with early type 2 diabetes received a standardized mixed meal (75 g carbohydrates, 50 g fat and 24 g proteins) and an oral glucose tolerance test (75 g glucose) on separate occasions. GLP-1 and GIP profiles up to t=120 minutes (oral glucose tolerance test) and t=240 minutes (mixed meal test) were measured in plasma, after extraction. Time-dependent GLP-1 and GIP profiles were analysed by linear mixed models. A significant interaction between time and type 2 diabetes state is interpreted as a stronger rate of increase (or decrease) attributable to type 2 diabetes state.

Results: Among all subgroups, oral glucose elicited a higher GLP-1 ($p<0.05$), but lower GIP ($p<0.05$) response than the mixed meal. As compared to persons with normal glucose metabolism, patients with diabetes had higher fasting levels of GLP-1 ($p<0.01$), but not GIP. Patients with diabetes had higher overall GLP-1 and GIP levels following oral glucose ($p<0.01$) as compared to persons with normal glucose metabolism (Figure). Persons with intermediate hyperglycaemia had intermediate GLP-1 ($p<0.05$) and GIP levels (NS). GLP-1 and GIP responses to the mixed meal showed comparable results (data not shown). More specifically, as compared to persons with normal glucose metabolism, the initial GLP-1 response (t=30) following oral glucose in diabetes patients was stronger (p -value interaction <0.01), followed by stronger suppression later on (t=120, p -value interaction <0.05). The GIP response was more pronounced in diabetes patients (t=15-90 min, p -value interaction <0.01).

Conclusion: We found higher fasting GLP-1 and an elevated early, but abridged GLP-1 response together with an increased overall GIP response among diabetes patients as compared to persons with normal glucose metabolism, from the general population. This suggests a role of GLP-1 and GIP in distinct pathophysiological mechanisms in type 2 diabetes.

Sex hormone-binding globuline correlates positively with insulin sensitivity in pubertal girls with type 1 diabetes mellitus

B. Mianowska¹, M. Perenc², E. Czerniawska¹, I. Pietrzak¹, A. Zmyslowska¹, W. Fendler¹, J. Bodalski³, W. Mlynarski¹, A. Szadkowska¹;

¹Department of Pediatrics, Oncology, Hematology and Diabetology,

²Department of Foetal Medicine and Gynaecology, ³Department of Pediatrics, Medical University, Lodz, Poland.

Background and aims: Low sex hormone binding globuline (SHBG) levels have been associated with insulin resistance and cardiovascular risk in people without diabetes. In adolescents with type 1 diabetes (T1DM) a decrease in insulin sensitivity is observed during puberty and girls are more insulin resistant than boys. The underlying conditions depend largely on endocrine factors, however the relationship between sex hormones and insulin sensitivity measured directly as glucose uptake has not been described in this population. The aim of the study was to assess the relationship between puberty-related hormones and insulin sensitivity in pubertal girls with T1DM.

Materials and methods: The study group consisted of 34 pubertal girls aged 11.3–18.9 years (mean±SD: 15.2±2.3) with T1DM duration of 4.57±3.4 years. Insulin sensitivity (glucose uptake) was expressed as M value in mg/kg/min calculated for the last 30 min of the euglycaemic hyperinsulinaemic clamp. SHBG was measured by solid-phase chemiluminescent assay, dehydroepiandrosterone sulfate (DHEAS) - by radioimmunoassay, estradiol and testosterone - by competitive immunoassay, luteinizing hormone, follicle stimulating hormone and prolactin - by immunometric technique. Correlation coefficient (r) and multivariable regression with backward stepwise variable selection were applied for statistical analysis.

Results: Only two hormones significantly correlated with insulin sensitivity. A significant positive correlation was found between M value and SHBG levels ($r=0.46$, $p=0.008$), this correlation remained significant after correction for potentially confounding factors ($\beta=0.46$, $p=0.004$). A negative correlation was found between DHEAS and M value ($r=-0.43$, $p=0.013$) but it was not statistically significant after correction for confounding factors.

Conclusion: Lower SHBG levels in pubertal girls with T1DM may promote insulin resistance increasing patients' cardiovascular risk.

528

Inverse correlation between serum insulin and sex hormone binding globulin in a population survey in the south-west of Sweden

B. Daka¹, P.A. Jansson², T. Rosen³, L. Råstam⁴, U. Lindblad¹;

¹Department of Public Health and Community Medicine/Primary Health Care, The Sahlgrenska Academy, University of Gothenburg, ²Sahlgrenska Center for Cardiovascular and Metabolic Research, Wallenberg Laboratory, Sahlgrenska University Hospital, Göteborg, ³Endocrine Section, Sahlgrenska University Hospital, Göteborg, ⁴Department of Clinical Sciences, Community Medicine, Malmö University Hospital, Lund University, Sweden.

Background and aims: Obesity is associated with low levels of sex hormone binding globulin (SHBG). While the reason is not fully understood we aimed to study the association between serum insulin and levels of SHBG in a random population.

Material and methods: Between 2001 and 2005 a random sample of 2816 participants aged 30–74 years were enrolled in a cross-sectional survey in the South-west of Sweden. Fasting blood samples were collected and a clinical evaluation was performed. An oral glucose tolerance test (OGTT) was conducted in all subjects without known diabetes. Diabetes mellitus (DM) was defined according to criteria from WHO, and clinical characteristics were used to discriminate between type 1 (T1D) and type 2 diabetes (T2D). Analyses of SHBG were successful in 2761 participants (98%), who thus constituted the current study population.

Results: We found significant inverse associations between levels of SHBG and fasting serum insulin in both genders (men: $\beta=-0.081$, $p<0.001$, women $\beta=-0.079$, $p=0.014$), which were independent of differences in age and BMI. The associations remained when also differences in fasting plasma glucose were accounted for (men: $\beta=-0.061$, $p=0.024$, women $\beta=-0.070$, $p=0.033$). On

the contrary, subjects with T1D exhibited significantly higher levels of SHBG than both subjects with T2D ($\delta=23\text{nmol/L}$ CI 8–38nmol/L $p=0.002$), and non-diabetic subjects ($\delta=15\text{nmol/L}$ CI 1–29nmol/L $p=0.035$).

Conclusion: These findings are consistent with high levels of SHBG in T1D, and correspondingly low levels in T2D subjects, suggesting an inhibitory effect of insulin on the SHBG production in the liver.

Testosterone, SHBG and the metabolic syndrome: an individual participant data meta-analysis

J.S. Brand, M.M. Rovers, Y.T. van der Schouw, The Endogenous Hormones and Metabolic Syndrome Collaborative Group;

Julius Center for Health Sciences and Primary Care, UMC Utrecht, Netherlands.

Background and aims: Increasing evidence suggests a role for testosterone and SHBG in the etiology of the metabolic syndrome (MetS). We performed a collaborative analysis to determine the strength of these associations overall and in different circumstances and to examine the contribution to individual MetS components.

Materials and methods: Individual data from 16 cross-sectional studies on 3661 men who did have the metabolic syndrome and 9565 men who did not. The metabolic syndrome was defined using the National Cholesterol Education Program-Third Adult Treatment Panel (NCEP-ATPIII) criteria. Odds ratios (ORs) for the metabolic syndrome by quartiles of total testosterone, SHBG and free testosterone were calculated and adjusted for study, age, smoking status, alcohol consumption, physical activity, and additionally for BMI and hormone levels.

Results: Men with low total testosterone, SHBG and free testosterone levels were more likely to have the metabolic syndrome. After adjustment for covariates, the ORs for the highest versus lowest quartile were 5.42 (95% CI 4.77–6.16; $P<0.001$ for continuous linear trend) for total testosterone, 4.66 (95% CI 3.91–5.54; $P<0.001$) for SHBG and 2.97 (95% CI 2.48–3.56, $P<0.001$) for free testosterone. The associations were attenuated but remained significant after further adjustment for BMI and hormone levels (total testosterone: OR_{Q4 vs Q1} 1.63, 95% CI 1.30–2.50, $P<0.001$; SHBG: OR_{Q4 vs Q1} 2.33, 95% CI 1.86–2.91, $P<0.001$ and free testosterone: OR_{Q4 vs Q1} 1.57 (1.27–1.94), $P<0.001$). A significant interaction between BMI and SHBG was found ($P<0.001$). ORs for Q4 versus Q1 of SHBG were 4.65 (95% CI 2.78–7.79) in men with a BMI $<25\text{ kg/m}^2$, 2.94 (95% CI 2.25–3.81) in men with a BMI of 25–30 kg/m^2 , and 2.18 (95% CI 1.46–3.25) in those with a BMI $>30\text{ kg/m}^2$. There were no significant subgroup effects for age, smoking status and other comorbidities. Among the five MetS components, associations were strongest for waist circumference and triglyceride and associations were weakest for blood pressure.

Conclusion: A robust, dose-response relationship exists between testosterone and SHBG levels and odds of the metabolic syndrome in men. The association between SHBG and MetS appears to be stronger in leaner men. The contribution of individual MetS components varies, with testosterone and SHBG being most strongly associated with abdominal obesity and hypertriglyceremia.

Testosterone: a possible mediator between bone remodelling and energy homeostasis

B. Literáti-Nagy¹, B. Buday¹, P.F. Pach², E. Kulcsár¹, M. Vitai¹, É. Péterfi¹, L. Korányi¹;

¹Drug Research Center, Balatonfüred, Hungary, ²Institute of Chemical and Processing Engineering, University of Pannonia, Veszprém, Hungary.

Background and aims: Recent findings show that osteocalcin (OCN) a newly identified osteoblast derived mediator of energy balance, not only enhances insulin secretion and insulin sensitivity, but also enhances testosterone production in the Leydig cells of male mice. Low testosterone levels have been linked to metabolic syndrome and increased insulin resistance in men in numerous human studies. Our aim was to assess the relationship between OCN and testosterone levels in normal and impaired glucose tolerant male subjects and the possible role of serum testosterone in the metabolic links of OCN because no human data are available until now.

Materials and methods: 61 obese and non-obese healthy and “prediabetic” male subjects (aged 38.6 ± 13.2 years) were examined who were previously non-treated for glucose intolerance. OGTT, ivGTT and hyperinsulinemic euglycemic clamp were done to assess glucose tolerance, insulin secretion and sensitivity. Full metabolic profiling, adipocytokines, OCN, osteoprotegerin (OPG), nuclear factor κ B ligand (RANKL) and sex steroids were measured. Lean and fat body mass were determined by DEXA.

Results: Based on the OGTT 22 subjects were normal (NGT), and 39 subjects impaired glucose intolerant (GI = IFG/IGT or 2DM). Strong positive bivariate correlation was found between OCN and testosterone levels ($r=0.37$, $p=0.003$) which was independent of age, body mass index (BMI) and body fat percent (BFP). No correlation was observed between OCN and FSH, oestradiol, or dehydroepiandrosterone. We found that the significant correlations observed between OCN and OGTT AUC (glucose area under the curve ($r=-0.4$, $p=0.001$), ivGTT glucose AUC ($r=-0.38$, $p=0.003$), fasting FFA ($r=-0.37$, $p=0.004$), HDL-cholesterol ($R=0.39$, $p=0.002$) were unaffected if data were adjusted with serum testosterone, but disappeared between OCN and clamp measured muscle glucose utilization. Feature selection (variable ranking) analysis showed that serum testosterone was ranked as 24.4/67 (average merit 0.1 ± 0.004) to determine OCN levels, ranked higher than BFP, BMI, M_{fat} , HbA1c%, or OGTT glucose levels but ranked lower than serum leptin, adiponectin, OPG and RANKL.

Conclusion: The connection between OCN and testosterone levels observed in animal models is supported by these human data. We found a strong positive correlation between serum OCN and testosterone levels in men which was not dependent of age and body composition. Our data suggest that in male subjects the antihyperglycemic effect of OCN is regulated not only by adipokines but by serum testosterone levels and OPG and RANKL forming the possible “OCN - insulin” axis.

Prevention of obesity and insulin resistance by estrogens: dispensable role of the estrogen receptor alpha activation function 1

E. Riant¹, S. Handgraaf¹, A. Fabre¹, M.-J. Fouque¹, A. Krust², P. Chambon², J.-F. Arnal¹, P. Gourdy^{1,3}

¹Institut of Metabolic and Cardiovascular Diseases, INSERM U1048, Toulouse, ²IGBMC, Illkirch, ³Diabetology Department, Toulouse University Hospital, France.

Background and aims: Estrogens prevent visceral adiposity, insulin resistance and type 2 diabetes, but their therapeutic potential is strongly limited by their deleterious proliferative action on sexual targets, namely the mammary gland and the uterus. These beneficial metabolic effects result from activation of estrogen receptor alpha ER α which regulates the transcription of many genes through two activation functions (AF-1 and AF-2). We recently demonstrated that, although ER α AF-1 is absolutely required for the uterine proliferative action of estrogens, it is dispensable for their beneficial atheroprotective action of estrogens, paving the way for a selective AF-1-independent ER α modulation devoid of sexual effects. In the present study, we aimed to characterize the involvement of ER α AF-1 domain in the beneficial effects of estrogens on body composition and glucose homeostasis.

Materials and methods: ER α -deficient (ER $\alpha^{-/-}$) AF-1-deficient (AF-1 $^{\Delta}$) female and male mice have been maintained under a chow diet until 7 months of age or submitted to a high-glucose high-fat diet, and compared to their respective littermate wild-type controls in terms of weight gain, body composition and i.p. glucose tolerance test ($n=8-10$ by genotype). Then, to avoid interference with endogenous steroid levels, female mice were ovariectomized at 4 weeks of age and were implanted with subcutaneous pellets allowing a chronic and stable administration of 17 β -estradiol (E2, 80 μ g/kg/d) for 3 months.

Results: As compared to their littermates, female and male ER $\alpha^{-/-}$ mice were both characterized by significantly accelerated weight gain (+36% and +58% for male and female mice on chow diet respectively), massive accumulation of adipose tissue in subcutaneous (+61% and +64% for male and female mice on chow diet respectively) and perigonadic (+62% and +63% for male and female mice on chow diet respectively) sites, hyperinsulinemia and glucose intolerance (AUC: +32% and +35% for male and female mice on chow diet respectively). Similar results were observed under high-fat diet. In striking contrast, weight gain and adiposity constitution were not altered in female and male AF-1 $^{\Delta}$ mice fed either a chow or high-fat diet. Furthermore, glucose tolerance was totally preserved in male AF-1 $^{\Delta}$ mice and modestly impaired in female AF-1 $^{\Delta}$ mice. Since we confirmed that ER $\alpha^{-/-}$ mice exhibit a significant

elevation of endogenous levels of sex steroids, we then studied the effect of chronic E2 administration in ovariectomized female mice on a chow diet. As expected, E2 exerted a strong preventive effect against fat mass accumulation in wild-type mice (-61% subcutaneous and -68% perigonadic, $p<0.001$). This beneficial action on body composition was abolished in ER $\alpha^{-/-}$ mice, but conserved in AF-1 $^{\Delta}$ mice.

Conclusion: As previously demonstrated for the vasculoprotective actions of estrogens, we now provide evidence that ER α -mediated beneficial effects on body composition and glucose tolerance can be obtained in the absence of ER α AF-1 domain. The present study thus reinforces the interest for an AF-1-independent specific modulation of ER α aiming to uncouple the metabolic and vascular protective actions from undesired proliferative effects on reproductive tissues.

Association of insulin, proinsulin and IGFBP1 with cardiometabolic risk factors and cardiovascular mortality in an elderly population

I.S. Chisalita¹, U. Dahlström², H.J. Arnqvist³, U. Alehagen²

¹Department of Emergency Medicine, ²Department of Cardiology, Sweden, ³Department of Cell Biology, University Hospital, Linköping, Sweden.

Background and aims: Insulin and the insulin-like growth (IGF) systems are phylogenetically closely related. Insulin down-regulate the secretion of insulin-like growth factor binding protein 1 (IGFBP1) from the liver. Previous studies have shown conflicting results regarding the association of circulating insulin, proinsulin and IGFBP1 with cardiometabolic risk factors and mortality. Our aim was to examine the association of insulin, proinsulin and IGFBP1 with cardiovascular (CV) mortality in an elderly population.

Materials and methods: Of all persons aged 70 to 80 years, in a rural Swedish municipality, 852 (73%) accepted to participate in the project. Participants were evaluated by disease history, clinical examination and fasting blood samples including insulin, proinsulin and IGFBP1. They were then followed for 8 years.

Results: Circulating insulin and proinsulin levels were highly correlated at the initial examination and were positively associated with diabetes mellitus, BMI (body mass index), triglycerides but negatively with IGFBP1. IGFBP1 levels were negatively associated with cardiometabolic risk factors as BMI and triglycerides and positively associated with age. At follow up 231 individuals had died, 134 of cardiovascular causes, 40 of malignancies. When insulin, proinsulin and IGFBP1 levels were divided into quintiles, CV mortality was significantly increased for quintile 5 of proinsulin and quintile 4 and 5 of IGFBP1. For insulin a U-shaped relation was found with the lowest CV mortality in quintile 3. When adjusted for cholesterol, BMI, fasting blood glucose, smoking and systolic blood pressure the CV mortality risk remained significant for proinsulin and IGFBP1, but not for insulin.

Conclusion: Our results in an unselected community population of elderly show that proinsulin and IGFBP1 are associated with CV mortality.

Does amylin affect bone structure in the diabetic state?

I. Gutiérrez-Rojas¹, D. Lozano², P. Moreno¹, B. Nuche-Berenguer¹, I. Ramos-Álvarez¹, N. González¹, A. Acitores¹, A. Novials³, I. Valverde¹, P. Esbrit², M.L. Villanueva-Peñacarrillo¹

¹Dpt. Metabolism, Nutrition & Hormones, Fundacion Jimenez Diaz, Madrid,

²Laboratory of Bone & Mineral Metabolism, Fundacion Jimenez Diaz, Madrid, ³Laboratory of Diabetes & Obesity, IDIBABS, Hospital Clínic, Barcelona, Spain.

Background and aims: Amylin is co-secreted with insulin from the β -cell, both hormones responding to the same stimuli; it shows some of the effects reported for GLP-1 such as diminishing food intake, slowing gastric emptying and being lipolytic. Amylin also reduces body fat, and is being proposed for the therapy of obesity and diabetes. It has been shown that GLP-1 ameliorates the impaired bone turnover of insulin-resistant (IR) and type 2 diabetic (T2D) models. We have investigated the possible effect of prolonged treatment with amylin on the altered trabecular bone structure in IR and T2D states.

Materials and methods: Male Wistar rats were kept on standard chow and water ad libitum. Normal (N), IR (by fructose) and T2D (streptozotocin at

birth) were 3-day treated with amylin (10^{-9} M) or saline (control), $n=10$ /group, through an osmotic pump subcutaneously implanted. In fed conditions, blood samples were taken before (basal) and by the end of treatment for plasma glucose, insulin (RIA) and amylin (ELISA) measurements; then, rats were sacrificed and the femora were collected, embedded in methylmethacrylate, and sections of the proximal metaphysis were stained with von Kossa's and Goldner's trichrome for the analysis of bone static parameters: bone mineral density (BMD) and mineral content (BMC) -by Lunar PIXImus-, bone volume per total tissue volume ratio (BV/TV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), trabecular number (Tb.N), erosive surface/bone surface (ES/BS) and osteoclastic surface (OcS/BS) -light microscopy-.

Results: In plasma, basal insulin and glycaemia, as expected, were higher in IR than those in N (both $p<0.05$); in T2D, insulin was lower, and glycaemia, higher (both, $p<0.01$ vs N); amylin did not affect glycaemia in any group, but reduced insulin in IR ($p<0.001$); basal amylin was equal in the three groups (overall mean: 15 ± 3 fmol/ml), and increased to 34 ± 5 fmol/ml during treatment, within the physiological range. In femur, no differences were observed in BMD or BMC in either model vs N (0.162 ± 0.005 mg/cm³ and 0.300 ± 0.014 g, respectively); however, BV/TV and Tb.N were decreased in both ($p<0.01$ vs N), IR (19.1 ± 1.5 % and 1.01 ± 0.09 mm⁻¹, respectively) and T2D (18.8 ± 2.1 % and 1.03 ± 0.09 mm⁻¹), these corresponding values in N being 26.2 ± 1.9 % and 1.67 ± 0.07 mm⁻¹. Conversely, trabecular separation, which was 465 ± 26 μ m in N, showed to be increased to 820 ± 43 μ m and 769 ± 59 μ m in IR and T2D, respectively (both, $p<0.01$); no decrease in Tb.Th was observed in the latter groups vs N. Amylin treatment normalized these altered trabecular structure parameters only in T2D rats (BV/TV: 29.4 ± 3.1 %, Tb.N: 1.54 ± 0.17 mm⁻¹ and Tb.Sp: 433 ± 54 μ m; all $p<0.05$ vs T2D-control); in addition, about a 30% decrease in both ES/BS and OcS/BS was also detected in T2D after amylin.

Conclusion: These data demonstrate, for the first time to our knowledge, that a sustained high physiological concentration of amylin exerts an osteogenic action in the femoral metaphysis in these T2D rats. Since this osteogenic effect of amylin is absent in our IR model, we hypothesize that this hormone might require an intact insulin signalling.

Study on the effect of aldosterone excess on abnormal glucose metabolism

Y. Matsuzawa, H. Sellami, J. Saito, M. Omura, T. Nishikawa;
Medicine, Yokoham Rosai Hospital, Yokohama, Japan.

Background and aims: Primary aldosteronism (PA) is often associated with glucose intolerance and diabetes. An impairment in glucose metabolism and insulin action may be induced by excess aldosterone, although its mechanism remains unresolved. Thus we intended to clarify the characteristics of glucose metabolism in PA.

Materials and methods: We enrolled 72 cases with PA (33 males and 39 females, mean age=52.7 years old) who had no history of diabetes. Localization of adrenal lesion was determined by adrenal venous sampling. The patients with Cushing or subclinical Cushing syndrome were excluded by 1mg dexamethasone suppression test. For the control group, we subjected 239 cases of essential hypertension (EHT) who were admitted to our hospital for general health check-up. EHT group was matched with PA group for age and BMI. 75g OGTT was performed to all the subjects, and plasma glucose and insulin were measured at 0, 30, 60, 90 and 120 minutes. The homeostatic model assessment (HOMA) was used to evaluate insulin sensitivity. We also compared Matsuda index (M-I), insulinogenic index (IGI) and disposition index (D-I) from the results of glucose and IRI response to OGTT. In addition, 26 patients went through OGTT before and one year after surgical treatment of PA.

Results: The frequency of abnormal glucose tolerance was not different between the PA and EHT group. However, HOMA-R was higher and M-I was lower in the PA patients with abnormal glucose tolerance compared with EHT patients, reflecting decreased insulin sensitivity in PA patients. The PA patients demonstrated higher acute insulin secretion determined as IGI than EHT patients. Moreover, when we compared the glucose metabolism of PA patients before and one year after adrenal resection, the glucose tolerance was apparently improved in 10 of 26 cases (38.5%) after surgical treatment.

Conclusion: These findings raise the possibility that aldosterone excess may cause impaired glucose metabolism in PA patients, and that abnormal glucose tolerance in PA is characterized by presence of decreased insulin sensitivity. Moreover, we should focus on the importance of aldosterone in pathogenesis of diabetes.

Beneficial effect of fibroblast growth factor 21 to the insulin resistance induced by palmitate in skeletal muscle cells

M.-S. Lee¹, S.-Y. An¹, E. Kim¹, E. Ha¹, S.-E. Choi¹, T. Kim², S. Han¹, H. Kim¹, D. Kim¹, Y. Kang³, K.-W. Lee¹;

¹Department of Endocrinology and Metabolism, Ajou University School of Medicine, Suwon, ²Department of Endocrinology and Metabolism, Kwandong University, College of Medicine, Goyang, ³Institute of Medical Science, Ajou University School of Medicine, Suwon, Republic of Korea.

Background and aims: Insulin resistance is an important mechanism of type 2 diabetes mellitus. Fibroblast growth factor 21 (FGF21) has been identified as a potent metabolic regulator with specific effects not only on glucose and lipid metabolism, but also as a regulator of energy balance, especially in adipocytes and the liver. However, it is not yet clear whether FGF21 contributes to insulin resistance in skeletal muscle cells. Palmitate causes insulin resistance in skeletal muscle cells through the activation of a chronic inflammatory process. Here, we investigated the potential contribution of FGF21 to the insulin resistance induced by palmitate in skeletal muscle cells.

Materials and methods: First, confirming the contribution of FGF21 to the palmitate-induced insulin resistance, we determined 2-[N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-D-glucose (2-NDBG) uptake and levels of proteins related to insulin signaling pathways (IRS-1, Akt) in human skeletal muscle myotubes (HSMM) exposed to palmitate (100, 200 μ M) for 24 h and compared those in HSMM exposed to both palmitate and different doses of recombinant FGF21 (100, 200 ng/mL). Second, to determine the mechanisms underlying the contribution of FGF21 to palmitate-induced insulin resistance, we compared levels of protein related to palmitate-induced insulin resistance (PKC- θ , IKK β , JNK, p38, I κ B α , NF- κ B) in HSMM exposed to palmitate and different doses of recombinant FGF21 (100, 200 ng/mL) for 24 h.

Results: Palmitate reduced the insulin-stimulated glucose uptake in HSMM. However, palmitate-reduced glucose uptake was restored by FGF21. Palmitate also inhibited phosphorylation of Akt, and thus impaired the insulin signaling pathway in HSMM, but FGF21 prevented the palmitate-inhibited phosphorylation of Akt. These results indicated that FGF21 prevented palmitate-induced insulin resistance in HSMM. Palmitate activated NF- κ B in HSMM, and thus impaired the action of insulin and initiated chronic inflammation in HSMM. However, FGF21 inhibited the palmitate-induced NF- κ B activation in HSMM. **Conclusion:** The results of the present study suggest that FGF21 prevents palmitate-induced insulin resistance in HSMM by inhibiting activation of stress kinase and NF- κ B.

Functional characterisation of the Rab GTPase activating protein TBC1D1 *in vitro*

F. Neumann¹, H. Klein², A. Chad¹, J. Dokas¹, H.-G. Joost¹, H. Al-Hasani^{1,3};

¹Department of Pharmacology, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, ²Institute for Biochemistry, University of Cologne, ³Institute of Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, Leibniz Center for Diabetes Research at the Heinrich-Heine-University Duesseldorf, Germany.

Background and aims: TBC1D1 is a homolog of the insulin signal protein AS160 and regulates the insulin-stimulated glucose uptake in skeletal muscle. The biological activity of TBC1D1 is regulated by phosphorylation on multiple serine/threonine residues and strictly depends on its intrinsic Rab-GTPase activating protein (GAP) activity. A human variation (R125W) is associated with familial obesity, whereas a loss-of-function mutation of Tbc1d1 in lean SJL mice leads to increased fatty acid uptake and oxidation in skeletal muscle and thus protects from HFD-induced obesity and diabetes. The aim of this study is to investigate the molecular mechanism for regulating TBC1D1's GAP activity and to identify new Rab proteins within the TBC1D1 signal pathway. Therefore, we established an *in vitro* test procedure to functionally characterize the enzymatic specificity and Rab-GAP activity of purified recombinant TBC1D1.

Materials and methods: The mRNA expression level of 56 Rab-GTPases was quantified in skeletal muscle and white adipose tissue of lean and obese

mouse strains using Affimetrix Chip analysis. For establishment of an *in vitro* test procedure, cDNAs of 8 Rab-GTPases highly expressed in skeletal muscle, and the 48 kDa GAP domain of TBC1D1 as well as an inactive mutant (R941K), were cloned and expressed as glutathione-S-transferase (GST)-fusion proteins in *E. coli* and purified by glutathione affinity chromatography. In addition, full length histidine-tagged TBC1D1 (1255 aa) and the inactive mutant (His6-R941K) were produced by baculovirus-mediated expression in Sf9 insect cells. His6-TBC1D1 proteins were purified via Ni-NTA-affinity chromatography. The GAP activity of TBC1D1 was determined by measuring GTP turnover using isotope techniques.

Results: Soluble forms of the GST-Rab proteins and GST-GAP domains were purified from bacterial lysates with a yield of about 0.1 mg/l of culture. Of all Rab proteins tested, the recombinant TBC1D1-GAP domain showed highest specific activity to Rab10, which represents the most abundant Rab isoform in skeletal muscle. The GTPase activity of Rab10 was stimulated >10-fold in the presence of the GAP domain. The His6-tagged 160 kDa TBC1D1 protein was expressed in baculovirus-infected Sf9 cells and subsequently purified with high yield (0.3 mg/l of culture). First experiments showed catalytic GAP activity of His6-TBC1D1 towards GST-Rab10 *in vitro*. Nevertheless, purification and reaction conditions have to be optimised further to enhance the stability of His6-TBC1D1 and to improve the robustness of the test procedure.

Conclusion: The Rab10 isoform is a likely downstream target of TBC1D1 in the insulin signal cascade in skeletal muscle. Our assay now allows functional *in vitro* characterization of TBC1D1 and the search for TBC1D1 inhibitors as well as the development of novel pharmacological modulators of TBC1D1 that might be suitable for the treatment of obesity.

Skeletal muscle mitochondrial cytochrome c oxidase activity is reduced in obese prediabetic individuals

T. Kurdiova¹, B. Ukropcova¹, M. Balaz¹, M. Vician², M. Vlcek¹, M. Srbecky³, J. Olejnik², R. Imrich¹, V. Belan¹, I. Klimes¹, D. Gasperikova¹, J. Ukropec¹

¹Institute of Experimental Endocrinology, Slovak Academy of Sciences,

²Department of Surgery, Slovak Medical University, ³Radiodiagnostic Clinic, University Hospital, Bratislava, Slovakia.

Background and aims: Obesity is considered a risk factor for the development of insulin resistance and type 2 diabetes. Evidence exists for the connection between the number and function of skeletal muscle mitochondria and insulin resistance. However, a causative role of mitochondrial dysfunction in obesity related type 2 diabetes development is unclear. Therefore, we compared skeletal muscle mitochondrial content and function in the group of young (31.2±1.1 yrs.) lean healthy men (n=18; 22.3±0.5 kg.m⁻²; body fat 16.8±1.0%) with that of obese/overweight men with normal glucose tolerance (n=14; 30.5±0.9 kg.m⁻²; body fat 28.9±1.3%), and with prediabetes (n=12; 30.2±0.8 kg.m⁻²; body fat 28.0±1.1%).

Materials and methods: Complex metabolic phenotyping included euglycemic hyperinsulinemic clamp (assessment of insulin sensitivity), oral glucose tolerance test, magnetic resonance imaging (adipose tissue size and distribution) and ¹H-MR spectroscopy (hepatic and intramyocellular fat content). Physical activity was monitored with accelerometers and “Beacke” activity questionnaire. Samples of vastus lateralis skeletal muscle were obtained by needle biopsy. The expression of mitochondrial markers cytochrome c, peroxisome proliferator activated receptor coactivator 1 alpha, ATP-Mg2+/Pi mitochondrial carrier SLC25A25 as well as mitochondrial DNA content were determined by qRT PCR. The activity of cytochrome c oxidase was measured by oximetry in permeabilised muscle fibers.

Results: Markers of mitochondrial biogenesis, activity (cytochrome c, ATP-Mg2+/Pi mitochondrial carrier) and mtDNA copy number did not differ between the groups. However, cytochrome c oxidase activity was decreased specifically in obese prediabetics. Activity of cytochrome c oxidase was negatively associated with % of body fat (p=0.031, r=0.383), subcutaneous (p=0.027, r=0.397) and visceral fat content (p=0.037, r=0.375), fat cell size (p=0.003, r=0.518), marginally with hepatic lipid content and positively with insulin sensitivity (p=0.027, r=0.394), sport index (p=0.015, r=0.420) and leisure-time index (p=0.034, r=0.371). Gene expression of the ATP-Mg2+/Pi mitochondrial carrier SLC25a25 which has been shown to decrease metabolic efficiency and physical endurance in mice, correlated negatively with several parameters of physical activity (number of steps/24h p=0.018, r=0.377, walking distance p=0.015, r=0.389, high intensity ambulatory activity/24h p=0.011, r=0.401) and with cytochrome c oxidase activity (p=0.026, r=0.387).

Conclusion: Our results indicate that reduced skeletal muscle mitochondrial function found in prediabetes, a clinical precursor of type 2 diabetes, might play an active role in the pathogenesis of type 2 diabetes. The skeletal muscle mitochondrial function mirrors metabolic phenotypes and the physical activity profile, pointing at the importance of physical activity in the maintenance of metabolic health.

COX2 inhibition with celecoxib improves mitochondrial density in diabetic rat muscle

S. Kang¹, H. Kim¹, J. Moon², H. Kim², B. Lee², E. Kang², H. Lee², B. Cha²;

¹Brain Korea 21 for Medical Science, ²Yonsei University College of Medicine, Seoul, Republic of Korea

Background and aims: Both mitochondrial dysfunction and alterations in mitochondrial DNA (mtDNA) are implications of type 2 diabetes mellitus and insulin resistance. Recent evidences suggest that metabolism of cyclooxygenase-2 (COX2) is associated with mitochondrial dysfunction and insulin resistance.

Materials and methods: We investigated the effect of celecoxib as a COX2 inhibitor on mtDNA density and insulin sensitivity using the obese diabetic OLETF rats and lean nondiabetic LETO rats. We produced severe insulin resistance in twenty-week-old male OLETF rats with high fat diet for 5 weeks. OLETF rats were further subdivided into two groups: control (in drinking water, n=10), celecoxib (15mg/kg, in drinking water, n=10).

Results: In high-fat diet OLETF rats, 5-week treatment with celecoxib did not change body weight (control vs celecoxib, 643±35 vs 653±63g), overnight-fasting glucose (150±62 vs 108±18mg/dL), and fasting insulin (1045±281 vs 895±221pmol/L). In OLETF rats, skeletal muscle mitochondria were severely destroyed and mtDNA density was decreased compare to lean LETO rats. These mitochondrial impairment was remarkably preserved in celecoxib-treatment OLETF rats (Figure).

Conclusion: COX2 inhibition with celecoxib in obese, insulin resistant diabetic rats might preserve mitochondrial dysfunction in skeletal muscle.

Leucine changes the timing and magnitude of insulin signalling in human myotube cultures, increasing baseline AKT, mTOR and ERK1/2 phosphorylation

E.M. Murphy^{1,2}, B. Di Camillo³, A. Avogaro¹, K.S. Nair², G.M. Toffolo³;

¹Department of Clinical and Experimental Medicine, University of

Padua, Italy, ²Endocrine Research Unit, The Mayo Clinic, Rochester, USA,

³Department of Engineering of Information, University of Padua, Italy.

Background and aims: Phosphorylation events along the insulin signaling pathway are important in determining insulin sensitivity, which is altered in diabetes and obesity. There is an important interplay between amino acids

such as leucine and insulin signaling pathways which mediate insulin sensitivity and glucose disposal. This study's aim was to test the effect of leucine treatment on insulin signaling in a cell culture of differentiated human myotubes. Key target proteins along the insulin signaling pathway and their phosphorylation patterns at relevant sites were quantified in a time-dependent manner to elucidate the mechanisms by which leucine can induce insulin resistance in skeletal muscle, which has important implications for whole body glucose metabolism.

Materials and methods: Commercially available human myoblasts from skeletal muscle were induced to differentiate into myotubes by exposing them to DMEM:F12 with 2% horse serum and 50 µg/ml gentamycin for ten days, after which they were serum-starved overnight with 5.5 mmol/l glucose DMEM. Cells were then switched to a balanced salt solution for 1h and either treated with DMEM + 100 nmol/l insulin or primed with DMEM + 400 µmol/l leucine for 1h, followed by treatment with DMEM + 100 nmol/l insulin + 400 µmol/l leucine at five time points, after which cells were lysed and total and phosphorylated protein targets were quantified by Western blot and/or Nanopro immunoassay. Medium glucose concentrations for each time point were enzymatically determined.

Results: Leucine priming increased baseline AKT phosphorylation at Ser473 more than fourfold relative to without leucine priming ($p<0.04$, two-tailed t test). In the absence of leucine, insulin induced maximal AKT phosphorylation at Ser473 at 10 min (tenfold relative to baseline). In the presence of leucine, insulin induced maximal Ser473 AKT phosphorylation earlier, at 5 min, but the magnitude was reduced (twofold relative to baseline), and the duration was reduced, returning back to pre-insulin levels by 10 min. In the absence of leucine, phosphorylation was sustained fivefold relative to baseline even after 60 min insulin exposure. Absolute magnitude of peak AKT Ser473 phosphorylation was increased 41% with insulin in the absence of leucine relative to in the presence of leucine. Nanopro immunoassay results confirmed Western blot findings for the effect of leucine on AKT phosphorylation. Leucine priming increased baseline ppERK12/ERK12 (Thr202/Tyr204) more than twofold ($p<0.03$, two-tailed t test) and p-mTOR/mTOR (Ser2448) twofold ($p<0.006$, two-tailed t test) relative to without leucine priming. In addition, the presence of leucine results in a more rapid but smaller acute drop in medium glucose concentrations (5 min, Δ glucose = -0.82 mmol/l) relative to insulin alone (10 min, Δ glucose = -1.79 mmol/l) though the effect of leucine on medium glucose is no longer apparent after 60 min.

Conclusion: Leucine attenuates the insulin-induced decline in glucose levels in the culture media by blunting insulin signaling, increasing baseline phosphorylation on AKT, ERK12 and mTOR, and reducing insulin's induction of phosphorylation events.

540

Relationships between mitochondrial function and metabolic flexibility in type 2 diabetes mellitus

T. van de Weijer¹, V.B. Schrauwen-Hinderling², E. Phielix¹, R. Meex³, N. van Herpen¹, M.K.C. Hesselink³, P. Schrauwen¹;

¹Human Biology, ²Radiology, ³Human Movement Sciences, Maastricht University Medical Center, Netherlands.

Background and aims: Mitochondrial dysfunction, metabolic inflexibility and intramuscular fat accumulation (IMCL) have been suggested to underlie the development of insulin resistance, but their interrelationship has not been well established. Here we determined these aspects in a relatively large group of type 2 diabetic patients and control subjects and determined the relationship with the oxidative and non-oxidative aspects of insulin resistance.

Materials and methods: In total 49 non-insulin dependent diabetic patients and 54 control subjects were enrolled, in which a 3-h hyperinsulinemic-euglycemic (40 mU /m²/min) clamp was performed, primed with an infusion of [6,6-2H2]glucose (0.04 mg/kg/min) to determine rates of glucose appearance (Ra) and disposal (Rd). Indirect calorimetry was performed to assess substrate metabolism. A muscle biopsy was taken, in which IMCL was determined with oil red O staining. In 31 control subjects and 30 diabetic patients PCr-recovery was measured for determination of *in vivo* mitochondrial function. Differences were analyzed with a one-way ANOVA. Linear regression was performed after adjustment for age, BMI and percentage of body fat. Data are reported as means \pm SE.

Results: Type 2 diabetic patients and control subjects had similar body weights (91.7 \pm 11.9 vs. 92.4 \pm 11.3 kg), BMI (29.8 \pm 3.1 vs. 29.4 \pm 3.3 kg/m²) and age (61.2 \pm 3.7 vs. 59.8 \pm 4.8 years). IMCL was not significantly different between the groups (0.96 \pm 0.66 vs. 1.10 \pm 0.64 AU). Baseline Rd was significantly higher in diabetic patients compared with control subjects (11.9 \pm 3.9 vs. 9.4 \pm 2.3

µmol/kg/min, $p<0.01$), with a higher glucose oxidation (8.3 \pm 2.6 vs. 6.7 \pm 2.2 µmol/kg/min, $p<0.05$), and no differences in non-oxidative glucose disposal (NOGD). Rd during insulin stimulation was significantly lower in diabetic patients (20.3 \pm 7.5 vs. 28.7 \pm 9.5 µmol/kg/min, $p<0.01$). This was due to a lower NOGD (8.4 \pm 6.9 vs. 15.4 \pm 8.1 µmol/kg/min $p<0.01$) and a lower glucose oxidation rate (12.0 \pm 3.3 vs. 13.7 \pm 3.7 µmol/kg/min, $p<0.05$) in diabetic patients upon insulin stimulation. The respiratory quotient (RER) was significantly higher at baseline (0.82 \pm 0.03 vs. 0.79 \pm 0.03, $p<0.01$) and was lower upon insulin stimulation (0.87 \pm 0.04 vs. 0.89 \pm 0.04, $p<0.05$) in diabetic patients. This resulted in a lower metabolic flexibility in diabetic patients (+0.05 \pm 0.03 vs. +0.09 \pm 0.05, $p<0.01$). Diabetic patients had a prolonged PCr-recovery half-time (PCr- $t_{1/2}$) by 12.5% compared to control subjects (22.3 \pm 6.9 vs. 19.8 \pm 4.5 s, respectively; $p<0.01$). PCr-recovery rates did not correlate with IMCL, but there was a negative correlation with insulin stimulated Rd ($R^2=0.10$, $p<0.05$). Metabolic flexibility not only correlated with Rd, but also independently correlated with *in vivo* mitochondrial function (Rd $R^2=0.17$, $p<0.01$, PCr- $t_{1/2}$ $R^2=0.07$, $p<0.05$).

Conclusion: These results indicate that defects in mitochondrial function, irrespective of lipid accumulation, might contribute to defects in insulin stimulated glucose disposal and oxidation in type 2 diabetes.

Endoplasmic reticulum stress does not mediate palmitate-induced insulin resistance in muscle cells

R. Hage Hassan, I. Hainault, F. Lasnier, P. Ferré, F. Fougelle, E. Hajdouch; Centre de Recherche des Cordeliers, INSERM U872, Paris, France.

Background and aims: Insulin resistance observed in skeletal muscle is a main feature of obesity and type 2 diabetes. Both diseases are interconnected, and elevated plasma concentrations of non-esterified fatty acids (NEFA) are always observed, leading to lipotoxicity through the over-accumulation of lipid derivatives such as ceramide in non-adipose tissues. We, and others, have shown that palmitate-generated ceramide inhibited insulin signalling in muscle cells by targeting specifically the protein kinase B, or Akt (PKB/Akt), a kinase implicated in the stimulation of glycogen synthesis and glucose transport. Recent experiments in liver and adipocyte cell lines indicate that palmitate could also initiate a response called Endoplasmic reticulum (ER) stress. In liver, ER stress has been shown to play a role in the pathogenesis of diabetes, contributing to steatosis, β -cell loss and insulin resistance through the activation of stress-activating kinases such as the Jun Kinase (JNK). Because ceramide biosynthesis from palmitate occurred at the level of the ER, our hypothesis was that the deleterious action of palmitate on the insulin signalling pathway could also involve an ER stress in muscle cells.

Materials and methods: We used C2C12 myotubes that were treated either with 0.75mM palmitate or 0.5µg/ml tunicamycin for 16h. Then total lysates and RNA were prepared for western blotting or quantitative RT-PCR respectively.

Results: Incubation of C2C12 myotubes for 16h with palmitate or tunicamycin, an agent that is known to induce hepatic insulin resistance through the activation of ER stress, induced an inhibition of insulin-stimulated PKB/Akt. In parallel, an increase in ER stress markers was observed in response to both palmitate and tunicamycin in these cells (i.e. phosphorylation of eIF2 α , splicing of XBP-1, activation of ER stress chaperones and foldases). We then examined whether tauroursodeoxycholic acid (TUDCA), a well-established chemical chaperone that has been demonstrated to inhibit ER stress, could improve insulin resistance in both cases. Results showed that pre-incubation of cells with TUDCA only prevented tunicamycin-induced insulin resistance, with no effect on the harmful action of palmitate on PKB/Akt. Our hypothesis to explain this discrepancy was that the level of activation of the ER stress induced by the lipid may be not high enough. Indeed, tunicamycin induced robust activation of the IRE1/JNK pathway, leading to serine phosphorylation-induced inhibition of IRS1. On the other side, palmitate only induced a mild activation of the IRE1/JNK pathway, with no phosphorylation of IRS1 on serine residues.

Conclusion: These data show that the onset of insulin resistance induced by palmitate is not related to ER stress in muscle cells. Production of ceramide from palmitate remains a crucial step to downregulate the insulin signalling pathway at the level of PKB/Akt. However we cannot exclude that a chronic exposure of the muscle cells to saturated fatty acids, like it could be the case in obesity, may induce a more important ER stress than seen in our conditions, therefore affecting in that case the insulin pathway.

Strongly increased intramyocellular lipids, but normal muscular mitochondrial oxidative capacity in adipose triglyceride lipase deficient mice

P.M. Nunes¹, A. Veltien¹, H. Arnts², T. van de Weijer³, P. Schrauwen³, C.J. Tack⁴, A. Heerschap¹;

¹Radiology, Radboud University Nijmegen Medical Centre, ²Central Animal Laboratory, Radboud University Nijmegen Medical Centre, ³Human Biology, NUTRIM, School of Nutrition Toxicology and Metabolism, Maastricht University Medical Centre, ⁴General Internal Medicine, Radboud University Nijmegen Medical Centre, Netherlands.

Background and aims: Adipose triglyceride lipase (ATGL) is the rate-limiting enzyme of triglyceride hydrolysis and is mainly expressed in adipocytes and myocytes, thus ATGL-KO mice show abnormal triglyceride accumulation in those tissues. Intramyocellular lipids (IMCL) are often used as biomarker of insulin resistance and type 2 diabetes, potentially reflecting lipotoxic effects on mitochondrial function. Whether IMCL accumulation per se has adverse effects on mitochondria is unclear. Therefore, we assessed IMCL levels and mitochondrial oxidative capacity of ATGL-KO mice *in vivo* with ¹HMRS and gated dynamic ³¹PMRS of contracting calf-muscles.

Materials and methods: Adult ATGL KO (n=9) and WT (n=10) mice were included in these experiments. ipGTT was done in all mice after 6h of fasting with a glucose bolus of 1.5g/kg. Plasma glucose levels were analyzed with a glucometer at 0, 15, 30, 60, 90 and 120min post-load. *In vivo* MR spectroscopy was performed at 7T (Clinscan, Bruker Biospin). The IMCL assessment was done in tibialis anterior using single voxel ¹HMRS. Briefly, all animals were anaesthetized with isoflurane and their left hindleg positioned under a ¹H surface coil and oriented with the magnetic field. IMCL level was quantified from the ¹H spectra and normalized to [creatine]. To investigate whether mitochondrial oxidative capacity was affected by the IMCL accumulation in ATGL-KO mice, we assessed phosphocreatine (PCr) recovery time in post-contracted muscles. Tetanic contraction of the calf muscle was achieved by stimulation of the sciatic nerve and occurred every 3 seconds over one minute. Eight time series of ³¹PMRS spectra were acquired before, during and after the muscle contraction. The PCr recovery curve was fitted with a mono-exponential function and recovery time calculated. Samples from the exercised and non-exercised calf muscles were freeze-clamped and extracted to determine glycogen level using the hot-alkali method.

Results: The ¹HMRS examination of skeletal muscle showed that IMCL/Cr ratio of ATGL-KO was ~5 fold higher than their counterparts (5.6±1.1 vs 1.1±0.3, p=0.0007). IpGTT revealed that ATGL-KO mice were more glucose tolerant than the WT mice with an AUC of 1067±54 vs 1277±56, p=0.01, respectively. ³¹P spectra showed that electro-stimulated muscles of ATGL-KO and WT had similar PCr depletions (~40–50%) and analysis of PCr recovery curves resulted in similar recovery times for ATGL-KO (59.8±6.6s) and WT (57.2±6.3s). Glycogen levels in ATGL-KO muscle were lower than in WT, in contracted (7.1±1.9 vs 10.7±1.7 μmolglucosyl/gww) and non-contracted muscle (15.8±1.7 vs 25.1±2.3 μmolglucosyl/gww, p<0.01).

Conclusion: Skeletal muscle of ATGL-KO mice have a ~5-fold increase in IMCL pool, but this did not affect mitochondrial oxidative capacity. The hampered fatty acid catabolism boosts glucose oxidation as shown by improved glucose tolerance and decreased glycogen stores.

Electric pulse stimulation of human skeletal muscle cells induces enhanced insulin response and anti-inflammatory signalling

S. Lambernd, K. Eckardt, A. Schober, B. Platzbecker, J. Eckel; Paul-Langerhans-Group, German Diabetes Center, Düsseldorf, Germany.

Background and aims: In the context of obesity, physical inactivity is associated with chronic systemic inflammation and represents a major risk factor for the pathogenesis of type 2 diabetes. Several studies could show that regular activity considerably improves insulin sensitivity and skeletal muscle metabolism. For our recently established contraction model we used *in vitro* electric pulse stimulation (EPS) of primary human skeletal muscle (hSkM) cells. Cells start to contract after few hours, AMPK is activated and secretion of myokines like IL-6 and VEGF were increased as it was shown before for exercise of skeletal muscle *in vivo*. Adipocyte conditioned medium (CM)-induced impairment of insulin signaling was completely prevented by contractile activity of hSkM cells. Therefore, the aim of this study was to further

characterize beneficial effects of muscle activity and to identify underlying signaling pathways and mechanisms.

Materials and methods: Differentiated hSkM cells were stimulated with a C-pulse generator for up to 24 h (1 Hz, 2 ms, 11.5 V). Cells were stimulated with 100 nM insulin for 30 min and 2-DOG glucose uptake was determined. For analysis of inflammatory signaling hSkM cells were incubated with 50 pg/ml TNFα for 5, 10 and 20 min, with 1 ng/ml MCP-1, 2 μg/ml chemerin and CM for 30 min. Protein expression and phosphorylation of Akt, GSK3α/β and NFκB cascade were analyzed by Western blotting.

Results: Glucose uptake was significantly increased after insulin stimulation (2.5 fold) and by EPS alone (2.2 fold). Cells showed a substantial increase in insulin-stimulated glucose uptake after EPS compared to basal control (4.6 fold) and synergistically to insulin-stimulated control (1.8 fold, n>3). MCP-1 and chemerin induced impairment of insulin signaling by 32 and 39 % at the level of Akt phosphorylation (n=4). This effect was completely prevented by contractile activity of hSkM cells. CM and chemerin induced an activation of NFκB (1.8 fold and 1.5 fold, n=4), while MCP-1 induced the activation of p44/p42 MAPK (1.5 fold). Both effects on NFκB and p44/p42 MAPK activation were diminished to control level after EPS. Incubation of hSkM cells with TNFα induced pro-inflammatory signaling reaching a maximal activation of NFκB after 10 min (3.2 fold, n>4). The application of EPS during the treatment with TNFα diminished the activation of NFκB at all analyzed time points compared to unstimulated control (1.7 fold after 10min, n>4). NFκB and IKKβ protein level were significantly reduced by 35 % after 8 h EPS compared to unstimulated controls (n=4), while protein level of IKKα and IκBα were not changed. Incubation with TNFα diminished IκBα protein level significantly to 36 % after 20 min, while TNFα had no effect on IκBα protein level of contracting cells (n=4).

Conclusion: Our results provide direct evidence that muscle contractile activity triggered by EPS synergistically improves insulin response as demonstrated by an increased glucose uptake. Furthermore, EPS could prevent MCP-1 and chemerin-induced impairment of insulin signaling. This positive effect can in part be explained by the anti-inflammatory effect of contractile activity, which was demonstrated by a diminished activation of key proteins in the pro-inflammatory NFκB pathway by adipokines. In summary, our model provides a unique tool which shows that the anti-inflammatory potential of contraction might mediate the beneficial effect of muscle contraction.

Improved intramyocellular triglyceride fatty acid content and composition during moderate weight loss: impact of sex

S. Madsbad¹, A. Vaag², H. Mu³, S.B. Haugaard^{1,4};

¹Dept. of Endocrinology, Copenhagen University Hospital, Hvidovre, ²Dept. of Endocrinology, Copenhagen University Hospital, Rigshospitalet, ³Dept. of Pharmaceutics and Analytical Chemistry, Faculty of Pharmaceutical Sciences, University of Copenhagen, ⁴Dept. of Internal Medicine, Copenhagen University Hospital, Amager, Copenhagen, Denmark.

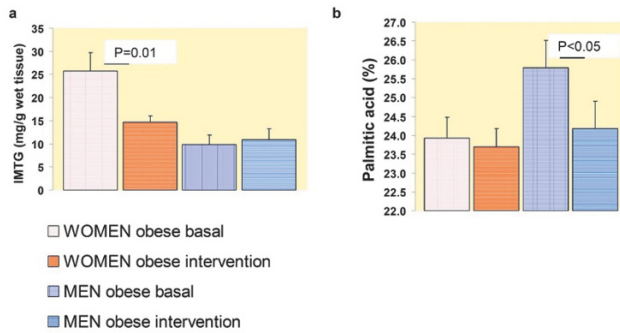

Background and aims: The content and fatty acid composition of intramyocellular triglyceride (IMTG) implicates on glucose metabolism and may show gender specificity. We investigated whether a low-calorie dietary intervention influences IMTG content and composition with emphasis on sex differences.

Materials and methods: Twenty-one insulin resistant obese subjects (12/9 women/men of whom 4/3 had diabetes) of mean BMI=36.5 kg/m² completed a 6-months low-calorie dietary intervention (approx. 7 MJ/d). Dietary advising emphasized low intake of fish-oil by recommending lean fish and prohibiting fatty fish and fish-oil supplements. IMTG content and fatty acid composition was determined in vastus lateralis biopsies by thin-layer and gas-liquid chromatography.

Results: Obese women lost 43% of IMTG (from 25.8 mg/g wet weight, P=0.01), whereas in obese men IMTG remained unchanged at a lower level (baseline 9.8 mg/g wet weight, P=ns). Long-chain-polyunsaturated fatty acids (LCPUFA) and LCPUFA-n-3 of IMTG increased both in women and men (84%, P<0.001 and 107%, P<0.001). Interestingly, the content of the potential diabetogenic palmitic acid (C16:0) decreased in men only (-6.2%, P<0.05) rendering gender difference significant (P<0.05). Subjects experienced weight-loss (5.1 kg, P<0.001), less stress on betacell (decrease in fasting C-peptide of 15%, P<0.05), decreased fasting glucose (9% from 7.1 mmol/L, P=0.057), and decreased glycosylated hemoglobin (0.5 percentage point from 6.7%, P=0.081), respectively, with no significant gender difference observed.

Conclusion: Moderate weight-loss in obese subjects was associated with decreased IMTG content in women only, increased LCPUFA-n-3 irrespective of gender, and reduced palmitic acid content in men. Gender specific responses

of intramyocellular lipids to diet induced weight-loss may be linked mechanistically to improvement of glucose metabolism.

Effect of moderate weight loss on intramyocellular triglyceride (IMTG) content (panel a) and diabetogenic IMTG palmitic acid (panel b) in obese insulin resistant women (n=12) and men (n=9)

GLUT2 and its transcriptional regulation by HNF-4α: participation in kidney and liver

A.D. Silva, H.S. Freitas, M.M. Okamoto, A.C. Poletto, D.T. Furuya, R.S. Silva, G.A. Lima, U.F. Machado;

Department of Physiology and Biophysics, University of Sao Paulo, Brazil.

Background and aims: In diabetes mellitus, increased expression of GLUT2, as well as, augmented production of extracellular matrix proteins by mesangial cells could collaborate to development of glomerulosclerosis. Moreover, the increased expression of GLUT2 may be associated with NASH (Nonalcoholic Steatohepatitis) and Fanconi Bickel syndrome. We have investigated the effect of insulin and demonstrated a downregulated GLUT2 expression in kidney and liver, which returned to non diabetic levels, and points out the glucose concentration as the key regulator of this gene. These results indicate a transcriptional control was involved, and HNF-4α was identified and characterized in GLUT2 gene promoter. The aim of present study was to investigate the role of HNF-4α in kidney and liver of diabetic rats and insulin treated diabetic rats.

Materials and methods: We studied 3 month old Wistar rats, randomly allocated into non diabetic (C), diabetic (D), diabetic treated with saline (DS) and insulin (I-I, 4 and 6 days of treatment). The experimental protocols were submitted to the Ethics Committee for Experimentation with Laboratory Animals of the ICB-USP (protocol 41/2009). Diabetes was induced by single endovenous dose of alloxan (38 mg/Kg). The mRNA of HNF-4α was analyzed by RT-PCR. The HNF-4α binding activity of nuclear protein into GLUT2 promoter was analyzed by Electrophoretic Mobility Assay.

Results: In comparison to C animals, D rats showed: hyperglycemia, polyuria, glycosuria without ketonuria, increased GLUT2 mRNA content in kidney (P<0,001) and liver (P<0,0001), increased HNF-4α mRNA content (P<0,01) and binding activity of nuclear protein into GLUT2 promoter (P<0,0001) in kidney and increased HNF-4α mRNA content (P<0,01) and binding activity of nuclear protein into GLUT2 promoter (P<0,01) in liver. In comparison to D animals, the DI animals showed: a) reduction of glycemia in DI rats 10% (1 day), 22% (4 days) and 48% (6 days); b) progressive increase of body weight 2% (1 day), 5,4% (4 days) and 24% (6 days); c) decrease of GLUT2 mRNA content after 1 day of insulin treatment (P<0,05) in kidney and after 4 days of insulin treatment in liver, e) decrease of HNF-4α mRNA content after 6 days of insulin treatment (P<0,05) in kidney and liver and decreased of the HNF-4α binding activity of nuclear protein into GLUT2 promoter, after 6 days of insulin treatment (P<0,001) in kidney and liver.

Conclusion: The study showed that HNF-4α plays important role in the GLUT2 gene regulation, which was demonstrated by increased HNF-4α gene expression and binding activity into GLUT2 promoter in diabetic rats. These data suggest that in insulin treatment HNF-4α also could be an important transcriptional regulator of GLUT2 gene and probably acts as mediator on GLUT2 gene in kidney and liver of insulin treated diabetic rats.

Determining the renal threshold for glucose excretion: validation of a new method

D. Polidori¹, S. Sha², A. Ghosh², K. Farrell², P. Rothenberg², T. Heise³;

¹Johnson & Johnson, La Jolla, USA, ²Johnson & Johnson, Raritan, USA,

³Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany.

Background and aims: There is a threshold relationship between urinary glucose excretion (UGE) and blood glucose (BG) in which there is virtually no UGE under euglycemic conditions and UGE increases with BG when BG exceeds the renal threshold for glucose (RT_G). Recent reports of increased renal glucose transporter expression in subjects with type 2 diabetes mellitus (T2DM) and the emergence of sodium glucose co-transporters 2 (SGLT2) inhibitors as potential treatments for T2DM have led to increased interest in renal glucose handling. However, the only accepted methods to determine RT_G require multi-step hyperglycemic clamps or graded glucose infusions with frequent blood and urine sampling and are therefore limited to small studies. The purpose of this study is to validate a new method for determining RT_G that is suitable for use in larger studies.

Materials and methods: Fourteen subjects with T2DM (mean age = 56 y, BMI = 30 kg/m², HbA1c = 8.3%, eGFR = 89 mL/min/1.73 m²) who were either

on a stable metformin regimen or no antihyperglycemic agents were studied. On day 1, a standard mixed meal tolerance test (MMTT) was performed and BG profiles and UGE were measured over 4 hours. RT_{GMMTT} was determined using an extension of the method used to determine $RT_{GMMTT}^{phosphate}$ that accounts for intraday BG variability. The UGE vs BG relationship was approximated by a perfect threshold relationship: rate of UGE = $GFR \times (BG - RTG)$ if $BG > RTG$ and rate of UGE = 0 if $BG \leq RTG$. Using measured BG and measured creatinine clearance to estimate GFR, this equation was integrated over the 0–4 hour interval of the MMTT, giving the calculated UGE amount as a function of RT_G . The unique value of RT_G making calculated UGE = measured UGE was determined using an iterative procedure. On day 2, the subjects underwent a 5-step hyperglycemic clamp ($BG = 7, 9.5, 12, 14.5, 17$ mM), and UGE and BG were measured during the last 1.5 hours of each step. RT_{Gclamp} was determined using nonlinear regression of the measured BG and UGE rates during the 5 steps. Application of either procedure requires BG exceeding RT_G during the experiment so that an appreciable amount of UGE is measured.

Results: RT_{Gclamp} was determined in all 14 subjects, with mean \pm SD $RT_{Gclamp} = 12.0 \pm 1.3$ mM. In 3 subjects, BG during the MMTT remained well below their RT_{Gclamp} ; these subjects had very little UGE during the MMTT (as expected) and their RT_{GMMTT} could not be determined. In the 11 subjects in whom RT_G was determined using both methods, mean values were similar for both methods ($RT_{GMMTT} = 11.4 \pm 1.6$ mM and $RT_{Gclamp} = 11.6 \pm 1.2$ mM) and the values obtained by the 2 methods were highly correlated (Figure), demonstrating good agreement between the 2 methods for determining RT_G . **Conclusion:** Using the methodology developed, RT_G may be reliably estimated in subjects with T2DM using UGE and BG measurements taken during an MMTT and estimated GFR values. The new MMTT-based method is well suited for determining RT_G in larger studies.

Key role of BRS-3 receptor in the glucose metabolism in human skeletal muscle

N. González¹, I. Ramos-Álvarez¹, A. Martín-Duce², R. Sanz³, S. Portal-Núñez⁴, I. Gutiérrez-Rojas¹, A. Acitores¹, P. Moreno¹, R.T. Jensen⁵, M.L. Villanueva-Peñacarrillo¹;

¹Metabolismo Nutrición y Hormonas, IIS-Fundación Jiménez Díaz, ²Cirugía, Universidad de Alcalá de Henares, ³Neurología, IIS-Fundación Jiménez Díaz, Madrid, Spain, ⁴Metabolismo mineral y óseo, IIS-Fundación Jiménez Díaz, Madrid, Spain, ⁵DDB, National Institutes of Health, Bethesda, USA.

Background and aims: It has been previously informed, an important role of human BRS-3 (hBRS-3) receptor in glucose homeostasis; its agonist peptide -D-Tyr⁶-β-Ala¹¹, Phe¹³, Nle¹⁴]bombesin₆₋₁₄ (BRS-3-AP)- induced, in normal human skeletal muscle, a clear stimulation of glucose transport (GT) which was abolished by wortmanin -PI3K/PKB inhibitor- and PD98059 -MAPKS inhibitor-, as well as increased phosphorylation of PKB and MAPKS; it was also shown that hBRS-3 gene expression was lower in diabetic and/or obese patients compared to that in normal. Furthermore, gene deletion of BRS-3 in mice leads to obesity, associated with metabolic disorders. The aim of this

work was to widen the knowledge of BRS-3 signalling pathway, using the BRS-3-AP, and to explore its effect on glucose transport and metabolism in normal human muscle.

Materials and methods: Myocytes were prepared from skeletal muscle pieces, obtained previous informed consent given, from 19 subjects (10F/9M; age: 48±2 yrs; fasting plasma glucose: 96±3 mg/dl; cholesterol: 188±12; tryglycerides: 104±12), with normal carbohydrate metabolism, undergoing surgery. We measured: PI3K -PIP₃ formation-, p70s6k phosphorylation -Western blot-, glut-4 gene expression -real time-PCR-, GT -³H-2-deoxy-D-glucose incorporation-, in the absence and presence of BRS-3-AP (10⁻⁸ M) and without (control) and with 10⁻⁷ M rapamycin -p70s6K inhibitor-; glycogen synthase a (GSa) and glycogen synthesis (GS) by using radioactive glucose precursors; insulin was included as positive control.

Results: BRS-3-AP at 10⁻⁹ M induced an increase in PI3K activity (154±10% control, p<0.05), while failing to modify p70s6k phosphorylation (10⁻¹⁰ M: 100±2% control); however, at 10⁻⁹ and 10⁻⁸ M, a stimulation (123±10% control and 176±22%, p<0.02 or lower, respectively) was detected in the activity of the enzyme similar to that by 10⁻⁸ M insulin (182±17%, p<0.001). BRS-3-AP, at 10⁻⁸ M increased (p<0.05) the level of glut-4 gene expression (7.540 ± 0.067 times, up-regulated, respect control: 1.00 ± 0.01). Maximal glucose uptake was detected by 10⁻⁸ M BRS-3-AP (175±7% control, p<0.001) which was not affected by the additional presence of rapamycin (161±7%). BRS-3-AP caused a concentration-related stimulation in GSa activity, which was already significant at 10⁻¹⁰ M (149±7% control, p<0.05) higher at 10⁻⁹ M (162±7%, p<0.05), and maximal at 10⁻⁸ M (207±18%, p<0.01), effect which was similar to that induced by 10⁻⁹ M insulin (183±19% control, p<0.05). GS was significantly (p<0.05) stimulated by either 10⁻⁹ M BRS-3-AP or insulin (168±23% control and 165±13, respectively) and maximal at 10⁻⁸ M BRS-3-AP (257±23%).

Conclusion: These results confirm the key role of human BRS-3 in the glucose metabolism, and add support to the idea of using this receptor as a molecular target, and/or its agonist peptide, as a tool in the therapy of obesity and diabetes.

Receptor subtype-3 (BRS-3): a candidate as therapeutic molecular target in obesity

I. Ramos-Álvarez¹, A. Martín-Duce², R. Sanz³, S. Portal-Núñez⁴, J. Muguerza⁵, Á. Rodríguez⁵, I. Gutiérrez-Rojas¹, A. Acitores¹, P. Moreno¹, R.T. Jensen⁶, M.L. Villanueva-Peñacarrillo¹, N. González¹;

¹Metabolismo, Nutrición y Hormonas, IIS-Fundación Jiménez Díaz, ²Cirugía, Universidad de Alcalá de Henares, ³Neurología, IIS-Fundación Jiménez Díaz, ⁴Metabolismo mineral y óseo, IIS-Fundación Jiménez Díaz, ⁵Hospital Príncipe de Asturias, Madrid, Spain, ⁶DDB, National Institutes of Health, Bethesda, USA.

Background and aims: BRS-3 deficient mice develop a mild-late-onset obesity with metabolic disorders. Human skeletal muscle expresses functional BRS-3, and its gene expression is lower in diabetic and/or obese patients compared to normal. Moreover, we reported that in myocytes from normal subjects, the synthetic agonist peptide BRS-3 [D-Tyr⁶-β-Ala¹¹, Phe¹³, Nle¹⁴] bombesin₆₋₁₄ (BRS-3-AP) induces a significant increase in glut-4, glucose transport (GT), glycogen synthase a activity (GSa), glycogen synthesis (GS), and phosphorylation of protein kinases. The aim of this study was to gain insight into the BRS-3 signalling pathways in obese human myocytes, by using the BRS-3-AP as a ligand, and to investigate its effect on glut-4 expression, GT, GSa and GS.

Materials and methods: Myocytes were established from pieces of skeletal muscle obtained, previous informed consent given, from 14 obese patients (1F/13M; age: 44±3 yrs; fasting plasma glucose: 115±6 mg/dl; cholesterol: 167±14; tryglycerides: 170±23; BMI: 45±2 kg/m²), undergoing surgery. We measured p42/44 MAPKS activity -Western blot-, glut-4 gene expression -real time-PCR-, GT -³H-2-deoxy-D-glucose-, GSa -UDP-[¹⁴C]glucose- and GS -D-[U-¹⁴C]glucose-, in the absence (control) and presence of BRS-3-AP; insulin was included in all experiments as positive control.

Results: At 10⁻⁹ M, BRS-3-AP induced an increase (p<0.01 or lower) in the phosphorylation level of p42/44 MAPKS (p42: 197±26% control; p44: 166±24%), even higher than that by equimolar concentrations of insulin (p42: 141±6% control; p44: 136±8%) or the synthetic ligand in cells from normal subject. BRS-3-AP, at 10⁻¹⁰ M increased (p<0.05) the level of glut-4 gene expression (2.000 ± 0.023 times, up-regulated, respect control: 1.000 ± 0.006); also, it caused a concentration-related stimulation of GT, which was detectable at 10⁻¹⁰ M (163±10% control, (p<0.01), maximal at 10⁻⁹ M (226±14%,

$p < 0.001$), and maintained thereafter up to 10^{-7} M (10^{-8} M: $198 \pm 14\%$, $p < 0.001$; 10^{-7} M: $201 \pm 21\%$, $p < 0.001$), showing a higher potency ($p < 0.01$) in obese than in normal myocytes (10^{-9} M: $176 \pm 11\%$). In addition, the BRS-3 synthetic agonist significantly ($p < 0.05$) increased of GSa (10^{-9} M: $159 \pm 26\%$ control) and GS (10^{-9} M: $159 \pm 10\%$; 10^{-8} M $167 \pm 8\%$).

Conclusion: In myocytes from obese patients, BRS-3-AP not only increases protein kinase activities, improves GT and glucose metabolism but also the cells seem to be more sensitive to this analogue than normal myocytes. These results point out that BRS-3 receptor could be used as a molecular target, and/or its agonist peptide, in the therapy of obesity.

Effect of methylmercury on insulin-stimulated glucose uptake in mouse skeletal muscle

M. Ibrahim;

Seafood and Health, National Institute of Nutrition and Seafood Research, Bergen, Norway.

Background and aims: There is increasing evidence suggesting a role for environmental contaminants in the epidemic of the metabolic syndrome. For instance, several studies reported an association between increased body burdens of persistent organic pollutants (POPs) and type 2 diabetes as well as cardiovascular complications. Recently, we demonstrated that POPs commonly present in our food chains contribute to insulin resistance and impair glucose and lipid homeostasis in animals. The aim of the present study was to investigate whether methylmercury (MeHg), a toxic metal that accumulates in fish and sea mammals, could impair insulin action in mouse skeletal muscles.

Materials and methods: Male C57BL/6J mice (9 weeks of age) fed standard control diet were fasted for 5 h and anaesthetized by an intraperitoneal injection of pentobarbital (50 mg/ml). Soleus muscles (slow-twitch fiber) were dissected out, and insulin-stimulated glucose uptake and insulin signalling were assessed. For glucose uptake investigations, muscles were pre-incubated for at least 40 min in Krebs Henseleit buffer containing 5.5 mM glucose, 2 mM pyruvate, 5 mM HEPES and 0.1 % BSA, pH 7.4, and a continuous flow of gas (95 % O₂ - 5 % CO₂) was maintained during the incubation. After pre-incubation, muscles were incubated with 0, 1, 3, 10, 20, 50, 75, or 100 nM MeHg for 60 min. Other muscles were incubated with MeHg (75 nM) and N-acetyl-L-cysteine (NAC; 75 nM) or Selenium (Se; 75 nM). Then, muscles were incubated for 30 min with tracer amount of 2-[³H] deoxy-D-glucose and [¹⁴C]-mannitol in the presence or absence of insulin (60 and 0 nM, respectively). For insulin signalling investigations, western blots were performed to analyse total Akt and Akt phosphorylation (Ser⁴⁷³).

Results: Basal muscle glucose uptake did not change in the absence or presence of MeHg (75 nM). In muscles non-exposed to MeHg, insulin increased glucose uptake by 3-fold compared with basal glucose uptake. Incubation with low MeHg concentrations (1, 3, 10 nM) did not affect insulin-stimulated glucose uptake. At higher concentrations, MeHg dose-dependently inhibited insulin-stimulated glucose uptake (20 nM MeHg: - 31.4%, 50 nM MeHg: -32.5%, 75 nM MeHg: -51.4%, 100 nM MeHg: -65.9%). Consistent with these findings, we found that MeHg reduced insulin-stimulated phosphorylation of Akt, a key insulin signalling protein for glucose uptake. There was no effect of MeHg on total Akt expression. To investigate whether antioxidant could prevent the inhibitory effect of MeHg on insulin-stimulated glucose uptake, muscles were incubated with NAC or Se. NAC was able to totally prevent the inhibitory effect of MeHg on insulin-stimulated glucose uptake, while inclusion of Se showed no protective effect.

Conclusion: These results indicate that MeHg can interact with insulin action and impair glucose uptake in skeletal muscles. The antioxidant NAC but not Se can prevent the negative effect of MeHg on glucose uptake.

Methylglyoxal stimulates GLUT4-driven glucose-uptake and induces oxidative stress

B. Engelbrecht¹, B. Stratmann¹, D. Tschöpe¹, T. Gawlowski^{1,2};

¹Heart- and Diabetes Center NRW, Bad Oeynhausen, Germany,

²Department of Medicine, University of California, San Diego, USA.

Background and aims: Methylglyoxal (MG), a highly reactive α -dicarbonyl metabolite of glucose degradation pathways, protein and fatty acid metabo-

lism, plays an important role in the pathogenesis of diabetic complications. In diabetes, hyperglycemia triggers enhanced production of MG and increased generation of advanced glycation endproducts (AGEs). In a non-enzymatic reaction, MG reacts with arginine residues of proteins to form the AGEs argpyrimidine and hydroimidazolone. Glyoxalase 1 (GLO1), together with glyoxalase 2 and the co-factor glutathione, constitute the glyoxalase system, which is responsible for the detoxification of MG. A GLO1 specific knock down results in accumulation of MG in targeted cells. In this study the effects of MG-stimulation and down regulation of its detoxification system on insulin signaling and translocation of GLUT4 in myoblasts were investigated. **Methods:** L6 myoblasts cells, stably expressing c-myc epitope-tagged GLUT4, were transfected with GLO1-specific siRNA for 72h and cultured with 25mM glucose medium or stimulated with MG for 24h cultured with 5 mM glucose medium. Then cells were serum starved 4h before insulin stimulation for 1h. The impacts of the GLO1 knock down and MG treatment on the expression and phosphorylation of insulin-receptor substrate-1 (IRS-1) and AKT was analyzed by immunoblotting. The effects of the knock down and the MG treatment on the translocation of GLUT4, the glucose uptake and on oxidative stress were investigated by flow cytometry.

Results: Both, MG treatment as well as GLO1 knock down resulted in increased translocation of GLUT4 to the plasma membrane without insulin stimulation (100 μ M MG: 122% ($p > 0.05$), 400 μ M MG: 211% ($p < 0.001$) vs. 0 μ M MG and GLO1 knock down vs. scrambled siRNA: 239% ($p < 0.01$)). Enhanced glucose uptake was detected. Down regulation of GLO1 as well as MG treatment resulted in decreased expression of AKT but in increased phosphorylation of AKT: ratio phosphoAKT to totalAKT 100 μ M MG 350% ($p > 0.05$); 400 μ M MG 525% ($p < 0.01$) vs. 0 μ M MG, GLO1 knock down vs. scrambled siRNA: 243% ($p < 0.01$), respectively. The GLO1 knock down as well as MG treatment have no significant effect on the expression and phosphorylation of IRS-1. In addition, measurement of reactive oxygen species (ROS) showed that treatment with MG and down regulation of GLO1 induced oxidative stress.

Conclusion: MG, either intracellularly accumulated via GLO1 knockdown or extracellularly added, induces glucose uptake via an enhancement of GLUT4 translocation and oxidative stress. The interplay between these two phenomena is under current research using this cell line.

Effect of chronic caffeine administration on Glut-4 expression and plasma catecholamines in high sucrose diet rats

S.V. Conde¹, D.D. Antunes¹, M. Ribeiro¹, C. Gonzalez², M.P. Guarino¹;

¹CEDOC, Faculdade de Ciências Médicas, Lisbon, Portugal, ²Departamento de Bioquímica y Biología Molecular y Fisiología, Facultad de Medicina, Valladolid, Spain.

Background and aims: Previous results from our lab have shown that caffeine administration restores insulin sensitivity in rats submitted to a high sucrose (HSu) diet, an effect that was not related to changes in weight gain, visceral fat mass, serum free fatty acids, cortisol nor nitric oxide production. In the present work we have investigated if caffeine reversion of diet-induced insulin resistance was due to an effect on sympathetic nervous system activity, measured as plasma catecholamines, and/or to an altered expression of GLUT-4 in insulin-sensitive tissues.

Materials and methods: Four groups of Wistar rats, aged 9-12 weeks were used. The control group drank regular tap water. The HSu group was administered 35% sucrose in drinking water during 28 days. In each group the animals were randomly divided into two subgroups: treated with 1g/l caffeine during the last 15 days of the experimental protocol and not treated. The insulin tolerance test (ITT) was used to measure insulin sensitivity. Catecholamines were measured in serum by HPLC with electrochemical detection. GLUT-4 expression was determined by Western Blot in skeletal muscle, liver and adipose tissue and normalized to loading protein.

Results: HSu diet induced insulin resistance and hypertension which were prevented by caffeine treatment. HSu diet significantly increased plasma catecholamines by 211.9% from a control value of $50.03 \pm 6.91 \mu$ M ($n = 12$). Chronic caffeine intake did not modify plasma catecholamines in control animals, however when administered together with the HSu diet caffeine prevented the increase in circulating catecholamines suggesting that the metabolic and hemodynamic effects of chronic caffeine intake are mediated by a decrease in sympathetic activation. Moreover, KITT was negatively correlated with plasma catecholamines both in the absence ($r = -0.399$, $p = 0.0484$) and presence ($r = -0.419$, $p = 0.009$) of caffeine treatment. HSu diet decreased

Glut-4 expression in skeletal muscle by 54.9% ($n = 3$). Caffeine administration increases no significantly Glut-4 expression in skeletal muscle by 32.4%, an effect that was insufficient to restore Glut-4 expression to control levels.

Conclusion: The present results suggest that the effects of chronic caffeine administration on insulin resistance and hypertension induced by HSu diet involve a decrease in sympathetic activation and not an alteration of Glut-4 expression in skeletal muscle.

Pathogenesis of fasting hyperglycaemia in prediabetes

R. Basu, B. Norby, V. Pattan, B. Dicke, P. Reich, A. Basu, R. Rizza;
Endocrinology, Mayo Clinic College Of Medicine, Rochester, USA.

Background and aims: The exact mechanism of fasting hyperglycemia in individuals with prediabetes remains poorly understood. The present studies were undertaken to determine the cause/s of isolated fasting hyperglycemia in individuals with normal glucose tolerance (IFG/NGT).

Materials and methods: Following OGTT, 14 IFG/NGT and 16 age, sex and BMI matched subjects with NFG/NGT underwent a four hour somatostatin clamp with replacement glucagon and growth hormone. Insulin was infused at 0.35mu/kgTBW/min to maintain plasma glucose in prediabetic range (~6.1mM). Results were compared using averages for last forty minutes of basal and clamp periods using Wilcoxon rank sum tests.

Results: Despite slightly higher fasting insulin (49.0 ± 6.0 vs. 37.0 ± 4.0 pmol/L) and c-peptide (1.1 ± 0.1 vs. 0.77 ± 0.05 nmol/L) concentrations, fasting glucose concentration (6.1 ± 0.1 vs. 5.3 ± 0.1 mM) was significantly higher ($p < 0.001$) in IFG/NGT vs. NFG/NGT. In contrast, clamp glucose (6.3 ± 0.1 vs. 6.0 ± 0.1 mM) and all hormone concentrations were matched between groups ($p = ns$). Fasting endogenous glucose production (EGP) was significantly higher (16.4 ± 0.34 vs. 14.1 ± 0.6 μ mol/kg/min; $p < 0.01$) in IFG/NGT vs. NFG/NGT. On the other hand in the presence of matched glucose and insulin concentrations, EGP (10.5 ± 1.1 vs. 8.5 ± 1.0 μ mol/kg/min) and glucose disappearance (Rd) were no different (29.1 ± 4.6 vs. 34.1 ± 3.4 μ mol/kg/min) in IFG/NGT than NFG/NGT ($p = 0.8$).

Conclusion: In prediabetic individuals with isolated fasting hyperglycemia a) basal EGP is increased but suppresses normally when insulin is increased; b) basal Rd is not decreased and increases normally when insulin is increased; c) the increased EGP in the presence of an abnormal set point for insulin secretion explains the mechanism of increased fasting glucose. This is complementary to our previously published data that concluded that in subjects with isolated IFG, normal EGP and Rd in the presence of insulin concentrations in the postprandial range combined with normal post-prandial insulin secretion results in normal postprandial glucose metabolism.

Longitudinal multicenter analysis of glucose metabolism development in obese children

A. Körner¹, S. Wiegand², A. Hungele³, S. Tuschy⁴, K.P. Otto⁵,
D. I' Allemand-Jander⁶, K. Widhalm⁷, W. Kiess¹, R.W. Holl³;

¹Pediatric Research Center, University of Leipzig, Germany, ²Charité University Children's Hospital, Berlin, Germany, ³University of Ulm, Germany, ⁴SANA Klinikum Lichtenberg, Berlin, Germany, ⁵Kath.

Kinderkrankenhaus Wilhelmstift, Hamburg, Germany, ⁶Eastern Swiss Children's Hospital, St. Gallen, Switzerland, ⁷Medical University Vienna, Austria.

Background and aims: Although there is ample evidence of impaired glucose metabolism in obese children from single cohorts, data are lacking on the progression of glucose metabolism in obese children. We performed a large-scale multicentric longitudinal analysis on glucose metabolism development in obese children.

Materials and methods: Between years 2000 and 2010, 179758 patient visits were documented in the APV registry by 162 central European centers specialized in pediatric obesity. Of the 57988 obese patients, 19.35% (age 12.9 ± 3.0 y, BMI SDS 2.59 ± 0.58 , $n = 10364$) were evaluated by oGTT according to ADA criteria and 1.88% had at least two oGTTs. Patients were stratified for glucose metabolism pathology with impaired fasting glucose (IFG), impaired glucose tolerance (IGT) and type 2 diabetes (T2D).

Results: A total of 12.6% of the children presented with pathology in glucose metabolism (5.99% IFG, 5.51% IGT, 1.07% T2D). Children with more overt pathology (IGT and T2D) were significantly older, more (visceral) obese, and the percentage of girls was higher. Multivariate analysis identified pubertal group and BMI as significant predictors for impaired glucose metabolism. For the 929 patients with follow-up oGTT (observation interval 1.48 ± 1.32 y), we observed a slight though significant reduction in BMI SDS of 0.094 ± 0.42 . Along with this, mean levels of metabolic parameters improved. While 18.8%

of these patients showed abnormalities in glucose metabolism at baseline, the percentage decreased to 13.7% at follow-up. Of the children with IGT initially, more than 50% converted to normal glucose tolerance. Overall, the oGTT result deteriorated in only 8.5%, while 13.8% improved. The change in BMI SDS predicted improvement in oGTT as well as AUC BG, while sex, age, observation time, age and even BMI SDS at baseline did not have significant impact in multivariate analyses.

Conclusion: We provide evidence for significant improvement of oGTT parameters of obese patients treated in specialized treatment centers, even if reduction in BMI is mild.

Sources of hepatic glycogen synthesis in healthy subjects following a milk-containing breakfast

C. Barosa¹, A. Fagulha², L. Barros², M. Caldeira³, C. Silva³, M. Bastos², C. Baptista², M. Carvalheiro², J. Jones¹;

¹Center for Neurosciences and Cell Biology, ²Endocrinology-Hospitals of University of Coimbra, ³Chemistry Department-University of Coimbra, Portugal.

Background and aims: Following a mixed meal, the liver is able to synthesize glycogen from several carbohydrate sources including galactose. A single glass of skimmed milk contains sufficient galactose to contribute significantly to postprandial hepatic glycogen synthesis in healthy subjects. To date, no methods exist to measure this contribution, hence the goal of this study was to further develop the deuterated water (2H₂O) method to measure the contribution of dietary galactose to glycogen synthesis flux in addition to those of the direct and indirect pathways. Glucuronide enrichment from deuterated water (2H₂O) was used to quantify direct and indirect pathway contributions to hepatic glycogen synthesis following a breakfast meal that included 200 ml skimmed milk. Under these conditions, glucuronide position 2 enrichment (G2) was significantly less than that of body water. We hypothesized that incomplete glucose-6-P-fructose-6-P (G6P-F6P) exchange during direct pathway metabolism of glucose and/or inflow of unlabeled UDP-glucose from galactose were responsible. We resolved the exchange and galactose contributions to the reduced G2 enrichment by independently measuring G6P-F6P exchange.

Materials and methods: In Study 1, G6P-F6P exchange in six healthy subjects was quantified by supplementing a milk-containing breakfast meal with 10 grams of [U-2H₇]glucose and quantifying the depletion of position 2 enrichment in urinary menthol glucuronide. In Study 2, another six subjects ingested 2H₂O and Acetaminophen followed by an identical breakfast meal with 10 grams of [1-13C]glucose to resolve direct/indirect pathways and galactose contributions to glycogen synthesis. Glucuronide, glucose and body water 2H/13C-enrichments were determined by 2H- and 13C-NMR.

Results: In Study 1, G6P-F6P exchange approached 100%, therefore the difference between G2 and body water enrichments in Study 2 ($0.20 \pm 0.03\%$ versus $0.27 \pm 0.03\%$, $p < 0.005$) was attributed to galactose glycogenesis. Dietary galactose contributed $19 \pm 3\%$ to hepatic glycogen synthesis. Of the remainder, $58 \pm 5\%$ was derived from the direct pathway and $22 \pm 4\%$ via the indirect pathway.

Conclusion: The contribution of dietary galactose to hepatic glycogen synthesis was resolved from that of direct and indirect pathways using a combination of 2H₂O and [1-13C]glucose tracers. A breakfast meal that included 200 ml of skimmed milk accounted for about one-fifth of postprandial hepatic glycogen synthesis via galactose, a contribution that was comparable to that of the indirect pathway.

Analysis of glucose enrichment from a double tracer meal tolerance test by LC-MS

V. Mendes¹, J. Jones^{2,1}, P. Macedo^{2,3}, A.B. Fernandes^{3,2}, B. Manadas¹;

¹Center for Neurosciences, Coimbra, ²Associação Protectora dos Diabéticos de Portugal, ³CEDOC, Lisbon, Portugal.

Background and aims: The study of glucose kinetics during meal ingestion provides key insights into insulin-mediated control of postprandial glucose metabolism and can be followed with stable isotope glucose tracers. We

present a simple, rapid and sensitive LC-MS/MS method for direct analysis of glucose tracer enrichments from blood spots. We applied this method to quantify plasma [6,6-2H₂]glucose and [U-13C]glucose enrichments from healthy rats given a meal tolerance test enriched with [6,6-2H₂] and [U-13C] glucose and to evaluate endogenous glucose kinetics.

Methods: Seven 24 hr fasted male Wistar rats were anesthetized and cannulated with an a/v loop at the femoral vein. A primed infusion of [U-13C] glucose was started 60 min before meal delivery and continued throughout the study. A mixed meal containing 5% [6,6-2H₂]glucose was administered intestinally. Blood was periodically sampled from 15 min before to 120 min after the meal by spotting on to filter paper. The dried blood samples were washed with ethanol and passed through a 3K mw cutoff filter and the supernatant evaporated. It was further cleaned by micro solid phase extraction (Stage Tips C18) using acetonitrile and water solvents. Samples were analyzed in triplicate on an Ultimate 3000 LC system coupled to a 4000 QTrap mass spectrometer. Glucose enrichment was quantified using Multiple Reaction Monitoring (MRM). The MRM transitions used were 179/89 for unlabelled glucose, 181/90 and 181/91 for [6,6-2H₂] glucose, 185/92 for [U-13C]glucose and 192/94 for internal standard. Each sample was analyzed using an LC program of 15 min followed by a column cleaning step of 12 min.

Results: The limit of quantification for [U-13C]glucose and [6,6-2H₂]glucose was 0.5 pmol and the method was linear from 0.5-250 pmol/μL glucose concentrations. The mean coefficient of variance was $20.3 \pm 2.3\%$. Figure 1 shows glucose excursions and enrichment profiles before and during the meal tolerance test. Plasma glucose levels doubled within 15 min after the meal, then subsided for the remaining period. From plasma [U-13C]glucose enrichment levels measured before the meal, basal glucose production was estimated to be 70 ± 10 micromol/kg/min. During this period, there was no excess enrichment detected from [6,6-2H₂]glucose. In the initial 15 min after the meal, plasma [6,6-2H₂]glucose rose steeply, reflecting absorption of the meal glucose. At the same time, [U-13C]glucose enrichment declined reflecting dilution by absorbed glucose. The kinetics of meal glucose appearance was superimposable on that of plasma glucose levels indicating that postprandial plasma glucose excursion was tightly coupled to glucose absorption rates.

Conclusions: Plasma glucose enrichments from [U-13C]- and [6,6-2H₂]glucose were quantified by a simple and sensitive LC-MS/MS procedure. This approach was used to characterize systemic and meal tracer appearance profiles in a meal tolerance test.

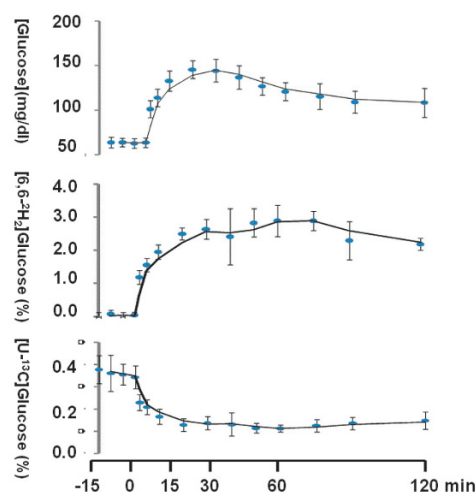

Figure 1: Plasma glucose levels, meal-derived [6,6-2H₂]glucose and infused [U-13C]glucose enrichments 15 min before and 0-120 min after a meal tolerance test.

Clinical Trial Registration Number: PTDC-EEB-BIO-98110-2008

Triple Tracer (TT) and Double Tracer (DT) techniques are reliable methods to estimate glucose appearance in type 1 diabetes

A. Haidar¹, D. Elleri¹, J.M. Allen¹, J. Harris¹, K. Kumareswaran¹, M. Nodale¹, C.L. Acerini¹, M.E. Wilinska¹, N. Jackson², A. Umpleby², M.L. Evans¹, D. Dunger³, R. Hovorka¹

¹Institute of Metabolic Science, University of Cambridge, ²University of Surrey, Guilford, ³Department of Paediatrics, University of Cambridge, UK.

Background and aims: Measurement of physiological postprandial glucose fluxes in type 1 diabetes could potentially facilitate improvements in modern insulin therapy regimens. TT technique has been proposed to be the gold standard technique to measure postprandial glucose appearance. We validated TT technique and compared it against DT technique in type 1 diabetes.

Materials and methods: Sixteen young subjects with type 1 diabetes (age 19.5 ± 3.8 yrs, BMI 23.4 ± 1.5 kg/m², HbA1c $8.7 \pm 1.7\%$, diabetes duration 9.0 ± 6.9 yrs, total daily insulin 0.9 ± 0.2 U/kg/day; mean \pm SD) were studied. From 1800 to 0200 next day, intravenous (iv) 20% dextrose enriched with [¹³C]glucose was infused at a variable rate mimicking meal-derived glucose appearance while iv insulin was administered to achieve basal and postprandial insulin concentration. The variable dextrose infusion mimicked a meal-derived glucose appearance of a slowly absorbed meal in the first eight subjects and a fast absorbed meal in the second eight subjects. From 1530 to 0200, primed iv [6,6-²H]₂glucose was infused in a manner that mimicked the expected endogenous glucose production. From 1800 to 0200, iv [¹³C; 1,2,3,4,5,6,7-²H]₇glucose was infused in a manner that mimicked the expected glucose appearance from a standard meal. The iv dextrose infusion was reconstructed using TT and DT techniques utilizing a modified stochastic Mari model. Plasma glucose was measured every 10–15 min. Glucose enrichment was measured by gas chromatography – mass spectrometry every 10–30 min.

Results: Figure shows actual and reconstructed dextrose infusion rates. The difference between individual actual and individual reconstructed dextrose infusion rates as assessed by the root mean square error (RMSE) was identical for the two methods (6.6 ± 1.9 vs. 7.98 ± 3.5 μ mol/kg/min; TT vs. DT; $P = \text{NS}$, paired t-test). RMSE did not differ when dextrose infusion mimicked a fast or a slow meal (6.96 ± 1.5 vs. 6.24 ± 2.0 μ mol/kg/min for TT and 6.81 ± 2.2 vs. 9.15 ± 4.3 μ mol/kg/min for DT; fast vs. slow; $P = \text{NS}$, unpaired t-test). RMSE associated with mean dextrose infusion was 2.5 and 3.3 μ mol/kg/min for TT and DT, respectively. Overall, $100 \pm 9\%$ and $92 \pm 12\%$ ($P = 0.02$) of the dextrose infusion was recovered. There was no difference in dextrose recovery when fast meal or slow meal mimicking dextrose infusion was used.

Conclusion: TT and DT techniques combined with advanced computational methods can measure reliably postprandial glucose appearance in type 1 diabetes. TT tends to outperform slightly DT but the latter benefits from reduced experimental and analytical complexity.

Figure. Actual infusion rate of dextrose and reconstructed infusion rate using triple tracer (TT) and double tracer (DT) techniques (N=16, mean is shown).

Estimating gluconeogenesis from position 3 enrichment of plasma glucose by deuterated water: avoidance of transaldolase exchange effects

J. Jones¹, R. Rizza², A. Basu², R. Basu²

¹Dept of Biochemistry, Center for Neurosciences, Coimbra, Portugal, ²Mayo Clinic, Rochester, USA.

Background and aims: Deuterated water 2H₂O is widely used to measure the gluconeogenic (GNG) contribution to endogenous glucose production (EGP) in humans by analysis of plasma glucose enrichment in position 5 (H5). We recently showed that transaldolase exchange (TA) accounts for ~35% of H5 resulting in GNG overestimation. TA does not influence the enrichment of hydrogen 3 (H3) from 2H₂O. H3 originates from triose phosphate isomerase (TPI) exchange and assuming that a) TPI exchange is complete and b), 2H incorporation by this mechanism is not subject to isotopic discrimination, then H3 reflects GNG flux and is insensitive to TA. We hypothesized that H3 provides equivalent estimates of GNG contributions to those derived from H5 following correction for TA. If so, then GNG fluxes can be directly derived by analysis of H3 from 2H₂O without the need for TA correction with additional tracers.

Materials and methods: 2H₂O, [3-¹³C]glucose and [1-¹³C]acetate were administered to 16 subjects with impaired fasting glucose/impaired glucose tolerance (IFG/IGT) and 14 age and BMI matched normal fasting glucose/normal glucose tolerance (NFG/NGT) subjects. Glucose enrichment from both tracers was measured by 2H and 13C NMR following an overnight fast and during a 0.35 μ U/kgFFM/min insulin infusion. Somatostatin, glucagon and growth hormone were infused during the clamp to ensure comparable and equal portal concentrations in both groups. The fraction of hepatic G6P that underwent TA was estimated from the distribution of 13C-enrichment in positions 3 and 4 of glucose. H5 was then corrected for the fraction derived by TA and GNG flux was estimated from this adjusted value (TA-adjusted). These estimates were then compared to GNG fluxes derived from H3 measured directly from the 2H NMR spectrum (Figure 1).

Results: Under basal conditions, fasting EGP was 14.1 ± 0.6 μ mol/kg/min. The GNG contribution (TA-corrected) was 5.0 ± 0.3 μ mol/kg/min while that estimated directly from H3 was 4.3 ± 0.3 μ mol/kg/min ($p = 0.30$) for the NFG/NGT group. During the clamp, EGP was 8.5 ± 1.0 μ mol/kg/min. GNG (TA-corrected) was 2.3 ± 0.3 μ mol/kg/min versus 2.4 ± 0.3 μ mol/kg/min derived by H3 analysis ($p = 0.93$). For the IFG/IGT group, basal EGP was significantly higher than control values (16.7 ± 0.3 μ mol/kg/min, $p < 0.001$). The GNG contribution (TA-corrected) was 5.7 ± 0.3 μ mol/kg/min versus 4.6 ± 0.3 μ mol/kg/min estimated directly from H3 ($p = 0.06$). During clamp EGP was 13.0 ± 1.1 μ mol/kg/min, significantly higher compared to controls ($p < 0.005$). The TA-corrected GNG contribution was 4.1 ± 0.4 μ mol/kg/min while H3 analysis yielded a value of 3.6 ± 0.4 μ mol/kg/min, ($p = 0.47$).

Conclusion: Glucose H3 can be directly measured by 2H NMR analysis of the monoacetone glucose derivative following 2H₂O ingestion precluding the requirement for additional tracer such as [1-¹³C]acetate to correct for transaldolase exchange.

Figure 1: ²H NMR spectrum of the monoacetone derivative of plasma glucose. The numbers above each signal represent their position in the glucose molecule and positions 3 and 5 are shown in bold.

Bed rest as a model for immobility induced insulin resistanceM. Heer^{1,2}, S. Wnendt³, P. Frings-Meuthen²;¹Nutritional Sciences, Profil Institute for Metabolic Research, Neuss, Germany, ²Space Physiology, German Aerospace Center (DLR), Cologne, ³MLM Medical Labs Moenchengladbach GmbH, Germany.

Background and aims: Physical inactivity decreases insulin sensitivity. In general, however, glucose and insulin levels show large variability. We therefore kept nutrient intake constant on a day-by-day level and used bed rest as a model for immobility. With this set up of highly standardized study conditions we wanted to demonstrate that 7 test subjects are sufficient to achieve significant differences in plasma glucose and insulin concentrations and hypothesized that 4 days of light physical workload will reverse the immobility induced impaired glucose tolerance.

Materials and methods: Seven healthy male volunteers (age: 27.6 ± 3.3 years (mean \pm SD); body mass: 78.6 ± 6.4 kg; height: 1.81 ± 0.04 m; BMI: 24.1 ± 1.9 kg/m²) participated in a randomized crossover study of 21 days head-down tilt bed rest. The volunteers stayed twice for the entire period of 28 days (7 days of adaptation, 21 days bed rest and 7 days recovery) in a metabolic ward. Nutrient intake was individually tailored and kept constant on a day-by-day basis. An oral glucose tolerance test was applied four days before, on day 21 of bed rest and 5 and 14 days after bed rest.

Results: After 21 days of bed rest, the test subjects had developed impaired glucose tolerance (plasma glucose, before: basal: 91 ± 4 mg/dL, after 120 min: 96 ± 12 mg/dL; day 21 of bed rest: basal: 92 ± 6 mg/dL, after 120 min: 145 ± 21 mg/dL $p < 0.001$). In addition, circulating insulin concentrations were increased compared to before bed rest (before: basal: 6.6 ± 1.7 mU/L, after 120 min: 22.7 ± 11.4 mU/L, day 21 of bed rest: basal: 6.7 ± 1.7 mU/L, after 120 min: 52.9 ± 28.1 mU/L; $p < 0.001$). Area under the curve (AUC) determinations for glucose were significantly increased on day 21 of bed rest ($p = 0.002$) and were back to their pre-bed rest level only after 14 days of recovery. While insulin resistance analyzed by HOMA IR index did not change, insulin sensitivity estimated by ISI_{composite} index was reduced during bed rest.

Conclusion: We conclude from these results that it takes up to 14 days of light physical workload to reverse impaired glucose tolerance in healthy young subjects induced by bed rest.

Biphasic relationship between glucose tolerance and gastric emptying in healthy subjectsC.S. Marathe^{1,2}, M. Horowitz^{1,2}, C.K. Rayner^{1,2}, K. Lange^{1,2}, K.L. Jones^{1,2};¹University of Adelaide, Discipline of Medicine, Royal Adelaide Hospital,²Centre for Clinical Research Excellence in Nutritional Physiology, Interventions and Outcomes, University of Adelaide, Australia.

Background and aims: The rate of gastric emptying (GE) is recognized as a major determinant of the magnitude of the initial rise (e.g. at 30min) in blood glucose following oral glucose (75g), or carbohydrate-containing meals in both health and type 2 diabetes i.e. when GE is faster, the increase in glucose is greater. In health, GE of glucose is highly reproducible and tightly regulated at a rate of 1–4 kcal/min and it has, accordingly, been suggested that relatively more rapid GE may predispose an individual to the development of type 2 diabetes. There is, however, little information about the impact of GE on blood glucose 120min after a 75g oral glucose load, which is used diagnostically. Moreover, recent studies employing direct infusion of glucose into the duodenum indicate that the relationship between the glycaemic response and GE is non-linear. We investigated the impact of GE on the magnitude of the glycaemic excursion and blood glucose 120min after a 75g oral glucose load in health.

Materials and methods: 52 healthy subjects aged 18–68 years, who each drank 350ml water containing 75g glucose and 20MBq 99mTc-sulphur colloid while sitting in front of a gamma camera, were studied. GE data were acquired for at least 120min and the 50% GE time (t50) calculated. Blood glucose was measured immediately before ($t = -2$) and at 15, 30, 60 and 120min following consumption of the glucose drink. Relationships between blood glucose and GE were evaluated using linear and non-linear models. Data are shown as mean \pm SEM.

Results: In all subjects GE approximated an overall linear pattern. The rate at which glucose emptied from the stomach (based on t50) was 1.52 ± 0.07 kcal/min. The blood glucose at 30min ($r = -0.33$, $P < 0.02$; Figure A),

and the change in blood glucose from baseline at 30min ($r = -0.28$, $P < 0.05$), were inversely related to the t50. In contrast, the blood glucose at 120min ($r = 0.40$, $P < 0.005$; Figure B) was related directly to the t50. Analysis of the relationship between the change in blood glucose at 30min with t50 demonstrated that a non-linear relationship, such as an exponential association ($r = 0.29$, $P < 0.05$) or S curve ($r = 0.30$, $P < 0.02$), were as compatible with the data as a linear relationship - both non-linear models showed an initial increase in glycaemia that slowed at higher rates of GE.

Conclusion: In healthy subjects, the relationship between glycaemia and GE of a 75g glucose load is 'biphasic', so that the initial rise is greater, and the blood glucose at 120min less, when GE is relatively more rapid.

Figure: Inverse relationship between the magnitude of the rise in blood glucose from baseline at 30min and the 50% emptying time (t50) (A) and direct relationship between the blood glucose concentration at 120min and t50 (B), following a 75g oral glucose load in healthy subjects ($n = 52$).

Simple and convenient alternatives to the mixed meal tolerance test

N.J.M. Thomas, R.E.J. Besser, A.G. Jones, T.J. McDonald, B.M. Shields, B.A. Knight, A.T. Hattersley; Peninsula Medical School, University of Exeter, UK.

Background: Mixed meal tolerance test (MMTT) stimulated serum C-peptide (SCP) is a gold standard measure of endogenous insulin secretion capacity but practical difficulties limit its clinical use. Urinary C-peptide creatinine ratio (UCPCR) allows assessment of C-peptide on a spot urine sample and is stable for 3 days in a standard mid stream urine container.

Aims: 1. Can UCPCR replace serum C-peptide in the MMTT. 2. Can home post meal UCPCR replace serum C-peptide in the MMTT

Materials and methods: We performed standardised MMTTs in a mixed group of 103 individuals with insulin treated diabetes (59 Type 1). We measured fasting and 90 minute post MMTT SCP and fasting and 2 hour post MMTT UCPCR. In addition all patients were asked to provide a urine sample 2 hours following their largest meal at home.

Results: MMTT UCPCR was highly correlated with Serum C-Peptide ($r = 0.92$, $p < 0.001$) and remained an excellent test for severe insulin deficiency (MMTT SCP < 0.2 nmol/L): using an optimal cut off of 0.47 nmol/mmol, giving 100% sensitivity and 95% specificity. Home UCPCR was also highly correlated with the gold standard serum C-Peptide ($r = 0.84$, $p < 0.001$) an optimal cut off 0.12 nmol/mmol with 92% sensitivity and 98% specificity.

Conclusion: UCPCR after a home meal is a reliable measure of endogenous insulin secretion which will allow practical assessment of beta cell function in primary care and the outpatient setting.

PS 035 Metabolic effects of bariatric surgery

561

Comparison of the effectiveness of bariatric surgery in type 2 diabetes according to the surgical procedure: retrospective analysis in 74 diabetic operated patients

G. Prevost¹, S. Pham¹, A. Gancel¹, M. Scotté², H. Lefebvre¹, J.-M. Kuhn¹;

¹Endocrinology, Diabetes and Metabolic Disease, ²Digestive Surgery, CHU Rouen, France.

Background and aims: French recommendations allow bariatric surgery as a treatment for morbid obesity (BMI > 40 kg/m²) or obesity (BMI > 35 kg/m²) associated with comorbidities including diabetes. Overall, the different published studies have reported a remission of diabetes in approximately 80% of patients after bariatric surgery. However, results vary as a function of the surgical procedure

Materials and methods: Among 970 patients who underwent bariatric surgery at our University Hospital since 2001, 74 patients were identified as type 2 diabetes (ICD Coding). Laparoscopic adjustable gastric banding (AG), intervention type Mason (MA), gastric bypass (BP) or sleeve-gastrectomy (SG) were performed respectively in 25%, 17%, 28% and 30% of this diabetic population. Clinical follow-up (weight, blood pressure, sleep apnea) and biological (blood glucose, HbA1c, lipid profile) was performed for 3±0.3 years after surgery. The results obtained in diabetic patients were compared to those of a population of 74 non diabetic obese matched for age, sex, BMI and surgical procedure.

Results: Weight loss was significantly lower in diabetic than in non-diabetic patients, except after SG which trend to induce a larger weight loss in diabetic group. SG appeared more effective than AG on HbA1c one year after operatively (-1.6% vs. -1.05%), similar results were obtained after BP (HbA1c -2.06%). The resolution rate of diabetes at 1 year was significantly ($p < 0.01$) higher after SG than AG: 62.5% vs 20%, but not significantly different between SG and BP (62.5% vs. 52.1%, $p = 0.5$). The evolution of diabetes evaluated using an index integrating the changes in HbA1c and in the modalities of the treatment after surgery showed that SG is followed by a statistically significant ($p < 0.002$) better improvement than AG. In terms of LDL-cholesterol reduction BP = SG > MA > AG ($p < 0.03$). For the evolution of the other cardiovascular risk factors, there is no significant difference according to surgical procedures.

Conclusion: These results suggest that SG may be the preferred surgical procedure for the management of type 2 diabetes obese patients.

562

Gastric bypass induces a more pronounced improvement in postprandial metabolism and the indices of cardiac function than sleeve gastrectomy

K. Alexiadou¹, A. Kokkinos¹, N. Tentolouris¹, I. Balla¹, G. Argyrakopoulou¹, C. Liaskos¹, I. Moyssakis², V. Argiana¹, D. Perrea³, A. Alexandrou⁴, T. Diamantis⁴, N. Katsilambros¹;

¹First Department of Propaedeutic Medicine, ²Cardiology Department,

³Laboratory of Experimental Surgery and Surgical Research, ⁴First Department of Surgery, Athens University Medical School, Laiko General Hospital, Greece.

Background and aims: Bariatric surgery is the most effective long-term treatment for morbid obesity. Roux-en-Y Gastric Bypass (GB) and Sleeve Gastrectomy (SG) are two of the most commonly applied bariatric modalities. The aim of the present study was to compare the effect of these procedures on postprandial glycemia and triglyceridemia as well as on cardiac function, since relevant data are scarce.

Materials and methods: Twenty two patients who underwent either GB (n=9) or SG (n=13), matched for age and BMI, were examined before, three and six months after surgery. A test meal was consumed, consisting of 200 ml ice cream (450 kcal). Blood samples were collected before meal initiation and every 30 minutes until 180 minutes postprandially. Differences in glucose and triglycerides were examined at different postprandial time points, as well as in terms of area under the curve divided by time (AUC) using the trapezoid rule. Epicardial fat thickness, aortic distensibility, left ventricular Tei index and left atrium diameter were assessed by cardiac ultrasonography before and six months after surgery in a subset of these patients (GB: 8, SG: 10).

Results: Both groups experienced significant ($p < 0.001$) and similar weight loss (BMI reduction at three months GB: -19.4% vs SG: -18.0%, $p = 0.57$, at six months GB: -26.9% vs SG: -26.1%, $p = 0.71$). Three months after surgery blood glucose levels were significantly lower in GB patients at 120 minutes postprandially compared to SG patients (GB: 92.2 ± 8.8 vs SG: 101.2 ± 9.7 mg/dl, $p = 0.04$). Triglyceride levels were also significantly lower in the GB group at 60, 90, 150 and 180 minutes postprandially ($p = 0.03, 0.01, 0.03$ and 0.01 respectively). The same was true for the triglyceride AUC (GB: 109.0 ± 26.6 vs SG: 144.4 ± 38.6 mg/dl, $p = 0.03$). Six months after surgery blood glucose levels were significantly lower in the GB group at 60, 90 and 120 minutes postprandially compared to those of the SG group ($p = 0.04, 0.02$ and 0.04 respectively), as well as in terms of AUC (GB: 86.6 ± 11.5 vs 99.3 ± 11.5 mg/dl, $p = 0.04$). Triglyceride levels were also significantly lower in the GB group both at all separate time points ($p < 0.01$), and when expressed as AUC (GB: 78.7 ± 19.2 vs SG: 123.8 ± 27.8 mg/dl, $p = 0.003$). Epicardial fat and Tei index were comparable in both groups preoperatively (ep. fat GB: 1.62 ± 0.09 vs SG: 1.61 ± 0.13 mm, $p = 0.8$, Tei GB: 0.45 ± 0.01 vs SG 0.46 ± 0.02, $p = 0.4$), and decreased to a greater extent in the GB group 6 months postoperatively (ep. fat GB: 1.38 ± 0.08 vs SG: 1.50 ± 0.07 mm, $p = 0.005$ and Tei GB: 0.41 ± 0.01 vs 0.43 ± 0.01, $p = 0.04$). No pre- or postoperative differences were found in aortic distensibility and left atrium diameter.

Conclusion: Gastric bypass resulted in better postprandial glucose and triglyceride responses 3 and 6 months after surgery, compared to sleeve gastrectomy, as well as in greater improvement in some of the ultrasonographic indices of cardiac function. This different cardiometabolic profile implies a role for the differences in the hormonal milieu produced by these procedures.

563

Effect of bariatric surgery induced weight loss on hepatic glucose uptake

H.M. Immonen¹, J.C. Hannukainen¹, M. Soinio², V. Lepomäki¹, R. Parkkola³, P. Iozzo¹, P. Salminen⁴, T. Pham¹, T. Lehtimäki⁵, L. Nelimarkka², P. Nuutila¹;

¹Turku PET Centre, University of Turku, ²Department of Medicine, Turku

University Hospital, ³Department of Radiology, Turku University Hospital,

⁴Department of Surgery, Turku University Hospital, ⁵Department of Clinical

Chemistry, Tampere University Hospital and University of Tampere Medical School, Finland.

Background and aims: Weight loss improves whole body insulin sensitivity, but its mechanisms are not well understood. The aim of this study was to investigate the effect of massive weight loss on hepatic insulin sensitivity.

Materials and methods: A total of 23 morbidly obese, eight non-diabetic and 15 diabetic or pre-diabetic patients, were studied before and six months after a bariatric surgery (either sleeve gastrectomy (n=10) or gastric bypass (n=13) surgery). Ten healthy controls (BMI 23.7 ± 1.8 kg/m²) were included. Hepatic glucose uptake (GU) was measured using positron emission tomography and ¹⁸F-fluorodeoxyglucose during euglycemic hyperinsulinemic clamp. Liver volume and fat content were measured using magnetic resonance imaging and spectroscopy.

Results: BMI decreased postoperatively by 25% (from 43 ± 4 to 32 ± 3 kg/m²) in diabetic and by 20% (from 44 ± 4 to 35 ± 5 kg/m²) in non-diabetic patients, both $p < 0.001$ vs. baseline. Abdominal visceral fat mass was reduced by 1.8 ± 1.1 kg ($p < 0.001$) and 1.2 ± 0.5 kg ($p = 0.001$), respectively. Whole-body insulin mediated glucose uptake (M value) was significantly impaired both in diabetic (11.8 ± 5.2 μmol/min/kg) and in non-diabetic patients (14.0 ± 7.0 μmol/min/kg) compared to controls (40.3 ± 9.5 μmol/min/kg), both $p < 0.001$, and increased by 119 % ($p < 0.001$) in diabetic and by 81 % in non-diabetic patients ($p = 0.001$) after surgery. OGTT was normalized in 10 out of 13 patients after follow-up. Diabetic subjects had lowest insulin stimulated hepatic GU at baseline, which increased significantly postoperatively (from 1.6 ± 0.5 to 2.1 ± 0.9 μmol/100ml/min, $p = 0.016$). No significant change was observed in hepatic GU in non-diabetic subjects. Also no group differences were observed in hepatic GU postoperatively. Postoperative hepatic GU results were similar between the two surgically treated groups (sleeve gastrectomy vs. gastric bypass). Liver volume decreased by 29 % in diabetic (from 1900 ± 334 to 1333 ± 266 ml $p < 0.001$) and by 15 % in non-diabetic patients (from 1747 ± 363 to 1452 ± 227 ml $p = 0.044$) but remained still higher than in healthy controls (1115 ± 99 ml) in both groups (diabetic vs. control group: $p = 0.023$ and non-diabetic vs. control group: $p < 0.001$). Liver fat content was reduced postoperatively in diabetic patients (from 12.0 ± 7.7 to 2.5 ± 1.4 % $p = 0.002$) but only a tendency was observed in non-diabetic subjects (from 8.5 ± 8.6 to 2.8 ± 2.8 % $p = 0.06$). No group differences were found in liver fat content postoperatively (1.9 ± 1.2 %, control subjects). Hepatic GU correlated positively with the M value through the study and (preoperatively) inversely

with WHR, liver volume, visceral fat and TNF- α . After bariatric surgery, a negative correlation was found between hepatic GU and WHR, liver fat and visceral fat, and a positive correlation between hepatic GU and ghrelin and adiponectin.

Conclusion: In conclusion, bariatric surgery normalized the excess in liver fat content and the defect in insulin-mediated hepatic GU in morbidly obese patients with diabetes and pre-diabetes. No difference was observed between sleeve gastrectomy and gastric bypass surgery.

Early aggressive weight loss efforts using adjustable gastric banding leads to “remission” or improvement of type 2 diabetes mellitus

T. Okerson^{1,2}, M.G. Oefelein¹, S. Bhoyrul³, J. Dixon^{4,5}

¹Medical Affairs, Allergan, Inc, Irvine, USA, ²Internal Medicine, University of California, Irvine, USA, ³Surgical Associates of La Jolla, USA, ⁴Human Neurotransmitters Laboratory, Baker IDI Heart and Diabetes Institute,

⁵Department of General Practice, Monash University, Melbourne, Australia.

Background and aims: Bariatric surgery (malabsorptive or restrictive techniques) has been established as an effective treatment to reduce weight in severely obese patients' refractory to behavioral and medical therapies. This study reports the 1 year “remission” and/or improvement of type 2 diabetes mellitus (T2D) after laparoscopic placement of the adjustable gastric band (AGB) as documented by T2D medication reduction/discontinuation, and the accompanying change in BMI as well as improvements in other co-morbidities of obesity and quality of life.

Materials and methods: The APEX study is an ongoing 5-year, prospective, multi-center, open-label, observational study to assess weight reduction, co-morbidities and quality of life after implantation of the LAP-BAND AP[®] gastric band, a restrictive weight loss technique. This is an interim analysis of subjects who reported daily medical therapy for T2D before AGB and who have completed the 1 year post-operative scheduled visit. “Remission” of diabetes was defined as elimination of hypoglycemic medication, and “improvement” as reduction in hypoglycemic medication.

Results: At baseline, 94 out of 436 subjects (22%) reported T2D requiring daily medical therapy; data from 64 subjects contained sufficient information to assess outcome at 48 weeks. Overall, 86% had “remission” and/or improvement in T2D, with remission more likely to occur in patients treated earlier after the diagnosis of T2D (as shown in table below).

		Remission	Improvement	Stable	Worse
% (n)		34 (22)	52 (33)	13 (8)	2 (1)
Mean	Duration T2D (mo)	63	76	90	1
	Baseline BMI	46	44	52	47
	Δ BMI	-8.9	-7.6	-8.1	-2.9
	Δ Wt (kg)	-25	-22	-24	-8
	% Wt Δ	-19	-21	-15	-6

Baseline BMI, reductions in BMI and % change in weight were not statistically different among the groups, although numbers were small. As in patients with T2D, resolution or improvement also occurred in other pre-existing co-morbidities measured: hypertension (78%), hyperlipidemia (57%), depression (71%), obstructive sleep apnea (69%) and GERD (93%). Quality of Life as measured by the Obesity and Weight Loss Quality of Life instrument also improved.

Conclusion: These data suggest that a minimally-invasive restrictive gastric banding procedure in obese patients with T2D results in clinically meaningful weight loss, as well as a reduction in T2D medication requirements, likely without the risk of nutrient deficiencies often seen with malabsorptive surgery. An earlier, aggressive weight loss intervention appears more apt to facilitate remission of disease, probably due to improvements in insulin sensitivity and beta cell health. Larger and longer-term studies are required to determine the duration of remission/improvement and the effects on beta cell function.

565

Effects of gastric bypass surgery on glucose metabolism 5 days, 3 months and 1 year after surgery in subjects with type 2 diabetes and normal glucose tolerance

N.B. Jorgensen^{1,2}, S.H. Jacobsen¹, C. Dirksen¹, K.N. Bojsen-Møller¹,

D. Worm¹, D.L. Hansen¹, T.R. Clausen³, B.S. Wulff³, L. Naver⁴, L. Hvolris⁴, J.J. Holst⁵, S. Madsbad¹;

¹Dep. of Endocrinology, Hvidovre Hospital, ²Dept of Biomedicine, University of Copenhagen, ³Novo Nordisk A/S, Måløv, ⁴Dept. of Surgery, Hvidovre Hospital, ⁵Dept. of Biomedicine, University of Copenhagen, Denmark.

Background and aims: Roux-en-Y gastric bypass (RYGB) has profound effects on glucose metabolism leading to a resolution of type 2 diabetes (T2D) early after surgery that persists for years; however, the mechanisms for this improvement remain uncertain.

Materials and methods: 13 obese T2D (BMI: 43.1 \pm 1.4 kg/m²) and 12 matched normal glucose tolerant (NGT) subjects were examined during a liquid meal 3 days before, 5 days, 3 months and 1 year after RYGB. Three fasting blood samples were drawn before the meal (Fresubin Energy, 1260 kJ, 200 mL, protein E% 15, carbohydrate E% 50, fat E% 35), followed by repeated blood sampling for 4 hrs for measurement of plasma glucose, insulin and C-peptide. Insulinogenic index was calculated as Δ C-peptide/ \rightarrow peak glucose-fasting glucose / Δ glucosepeak-fasting. To relate beta-cell function to the ambient insulin resistance, disposition index was calculated as the insulinogenic index multiplied by 1/HOMA-IR.

Results: A significant decrease in fasting glucose (T2D: pre: 8.8 \pm 0.6, post: 7.0 \pm 0.3 p<.01, 3 mo: 6.8 \pm 0.5 p<.01, 1y: 6.8 \pm 0.75 mmol/l p<.05; NGT: 5.5 \pm 0.2, 5.0 \pm 0.2 p<.01, 4.9 \pm 0.1 p<.01, 4.9 \pm 0.12 mmol/l) as well as fasting insulin levels (T2D: 125 \pm 21, 73 \pm 9 p<.01, 58 \pm 10 p<.01, 48 \pm 10 pmol/l p<.01; NGT: 82 \pm 8.2, 49 \pm 4 p<.01, 43 \pm 4 p<.01, 34 \pm 4 pmol/l p<.05) was observed after RYGB. HOMA-IR was halved in both groups after 5 days, followed by further non-significant falls by 3 mo and 1y (T2D: 6.6 \pm 1.0, 3.2 \pm 0.4 p<.01, 2.1 \pm 0.4 2.1 \pm 0.4 p<.01; NGT: 2.9 \pm 0.3, 1.6 \pm 0.2 p<.01, 1.2 \pm 0.2, 1.1 \pm 0.15). Following meal ingestion, 120 min post prandial glucose levels decreased in T2D subjects (11.4 \pm 0.8, 8.2 \pm 0.7 p<.01, 6.9 \pm 0.6 p<.01, 7.1 \pm 0.8 p<.01 mM), whereas levels were unchanged in NGT subjects immediately after RYGB, but decreased by 3 mo and 1 y (5.6 \pm 0.3, 5.2 \pm 0.2, 4.2 \pm 0.3 p<.01, 4.3 \pm 0.1 mM p<.01). Incremental AUC C-peptide was increased directly after surgery in the T2D group (188 \pm 21, 254 \pm 28 p<.05, 228 \pm 25, 171 \pm 24 nM min), whereas levels in the NGT group were significantly increased 5 d and 3 mo after, but had returned to pre surgical levels by 1y (168 \pm 17, 262 \pm 28 p<.01, 329 \pm 41 nM min p<.01, 176 \pm 19 nM min). IGI increased after RYGB in T2D, but did not change in NGT, whereas disposition index increased in both groups 5 d and 3 mo after surgery. After 1 y, disposition index continued to increase in the T2D group, but returned towards normal in the NGT subjects (T2D: 52 \pm 11, 119 \pm 12 p<.01, 164 \pm 30 p<.01, 220 \pm 72 p<.05; NGT: 415 \pm 68, 686 \pm 109 p<.05, 848 \pm 107 p<.01, 719 \pm 158).

Conclusion: Resolution of T2D after RYGB is associated with increased insulin sensitivity and beta cell function. Effects are seen as early as 5 days after surgery and persist for at least 1 year. Beta cell function of NGT subjects increase dramatically within the first months after RYGB, but after 1y, beta-cell function has adapted to the ambient insulin sensitivity.

566

The effect of metabolic surgery on beta cell function, hepatic insulin extraction, insulin sensitivity and post-hepatic insulin appearance in patients with morbid obesity

G. Scherthaner¹, J.M. Brix¹, H.P. Kopp¹, A. Kurtaran², G.-H. Scherthaner³, G. Pacini⁴;

¹Medicine I, Rudolf Foundation Hospital, ²Nuclear Medicine, Rudolf Foundation Hospital, ³Medicine II, Medical University Vienna, Austria,

⁴Metabolic Unit, ISIB-CNR, Padua, Italy.

Background and aims: The hormonal and metabolic changes following weight loss by metabolic surgery are of great interest, since it is still unclear why a resolution of type 2 diabetes is seen in the majority of patients. In addition, to changes of gastrointestinal hormones, amelioration of insulin action and beta cell function could play an important role. Since detailed integrated information is still lacking, we have evaluated beta cell function, hepatic insulin extraction, insulin sensitivity and post-hepatic insulin appearance in patients with morbid obesity (MO) before and after metabolic surgery (MS).

Materials and methods: We studied 67 patients with MO (BMI 45.1 ± 0.8 kg/m²; 40.3 ± 1.2 years) at baseline and at 2 years after MS (mean weight loss 40 kg). An oral glucose tolerance test (OGTT; 75 g glucose) was performed before and after MS, as well as in 30 nondiabetic control (CO) subjects (mean BMI 28.4 ± 1.4 kg/m²) matching for age and sex. In the fasting conditions, glucose (Gb; mg/dl), insulin (Ib; μ U/ml), C-peptide (CPb; pmol/ml) yielded beta cell function ($FBC = CPb/Gb$) and insulin sensitivity (QUICKI). From OGTT (post-prandial condition), we calculated the areas under glucose (AUCg; mol/L 2h) and insulin (AUCi; nmol/L 2h) concentration which yielded beta cell (pre-hepatic) function (IGI; pmol/mmol) and hepatic insulin extraction (HE,%). Modeling analysis provided systemic insulin sensitivity (OGIS, ml/min/m²) and the adaptation index (AI) that is the ability of the beta cell to compensate for increasing insulin resistance (also called: beta cell sensitivity to changes in insulin sensitivity).

Results: All data evaluated in the MO patients before and after MS at both fasting and dynamic conditions are summarized in the TABLE. Insulin action markedly ameliorated both at fasting and in dynamic conditions. This is demonstrated also by the marked improvement of the adaptation index, showing that the beta cell responds better to the changes in insulin resistance. Changes in peripheral insulin are due to pancreatic function (secretion) and not to changes in clearance, because hepatic extraction does not change significantly.

Conclusion: Our results show that surgery entails lower glucose levels, which cause a reduction of released insulin, despite a clear increase of the beta cell function. This implies that the pancreas is able to better respond to the glycemic stimulus, as observed when the beta cell is less stressed (less glucotoxicity).

Table 1. Pre- and post-surgery values of fasting and dynamic conditions

parameter	Pre-surgery	Post-surgery	p-value
Gb	97 ± 3	80 ± 2	<0.000001
Ib	26 ± 2	10 ± 1	<0.000001
CPb	1.2 ± 0.1	2.0 ± 0.5	0.011
FBC	0.23 ± 0.02	0.47 ± 0.13	0.0008
QUICKI	0.359 ± 0.004	0.441 ± 0.010	<0.000001

Mechanisms of improvement of glucose in type 2 diabetes after bariatric surgery: gastric bypass vs sleeve gastrectomy

M. Nannipieri¹, D. Guarino¹, A. Mari², M. Anselmino³, S. Baldi¹, B. Astiarraga¹, R. Berta³, E. Ferrannini¹

¹Internal Medicine, University of Pisa, ²Bio-Engineering, CNR of Padua,

³Bariatric Surgery, Azienda Ospedaliera Universitaria of Pisa, Italy.

Background and aims: In morbidly obese patients with T2DM, Roux-en-Y-gastric-bypass surgery (RYGB) restores euglycemia early after surgery, but effectiveness of sleeve gastrectomy (SLV) in improving T2DM are scarce. To investigate extent and mechanisms of recovery of β -cell function and insulin-sensitivity in severely obese T2DM patients undergoing RYGB or SLV.

Materials and methods: 28 obese T2DM subjects (19 RYGB and 9 SLV) were studied before and 15-d after surgery by comparing the response to a Mixed-Meal-Test (MMT) preceded by a week of low-calorie intake. Insulin-sensitivity was assessed by OGIS-index and β -cell function by modeling analysis of the C-peptide response to MMT. Plasma ghrelin concentrations were assessed during MMT.

Results: 15-d post-surgery, BMI had decreased to the same extent in RYGB and SLV (43.5 ± 6.1 vs 40.3 ± 5.6 ; 47.6 ± 5.2 vs 45.5 ± 7.5 kg.m⁻² respectively, $p < 0.0001$ vs baseline). Mean glucose improved in RYGB and SLV (8.2 ± 1.9 vs 7.0 ± 1.8 mmol/l, 8.8 ± 2.1 vs 6.9 ± 1.5 respectively, $p = 0.0002$ vs baseline) and mean insulin decreased (177 ± 64 vs 141 ± 76 pmol/l, 247 ± 130 vs 184 ± 79 , respectively, $p = 0.005$ vs baseline). β -cell glucose sensitivity improved in RYGB and SLV (28.8 ± 22.9 vs 47.9 ± 35.5 pmol.min⁻¹.m⁻².mM⁻¹, 33.0 ± 30.9 vs 48.8 ± 39.5 , respectively, $p = 0.02$ vs baseline). At baseline, insulin-sensitivity

was similar in RYGB and SLV (308 ± 53 vs 289 ± 39 ml.min⁻¹.m⁻²); following surgery, insulin-sensitivity improved (359 ± 53 and 354 ± 68 ml.min⁻¹.m⁻², respectively, $p = 0.0003$ vs baseline). Mean ghrelin decreased in RYGB and SLV (7643 ± 7871 vs 3630 ± 2848 , 4845 ± 5712 vs 1687 ± 782 pg/ml, $p = 0.02$). Plasma ghrelin changes were inversely correlated with β -cell glucose sensitivity variations ($r^2 = 0.096$, $p < 0.03$). After surgery, plasma PYY increased in GBP only (18.98 ± 8.18 vs 24.32 ± 8.57 , 14.42 ± 2.14 vs 14.59 ± 3.81 ng/ml, $p = 0.004$ in GBP and sLV respectively).

Conclusions: 15-d after surgery and under constant calorie intake, glucose tolerance is improved to a similar extent with RYGB and SLV, as a result of similar improvements in β -cell function and insulin-sensitivity. Furthermore, plasma ghrelin concentrations were reduced after both surgery and, correlated with β -cell glucose sensitivity.

PTH and vitamin D in morbid obese subjects: the effects of type 2 diabetes and roux en-y gastric bypass (RYGB)

M. Seghieri¹, D. Guarino¹, D. Colligiani¹, M. Anselmino², R. Berta², E. Ferrannini¹, M. Nannipieri¹

¹Internal Medicine, University of Pisa, ²Bariatric Surgery, Azienda Ospedaliera Universitaria Pisana, Italy.

Background and aims: Several lines of evidence indicate that vitamin D (25OH-D) deficit and hyperparathyroidism (hyperPTH) occur after bariatric surgery; some studies have reported that in morbid obesity vitamin D deficit may precede surgery. Furthermore, low 25OH-D and high PTH concentrations have been suggested to be independent risk factors for type 2 diabetes (T2DM). However, data regarding the effect of RYGB in morbidly obese diabetic subjects are scarce. Aim of this study was to investigate the relationship between 25OH-D, PTH concentrations and T2DM in severely obese patients before and after RYGB.

Materials and methods: 130 morbidly obese subjects wait-listed for RYGB (44 non-diabetic (NGT), 28 with impaired glucose tolerance (IGT) and 58 with T2DM) were studied before surgery. Among them, 50 subjects (24 NGT and 26 T2DM) were re-studied 3 months after RYGB. Serum PTH and 25OH-D were measured, insulin sensitivity was assessed by the OGTT-derived OGIS method.

Results: At baseline, BMI was similar in NGT, IGT and T2DM (45.5 ± 7.6 vs 47.4 ± 6.5 vs 48.82 ± 7.8 kg/m², mean \pm SD). In T2DM compared to NGT, PTH concentrations were significantly higher (79.5 ± 36.8 vs 70.7 ± 26.9 vs 66.8 ± 29.7 pg/ml in T2DM, IGT, NGT, respectively, mean \pm SD, $p = 0.05$), whereas 25OH-D levels were significantly lower (11.9 ± 7.3 vs 14.7 ± 12.9 vs 19.0 ± 12.7 ng/ml in T2DM, IGT, NGT, mean \pm SD, $p < 0.03$). Basal PTH was directly related with HbA1c ($p = 0.002$), but not with BMI; 25OH-D did not correlate with BMI or glycaemic control. Following surgery, BMI decreased similarly in both NGT and T2DM subjects and insulin sensitivity improved in both groups (358 ± 31.5 to 406 ; 263 ± 33 to 308 ± 54 ml.min⁻¹.m⁻², NGT and T2DM $p < 0.0001$). PTH concentrations decreased in both groups (from 68.7 ± 27.9 to 57.7 ± 40.9 pg/ml in NGT and from 79.7 ± 31.5 to 58.9 ± 27.2 pg/ml, $p < 0.001$), while 25OH-D increased in both groups (from 16.4 ± 13.1 to 22.0 ± 12.9 in NGT and from 13.2 ± 9.4 to 21.2 ± 14.9 ng/ml, $p < 0.002$).

Conclusion: In morbidly obese patients, high circulating concentrations of PTH and low vitamin D levels are associated with the presence of hyperglycaemia regardless of insulin sensitivity. Restrictive bariatric surgery rapidly corrects both vitamin D and PTH.

Diabetes is the main factor accounting for hypomagnesaemia in obese subjects

A. Lecube¹, J. Baena-Fustegueras², J. Fort², D. Pelegri³, C. Hernández¹, R. Simó¹

¹CIBER de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM). Instituto de Salud Carlos III (ISCIII). Diabetes and Metabolism Research Unit, Institut de Recerca Hospital ²Endocrinology Surgery Unit. General Surgery Department. ³Biochemistry Department. Hospital Universitari Vall d'Hebron, Barcelona, Spain.

Background and aims: To determine whether the presence of type 2 diabetes and the degree of metabolic control are related to low serum magnesium levels in obese individuals.

Material and methods: A) Case-control study: magnesium was measured in 200 obese subjects (50 with type 2 diabetes [cases] and 150 without diabetes [controls]) prospectively recruited. B) Interventional study: the effect of bariatric surgery on serum magnesium levels was examined in a subset of 120 obese subjects (40 with type 2 diabetes and 80 without diabetes). Statistics: comparisons between groups were performed using Student *t* test for continuous variables and the χ^2 test for categorical variables. For the analysis of the interventional study, the Student-*t* test for paired data was used. The relationship between continuous variables was examined by the Pearson linear correlation test. A stepwise multiple linear regression analyses was performed in order to explore the variables independently related to serum magnesium. The variables included were fasting glucose, HbA1c, BMI, age, gender, and HOMA-IR. Because of collinearity between fasting blood glucose and HbA1c, two regression models were performed, which took into account each of these variables. All *p* values were based on a two-sided test of statistical significance. This study was approved by the Local Ethics Committee and was performed in accordance with the ethical standards laid down in the Helsinki Declaration (see World Medical Association: www.wma.net).

Results: Type 2 diabetic patients showed lower serum magnesium levels [0.75 ± 0.07 vs. 0.81 ± 0.06 mmol/l; mean difference -0.06 (95% CI -0.09 to -0.04); $p < 0.001$] than non-diabetic patients. Ten percent of the diabetic subjects, but none of the non-diabetic subjects, showed a serum magnesium concentration lower than 0.65 mmol/l. Significant negative correlations between magnesium and fasting glucose ($r = -0.443$; $p < 0.001$), HbA1c ($r = -0.460$; $p < 0.001$), HOMA-IR (log) ($r = -0.182$; $p = 0.015$) and BMI ($r = -0.142$; $p = 0.046$) were detected. Multiple linear regression analyses showed that both fasting glucose and HbA1c were independently related to serum magnesium. After bariatric surgery, serum magnesium increased only in those patients in whom diabetes had been resolved, but otherwise remained unchanged, with no difference in weight loss between the groups. Changes in serum magnesium negatively correlated with changes in fasting glucose and HbA1c. Baseline fasting glucose and HbA1c independently predicted magnesium changes in the multiple linear regression analysis.

Conclusions: Our results provide evidence that the presence of diabetes and the degree of metabolic control are essential in accounting for the lower levels of magnesium that exist in obese subjects. Since low serum magnesium levels are an independent cardiovascular risk factor and favour diabetic complications, the normalization of serum magnesium levels is another good reason for recommending the optimization of blood glucose in type 2 diabetic patients.

PS 036 Insulin: metabolites and actions

Characteristics of insulin glargine signalling in rats

N. Tennagels, S. Welte, H. Jordan, M. Hoffmann, U. Werner; sanofi-aventis, Frankfurt, Germany.

Background and aims: Insulin glargine (GLA) is a long-acting insulin analogue that demonstrates safe and effective 24-hour glycemic control. In vitro, GLA has an insulin receptor (IR) profile similar to that of human insulin (HI) but has a slightly higher affinity for the insulin-like growth factor-1 receptor (IGF1R). [AspB10]Insulin (AspB10), the only insulin analog with proven carcinogenic activity, has IGF1R activity greater than HI and a higher IR affinity with a prolonged IR occupancy time when compared to GLA. In this study, we analyzed the time action profile of GLA in different tissues of rats with respect to pharmacological and signalling parameters and compared it to HI, insulin detemir (DET) and AspB10.

Materials and methods: Male Wistar rats were injected subcutaneously with 1 IU/kg of HI, GLA, DET or AspB10, and the effects on blood glucose and phosphorylation status of IR, IGF1R, AKT and ERK1/2 in tissue samples derived from muscle, fat, liver, heart and kidney investigated over time.

Results: After injection of HI and AspB10, glucose levels started to drop immediately and reached their minimum after 1 hour. Glucose lowering after injection of GLA reached the same minimum, however the onset of hypoglycemic action was delayed. Injection of an equal dose of DET failed to lower blood glucose in this setting and therefore was not further characterized. GLA treatment resulted in phosphorylation levels of IR and AKT that were comparable to HI although delayed in some tissues. In contrast, AspB10 treatment resulted in at least 2-3 fold higher phosphorylation levels and significantly longer duration of IR and AKT phosphorylation in most tissues in vivo, confirming the in vitro observations of increased affinity and occupancy time of the IR. Importantly, neither HI nor GLA nor AspB10 treatment resulted in any detectable IGF1R phosphorylation in muscle and heart tissue, whereas injection of IGF-1 increased the phosphorylation of this receptor.

Conclusion: The time course of insulin receptor signaling by human insulin and insulin glargine reflects the time course of their pharmacodynamic effects in a comparable and correlative way, which is distinctively different from [AspB10]Insulin.

Analysis of signalling pathways stimulated by insulin, [Asp^{B10}]insulin and insulin glargine and its metabolites in the human mammary epithelial cell lines MCF7 and MCF10

N. Schmidt, S. Welte, M. Sommerfeld, G. Müller, G. Tschank, N. Tennagels; sanofi-aventis, Frankfurt, Germany.

Background and aims: Insulin glargine (GLA) is a long-acting insulin analogue that in vitro displays a similar affinity for the insulin receptor (IR) as human insulin (HI) and an increased affinity for the insulin-like growth factor-1 receptor (IGF1R) comparable to that of [AspB10]insulin (AspB10). However, in contrast to AspB10 that is the only insulin analogue with proven tumorigenic properties in rats, GLA did not show increased incidence of mammary tumors in mice and rats in 2-year carcinogenicity studies. In both humans and animals, GLA is rapidly and significantly metabolized into the metabolites M1 and M2 that have a metabolic profile like GLA but a mitogenic profile identical to that of HI. The aim of this study was to compare the mitogenic activity and signaling behavior of GLA, M1 and M2 to IGF-1, HI and AspB10 in the human mammary epithelial cell lines MCF7 and MCF10a. These cell lines have different IGF1R/IR and IR-A/IR-B ratios (MCF7: 3.7:1 and 5:1; MCF10a 1.5:1 and 14:1) as measured by RT-PCR.

Materials and methods: MCF cells were incubated with increasing concentrations of HI, IGF-1, GLA or AspB10 and the amount of phosphorylation of AKT and ERK1/2 determined using western blotting. Thymidine incorporation into DNA was also determined.

Results: Compared to IGF-1, AspB10 and GLA showed a ~3- and ~2-fold lower EC₅₀ for AKT and ERK1/2 phosphorylation, respectively, and a more potent stimulation of thymidine incorporation in MCF7 cells. In contrast, the signaling behavior and mitogenicity of M1 and M2 were reduced com-

pared to HI. In MCF10a cells, AspB10 displayed increased mitogenic activity compared to HI that can be explained by its increased affinity and occupancy time at the IR, whereas GLA and its metabolites were comparable to HI.

Conclusion: Together the data indicate that in vitro mitogenicity of GLA cannot be directly linked to enhanced IGF1R affinity. In addition, in vitro data generated under artificial cell culture conditions cannot be translated into the in vivo situation, since biotransformation, distribution and the competition with levels of free endogenous IGF-1 critically affect the metabolic and mitogenic signaling properties of GLA in vivo as well. Only in vivo experiments generate evidence and explain the established efficacy and safety of GLA as observed in clinical practice and in long-term clinical trials. The current results emphasize the importance of studying the multiple steps in the action of an insulin analogue both in vitro and in vivo.

Plasma exposure to insulin glargine and its metabolites in patients with type 1 diabetes

A. Frick¹, R. Schmidt¹, T. Eisenblatter¹, R. Becker¹, G.B. Bolli²;

¹sanofi-aventis, Frankfurt, Germany, ²University of Perugia, Italy.

Background and aims: After subcutaneous (SC) injection in vivo, glargine (GLA) is enzymatically transformed to metabolites M1 and M2 with loss of the di-arginines at position 30a–30b of the B chain but retention of the glycine for asparagine substitution at position A21 of the A chain. In vitro, GLA exhibits slightly higher affinity while M1 and M2 exhibit lower affinity for IGF-1 receptors than human insulin (HI). Due to technical constraints few data on the plasma concentration of GLA, M1, and M2 in humans exist.

Materials and methods: Plasma concentrations of GLA, M1, and M2 were determined from samples taken in a single-center, randomized, euglycemic glucose clamp study, where 12 male subjects with type 1 diabetes (BMI 25 kg/m²; A1C < 8.0%) per group received single SC doses of 0.3, 0.6, or 1.2 U/kg GLA. GLA, M1, and M2 were extracted using immunoaffinity columns and quantified by a specific liquid chromatography tandem mass spectrometry assay, without cross-reactivity to endogenous HI or other insulins. LLOQ was 200 pg/ml. The areas under the GLA, M1, and M2 curves (PK-AUC_{0–24}) were determined. The PD effect was determined from the AUC under the glucose infusion rate curve (PD-AUC_{0–24}).

Results: GLA and M2 were only detectable in approximately one third of patients and at a few time points only. When detectable, GLA and M2 exposure did not increase with increasing dose, and concentrations were far below endogenous interprandial plasma insulin concentrations of nondiabetic subjects. Plasma exposure of M1 increased with increasing dose; geometric mean (%CV) PK-AUC_{0–24} was 7 (61), 18 (75), and 23 (24) ng·h/ml at doses of 0.3, 0.6, and 1.2 U/kg, respectively. The geometric mean (%CV) PD-AUC_{0–24} was 522 (64), 2330 (37), and 5231 (28) mg/kg, respectively.

Conclusion: After subcutaneous injection of GLA in subjects with T1DM, there is a rapid removal of di-arginines with nearly total transformation of GLA into M1, accounting almost totally for the PD effect of injected GLA. In vivo exposure to GLA, if any, appears to be marginal. The results demonstrate that in vivo glargine is rapidly metabolized to active products that have lower affinity for IGF-1 than endogenous human insulin.

Restoring metabolic control in diabetic rats by insulin replacement

A.F. Soares^{1,2}, R.A. Carvalho¹, F.J. Veiga², M.G. Alves¹, I. Viegas^{1,3}, J.D. González³, I. Metón³, I.V. Baanante³, J.G. Jones¹;

¹Center for Neuroscience and Cell Biology, ²Laboratory of Pharmaceutical Technology, University of Coimbra, Portugal, ³Department of Biochemistry and Molecular Biology, University of Barcelona, Spain.

Background and aims: With current insulin therapy the physiological release to the portal vein is not reproduced since the subcutaneous (sc) route results in higher peripheral insulinization relative to the splanchnic region. This may hamper the optimal metabolic regulation in insulin-treated diabetics. We tested whether intraperitoneal (ip) insulin delivery could improve the performance of diabetic rats in regards to hepatic-specific insulin metabolic actions, namely glycogen and lipid synthesis.

Materials and methods: Male Wistar rats were induced diabetes by streptozotocin (65 mg/kg) injection in the ip cavity (glycemia: 534±22 mg/dL; plasma insulin: 0.5±0.2 µg/l), insulin replacement started 8 days afterwards and consisted of two daily injections (15 U/kg) via the sc (group I-SC) or ip (group I-IP) route for 10 days. In the last day of treatment rats (groups: C, non-diabetic controls; D, diabetics; I-SC and I-IP) were kept under deuterated water (²H₂O) overnight while feeding ad lib. and pathways to hepatic glycogen and lipid synthesis addressed by ²H NMR methods. Gene expression was quantified by qPCR.

Results: Hepatic glycogen (µmol/g of tissue dry weight) decreased with diabetes: 907±84, C; 320±51, D (P<0.05 vs C, I-SC and I-IP); and increased with insulin treatments: 680±52, I-SC (P<0.05 vs D and C); 814±63, I-IP (P<0.05 vs D). Indirect (gluconeogenic) pathway contribution to glycogen increased with diabetes: 54±4%, C; 95±3%, D (P<0.05 vs C, I-SC and I-IP); and was restored with insulin: 47±2%, I-SC (P<0.05 vs D) and 49±2%, I-IP (P<0.05 vs D). Hepatic triglycerides (HTG, µmol/g of tissue dry weight) increased with diabetes: 212±22, C; 312±20, D (P<0.05 vs C); and remain elevated with insulin treatments: 301±15, I-SC (P<0.05 vs C) and 287±11, I-IP (P<0.05 vs C). Contribution of de novo lipogenesis (DNL) to HTG was 16±2% in C, only 2±1% in D (P<0.05 vs C, I-SC and I-IP), but increased with insulin replacement: 7±1%, I-SC (P<0.05 vs D and C) and 8±1%, I-IP (P<0.05 vs D and C). Gene expression analysis is shown in Figure 1.

Conclusion: Both insulin replacement therapies restored the direct/indirect pathway contributions to glycogen synthesis but hepatic stores were only recovered to control values by the ip route. The expression of glycolytic and lipogenic enzymes was stimulated, consistent with enhance DNL as determined by the ²H₂O method. Neither therapy effectively restrained the expression of gluconeogenic enzymes and CPT1a. Hence, gluconeogenic G6P synthesis, fuelled by mitochondrial fat oxidation, was also likely to be less controlled.

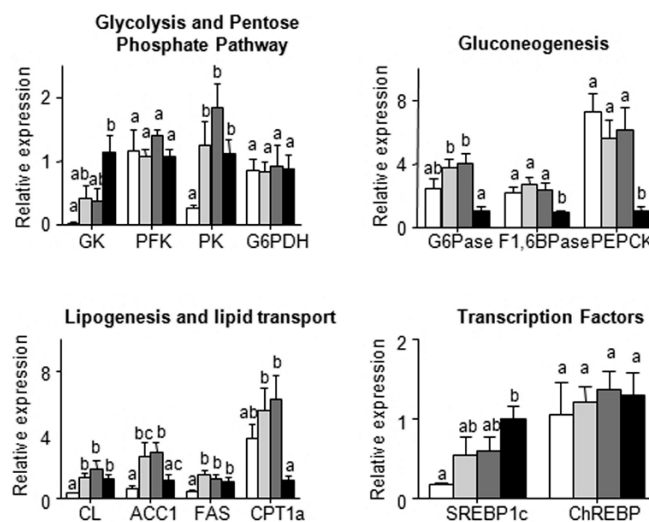

Figure 1: Gene expression determined in livers from groups D, white bars; I-SC, light grey bars; I-IP, dark grey bars and C, black bars; different letters indicate significant differences (P<0.05).

Effect of insulin detemir on adipocyte lipid metabolism in patients with type 2 diabetes

N. Alsini, F. Shojaae-Moradie, B. Sheldon, M.D. Robertson, D.L. Russell-Jones, A.M. Umpleby, J. Wright;

Diabetes & Metabolic Medicine, University of Surrey, Guildford, UK.

Background and aims: Subcutaneous administration of insulin may cause peripheral hyperinsulinaemia leading to abnormalities in adipocyte metabolism and possible weight gain. Insulin detemir has been shown to cause less weight gain than other insulin treatments. This may be related to insulin detemir's hepatoselective action which has the potential to restore the physiological insulin gradient.

Materials and methods: In a single-centre, 24 week, randomized parallel-group trial the effect of insulin detemir on adipocyte lipid metabolism was investigated in 22 type 2 diabetic subjects (14M, 8F, aged 60.4± 8.1y), BMI 32.3

$\pm 3.6 \text{ kg/m}^2$) (means \pm SD). Patients were optimized for 8 weeks with NPH insulin and then randomized to receive either insulin detemir or NPH insulin for 16 weeks. Weight change, glycemic control, NEFA and triglycerides were measured after 8 weeks and after 16-week treatment period. In a sub-set, basal and stimulated lipolytic activity, lipoprotein lipase (LPL) mass and activity were measured in subcutaneous fat tissue biopsy at the same time points.

Results: Weight change over the treatment period was $-0.62 \pm 0.84 \text{ kg}$ with insulin detemir and $+2.19 \pm 1.03 \text{ kg}$ with NPH ($p=0.049$). There was no difference in HbA1c. Fasting non-esterified fatty acids (NEFA) decreased significantly with detemir compared to NPH ($p=0.02$). Basal lipolysis in the fat biopsies also showed a significant reduction with detemir compared to NPH over the treatment period ($p<0.04$). LPL mass and activity increased with insulin detemir compared to NPH ($p=0.005$, $p=0.006$).

Conclusion: The decrease in basal NEFA levels and basal lipolysis and increase in LPL mass and activity suggests an improvement in fasting insulin sensitivity which may be due to a greater hepatoselective action of detemir reducing overinsulinisation of adipose tissue or may be the consequence of improved insulin sensitivity due to weight loss.

Differential roles of MEK/ERK1/2 in human insulin- and insulin glargine-induced proliferation of T24 and HepG2 cells

Y. Li¹, S. Liu², D. Liu¹, Y. Liang¹, W. Deng³, L. Yan¹, T. Lin²;

¹Endocrinology, ²Research Center of Medicine, Sun Yat-Sen University, Guangzhou, China.

Background and aims: MEK/ERK1/2 has been implicated in the mitogenic effects of insulin and its analogues in malignant cells. The results are varied with different experimental settings. This study was to compare the effects of MEK/ERK1/2 pathway in human insulin- and insulin glargine-induced proliferation in human bladder cancer T24 and human hepatocellular carcinoma HepG2 cell lines.

Materials and methods: Cultured T24 or HepG2 cells were treated with a selective MEK or ERK1/2 inhibitor either alone or in combination with insulin or glargine at different doses for the indicated time courses. U0126 is a highly selective inhibitor of both MEK1 and MEK2. The ERK inhibitor, (3-(2-Aminoethyl)-5-((4-ethoxy-phenyl)methylene)-2,4-thiazolidinedione), is known to block ERK-mediated phosphorylation of ribosomal S6 kinase-1 (RSK-1) and ternary complex factor Elk-1. Cell proliferation was evaluated by CCK-8 assay. Protein expression of insulin receptor (IR), type 1 insulin-like growth factor receptor (IGF1R), phosphorylated ERK1/2 (pERK1/2) and total ERK1/2 were detected by Western blotting.

Results: Human insulin and insulin glargine similarly promoted proliferation of HepG2 and T24 cells at 10 IU/L and 100IU/L. IR and IGF1R were detected in both cell lines. In T24 cells, insulin and glargine induced increases in pERK1/2 level at 15min, 30min and 60min while no change was detected at 24h. By contrast, pERK1/2 protein was abundantly expressed in untreated HepG2 cells. No change in pERK1/2 level was observed at early or late time points with either insulin or glargine treatment in HepG2 cells. Basal T24 and HepG2 cell proliferation was reduced in association with decreased pERK1/2 level by U0126. Insulin- and glargine-induced proliferation was blocked by U0126 and the ERK inhibitor in HepG2 cells, while unaffected in T24 cells.

Conclusion: Human insulin and insulin glargine-induced proliferation is MEK/ERK1/2 dependent in HepG2, not in T24 cells. The effect of MEK/ERK1/2 in the mitogenicity of insulin or its analogues may be cell lineage specific.

Differential metabolic and mitogenic signalling of Asp^{B10} and insulin glargine *in vitro* and *in vivo*

U. Werner, M. Sommerfeld, G. Müller, G. Tschank, P. Habermann, G. Seipke, N. Tennagels; sanofi-aventis, Frankfurt, Germany.

Background and aims: Treatment of diabetic patients with insulin analogues has been shown to provide a more efficient, reproducible, and convenient therapy than regular insulin. The analogues may vary from insulin with respect to metabolic potency, stability or onset and duration of action

that is achieved by either sequence or secondary structural modifications. These changes may lead to an altered activation profile of insulin (IR) and/or insulin-like growth factor-1 (IGF1R) receptor signaling pathways and may change metabolic or mitogenic responses. [Asp^{B10}]Insulin (AspB10) is an insulin analogue that was withdrawn from clinical development due to a higher incidence of breast cancer in rats. *In vitro*, AspB10 displays higher affinity toward both IR and IGF1R, a prolonged occupancy time at the IR and a higher proliferation rate in mammalian cell lines. This has led to the general belief that insulin analogues with increased affinity for IGF1R *in vitro* have increased growth promoting activity *in vivo* as well. Insulin glargine (GLA) has an *in vitro* IR signaling and metabolic profile comparable to that of insulin (HI) and displays slightly greater affinity for IGF1R. This long-acting analogue undergoes rapid and significant metabolism in humans and animals, leading to early formation of two main metabolites (M1 and M2) that have *in vitro* metabolic and mitogenic profiles comparable with HI. Our aim was to investigate *in vivo* the metabolic and mitogenic signaling profile of GLA and AspB10 compared with HI.

Materials and methods: Male Wistar rats were injected with 1 or 12.5 U/kg subcutaneously of HI, GLA or AspB10 or with 1 mg/kg des1-3 IGF-1 intravenously. Samples of skeletal muscle, liver, adipose tissue, kidney and heart were harvested at various times for analysis of IR, IGF1R, AKT and ERK1/2 phosphorylation.

Results: Injection of neither HI nor AspB10 nor GLA induced IGF1R autophosphorylation in responsive tissues, whereas injection of IGF-1 produced a robust activation of the receptor. Injection of AspB10 induced an increased and prolonged phosphorylation of IR signaling molecules in several tissues. This IR signaling pattern of AspB10 *in vivo* was distinctly different from that of HI and GLA and confirms earlier *in vitro* findings.

Conclusion: We hypothesize that the carcinogenic effect of AspB10 is based on its altered IR activation profile and is independent of its slightly greater IGF1R affinity *in vitro*.

Impairment of insulin clearance rather than beta cell function in the progression to type 2 diabetes

R.S. Patarrao¹, A.B. Fernandes¹, I.S. Lima¹, M.P. Macedo^{1,2};

¹CEDOC, FCM-UNL, ²APDP Research Center, Lisbon, Portugal.

Background and aims: From the insulin resistance state to the progression to type 2 diabetes the major metabolic dysfunctions are associated to β -cell secretion. The consensual overview is that, first β -cell increases insulin secretion (hyperinsulinemia) in order to compensate the burst of high glucose levels, and after this overproduction, β -cell drop its capacity to produce insulin, culminating in type 2 diabetes. Association between plasma insulin levels and β -cell secretion are commonly used. However, the evaluation of C-peptide seems to be a better predictor of β -cell function rather than insulin, and that is due to several alterations on insulin clearance that seems to occur during the progression of the disease. Therefore, our hypothesis is that from healthy to insulin resistance states, the major complications observed are not due to β -cell insulin/C-peptide secretion, but mainly due to a decrease on insulin clearance.

Materials and methods: Male Wistar rats (12 weeks old, control vs high-sucrose diet) were used. The high-sucrose diet group consisted in 2 groups of animals: Suc 4 - fed with a high-sucrose diet (35% (w/v)) for a 4 week period (8-12 weeks of age); Suc 9 - fed with a high-sucrose diet (35% (w/v)) for a 9 week period (3-12 weeks of age). Insulin sensitivity was assessed by the Rapid Insulin Sensitivity Test (RIST), in the fed state. To evaluate glucose excursions, insulin and C-peptide levels, a mixed meal (BOOST[®]) was administered and a Meal Tolerance Test (MTT) was performed. Blood samples were taken at time 2, 5, 10, 20, 30, 45, 60, 90 and 120 minutes after the BOOST[®]. Insulin clearance was calculated by the ratio of the area under the curve (AUC) of C-peptide and AUC of insulin.

Results: Postprandial insulin action was determined in both groups and we observed that high-sucrose diet animals showed a decreased in insulin action, which was not aggravated with the duration of the diet (Control: 193.2 ± 11.2 , n=9, Suc 4: 99.7 ± 7.2 , n=4, Suc 9: $107.4 \pm 14.9 \text{ mg glucose/kg bw}$, $p<0.001$). Only the Suc 9 group was hyperglycemic, both in the fasted and fed state, in comparison to the control group (Fasting: Control - 76.1 ± 3.4 , n=9, Suc 4 - 75.8 ± 3.4 , n=4, Suc 9 - $100.9 \pm 5.7 \text{ mg/dl}$, $p<0.05$, n=9; Fed: Control - 106.6 ± 3.0 , n=9, Suc 4 - 105.08 ± 6.7 , n=4, Suc 9 - $127.1 \pm 6.3 \text{ mg/dl}$, $p<0.05$, n=9). The results obtained during the MTT showed that there was only an increase in glucose excursions in the Suc 9 animals (AUC: Control - 14733 ± 445.6 ,

n=9, Suc 4 - 14660 ± 951.9 , n=4, Suc 9 - 16976 ± 1238 mg/dl, n=9). The evaluation of insulin clearance showed that Suc 4 and Suc 9 animals had a 34.1% and a 56.6% reduction on insulin clearance, respectively. From the 4 weeks to the 9 weeks of high-sucrose diet, the major alterations observed were the plasma insulin levels, while the C-peptide levels and insulin action remained unchanged, which indicates that it is the insulin clearance that is affecting the progression of the disease.

Conclusion: The results presented herein allow us to conclude that both Suc 4 and Suc 9 animals are insulin resistant with a decrease on insulin action that is not aggravated with the diet exposition. Comparing both groups of high-sucrose diet animals we observed that C-peptide levels are not altered between the groups but the major alterations are occurring on plasma insulin levels. The results obtained herein showed that from pre-diabetes to diabetes the major alteration that are occurring are due to dysfunctions on insulin clearance rather than β -cell dysfunction.

Reappraisal of hyperbolic relationship between insulin sensitivity (Si) and insulin secretion (β)

T. Aizawa¹, Y. Funase¹, K. Yamauchi¹, M. Katakura²;

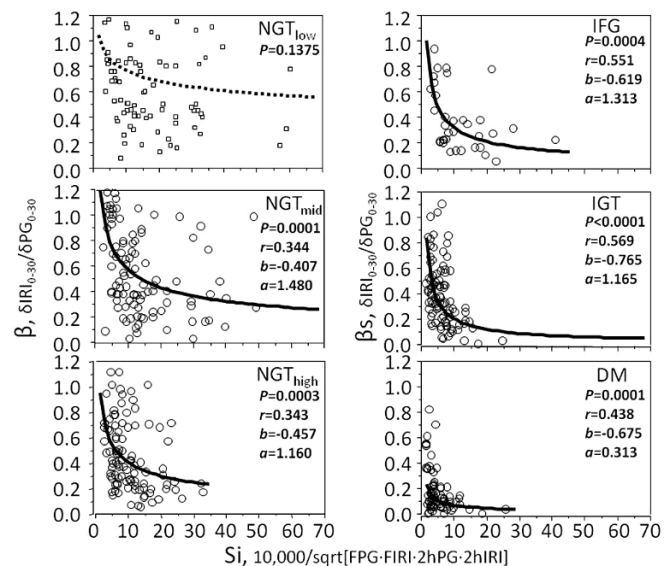

¹Aizawa Hospital, Matsumoto, ²Chikuma Central Hospital, Chikuma, Japan.

Background and aims: In healthy subjects, increase or decrease of Si is considered followed by lowered or elevated β , respectively, to maintain euglycaemia. Hyperbolic correlation between Si and β is in support of such idea, for which glucose allostasis has been proposed as an underlying mechanism especially in subjects with normal glucose tolerance (NGT). We systematically reexamined the issue.

Materials and methods: We analyzed data from 533 health examinees (the mean age 52.8 yrs and body mass index 23.6 kg/m^2). Those with a history of diabetes mellitus (DM) were excluded. Plasma glucose (PG) and immuno-reactive insulin (IRI) were determined in 0, 30 and 120 min samples at 75 g OGTT. In Analysis I (A_I), the participants were classified according to the current diagnostic criteria as NGT (n=328), impaired fasting glycaemia (IFG) (n=37), impaired glucose tolerance (IGT) (n=96) and DM (n=72). NGT was subdivided into NGT_{low} (n=103), NGT_{mid} (n=118) and NGT_{high} (n=107) by fasting PG (FPG) tertile, ≤ 4.9 , 5.0–5.4 and 5.5–6.0 mmol/l. In Analysis II (A_{II}), the subjects were classified based on FPG sextile. FPG range was ≤ 4.8 , 4.9–5.1, 5.2–5.4, 5.5–5.7, 5.8–6.3 and ≥ 6.4 mmol/l, for S_1 (n=91), S_2 (n=84), S_3 (n=83), S_4 (n=96), S_5 (n=94) and S_6 (n=85), respectively. As an index of β , $\delta IRI_{0-30}/\delta PG_{0-30}$ at 75 g OGTT was used. As a measure of Si, an index proposed by Matsuda, $Si = 10,000/\sqrt{[FPG \cdot FIRI \cdot 2hPG \cdot 2hIRI]}$, was used, where FIRI, 2hPG and 2hIRI are fasting IRI, 2-h post glucose PG and IRI at 75 g OGTT, respectively. Hyperbolic regression of β to Si, $[\beta] = a \cdot [Si]^b$, was compared between the 6 groups in A_I and A_{II} , respectively. Correlation coefficient (r) was obtained after log transformation by ordinary least-squares regression. Disposition index (DI) and beta cell demand index (BCDI) were calculated assuming each group of subjects is on a different hyperbola, i.e., $[Si]^b$ not $[Si]^{-1}$ was used.

Results: In A_I , Si- β correlation was most strong and hyperbolic in IGT, progressively less so in the groups of subjects with better glucose tolerance, and absent in NGT_{low} (Figure). b was significantly different from -1 in all NGT groups ($P < 0.01$ for all). The regression line was progressively nearer to the origin from NGT_{mid} to DM. The best-fit line for $[\beta] = a \cdot [Si]^b$ based on all values in each group is shown, with the same axes ($\beta = 0 \sim 1.2$ and $Si = 0 \sim 70$ with metric unit) for all groups. Results were qualitatively similar in A_{II} . Namely, Si- β correlation was most strong and hyperbolic in S_5 , progressively less so in the groups of subjects with better glucose tolerance, and absent in S_2 and S_1 . b was significantly different from -1 in all groups. The mean DI was significantly smaller in DM and S_6 than other groups in A_I and A_{II} , respectively ($P < 0.01$ for both). BCDI positively correlated with 2hPG in 3 NGT groups in A_I and in all sextiles in A_{II} ($P < 0.01$ for all), but not with FPG in any group.

Conclusion: Si- β correlation, which is not exactly hyperbolic, fades away in the group of subjects with superb glucose regulation, and glucose allostasis was confirmed on the basis of 2hPG.

Glucagon-like peptide-1 protects against tert-Butyl hydroperoxide-induced HUVEC apoptosis: involvement of PI3k/Akt pathway

L. Tang, Y. Lin, X. Liu, L. Liu;

Union Hospital, Fujian Medical University, Fuzhou, Fujian, China.

Background and aims: Endothelial cells have a robust capacity to recover vascular injury and maintain intimal layer integrity. Endothelial apoptosis is involved in the formation of atherosclerosis. In this study we investigated whether the anti-diabetic hormone exendin-4 could prevent oxidative stress-induced human umbilical vein endothelial cells (HUVECs) apoptosis and its underlying mechanisms.

Materials and methods: HUVECs were cultured in vitro and exposed to tert-butyl hydroperoxide (t-BHP), an H_2O_2 analogue, or t-BHP plus Exendin-4 (2.5, 5, 12.5 or 25nmol/l). Cell viability was determined by MTT assay and apoptosis was detected by fluorescence microscopic analysis after Hoechst33342/PI staining. HUVECs were pre-incubated with exendin-4 (25nmol/l) for 18 h, then phosphatidylinositol 3-kinase (PI3k) inhibitor, wortmannin (100nmol/l) were added to the medium 30 min before t-BHP exposure. The protein expression of phosphorylation of Akt, Bcl-2 and caspase-3 were measured by Western blot.

Results: The results showed that oxidative stress-induced endothelial cells injury was partially mediated by endothelial cell apoptosis. After pre-treatment with exendin-4 (25nmol/l), cell viability increased by 46.50% ($P<0.05$), and the number of apoptosis, characterized by chromatin condensation and marginalization, decreased significantly (7.98 ± 1.45 vs 36.00 ± 1.25 , $P<0.05$), compared with the t-BHP treated group alone. Going a further step, we examined the underlying regulation. Pre-incubation of HUVECs with exendin-4 resulted a reduction of active caspase-3 (by 48.53%, $P<0.05$), an enhancement of phosphorylated Akt (by 1.78 times, $P<0.05$) and an increase in anti-apoptotic protein Bcl-2 expression (by 1.08 times, $P<0.05$), compared with the t-BHP group. These results indicate that exendin-4 can protect t-BHP-induced HUVECs apoptosis. However, this protective effect was inhibited by the phosphatidylinositol-3 kinase (PI3k) inhibitor wortmannin.

Conclusion: Our findings showed that GLP-1 analogue exendin-4 has a protective effect against oxidative stress-induced endothelial injury by inhibiting cell apoptosis, which may associate to the regulation of survival pathway PI3k/Akt and anti-apoptosis protein Bcl-2.

Insulin sensitivity and paraoxonase-1 gene polymorphisms independently affect endothelial function in non-diabetic males with essential hypertension

L. Pucci¹, D. Lucchesi¹, G. Dell'Omo², E. Russo¹, G.A. Daniele¹, M. Garofolo¹, R. Miccoli¹, C. Bianchi¹, C. Pedrinelli², G. Penno¹, S. Del Prato¹;

¹Endocrinology and Metabolism, University of Pisa, ²Cardio-Thorax, University of Pisa and Azienda Ospedaliera Pisana, Italy.

Background and aims: Paraoxonase-1 (PON-1), a high-density lipoprotein-bound esterase, exerts a powerful anti-oxidant and anti-inflammatory effect. Variants of PON-1 gene have been shown to impair these properties. In the present study we have tested whether common PON-1 genetic variants may contribute to impaired endothelial function of non-diabetic hypertensive patients independently of haemodynamic and metabolic features.

Patients and methods: The Q192R and L55M variants of PON-1 gene were determined in 95 drug-naïve non-diabetic hypertensive male subjects (age 53 ± 13 years; BMI 26.4 ± 2.9 kg/m²; BP $146\pm15/92\pm10$ mmHg). Endothelial function was assessed by forearm blood flow (FBF) response to intra-brachial acetylcholine (Ach) and sodium nitroprussiate (SNP) infusion. In all subjects 24-hr ambulatory blood pressure was recorded. Finally, lipid profile, hs-CRP and insulin sensitivity (OGTT-based ISI) were determined.

Results: Genotype frequencies for Q192R were 56.8% QQ, 37.9% QR, and 5.3% RR; for L55M were 50.5% LL, 35.8% LM, and 13.7% MM, both consistent with HWE. There were no differences in any of the clinical and biochemical parameters according to alleles distributions for both PON-1 genetic variants. Similarly, there was no difference in basal FBF. The presence of the Q allele was not associated with a significant difference in endothelial response

to Ach or SNP. In contrast the presence of the M allele was associated with impaired FBF response to Ach ($AUC_{Ach-FBF}$ LL: 234 ± 106 ; LM: 187 ± 75 , and MM: 155 ± 58 ml/min*100ml tissue*15min; $p=0.009$). Marginally significant changes in SPN response were also found ($AUC_{SNP-FBF}$ LL: 198 ± 61 , LM: 171 ± 43 , and MM: 177 ± 42 ml/min*100ml tissue*15min; $p=0.057$). On multiple stepwise regression analysis, no parameter (age, BMI, fasting and 2-hr OGTT plasma glucose, HbA1c, hs-CRP, fasting plasma insulin, triglycerides, total-, LDL-, HDL-cholesterol) was associated with $AUC_{Ach-FBF}$, while ISI in a positive manner ($r=0.372$, $p=0.001$) and M allele in a negative one (cumulative $r=0.452$, $p=0.007$) remained independently associated with endothelial function. A weaker, although statistically significant, effect of the M allele was found to predict also $AUC_{SNP-FBF}$ ($p=0.027$), independently of OGTT-glucose- AUC (0.008) and BMI ($p=0.029$).

Conclusions: Insulin resistance and the M allele of the PON-1 L55M polymorphism, but not the Q192R ones are independently associated with impaired endothelial responses to acetylcholine and, to a lesser extent, nitroprussiate. Therefore, the coexistence of these two conditions may represent a worsening effect on the cardiovascular risk of hypertensive subjects.

Methylglyoxal impairs insulin signalling and endothelial function both in vitro and in vivo

C. Nigro^{1,2}, F. Fiory^{1,2}, L. Ulianich^{1,2}, T.H. Fleming³, A. Bierhaus³, P. Formisano^{1,2}, F. Beguinot^{1,2}, C. Miele^{1,2};

¹University of Naples Federico II, ²Icos, CNR, Italy, ³Dep. of Medicine I and Clinical Chemistry, University Hospital Heidelberg, Germany.

Background and aims: It has now become evident that insulin exerts a direct action on vascular cells, thereby conditioning the outcome and progression of vascular complication associated with diabetes. However, the mechanisms through which insulin signaling is impaired in the vascular endothelium remain still unclear. Chronic hyperglycaemia per se promotes insulin resistance and plays a pivotal role in the outcome and progression of diabetes-associated vascular complications. Hyperglycaemia may act through different mechanisms, including generation of advanced glycation end products (AGEs). In this work we evaluated the role of the AGEs precursor methylglyoxal (MG) in the generation of endothelial insulin-resistance in cellular and animal models.

Materials and methods: Time-courses experiments were performed on NIH-3T3 fibroblasts and bovine aortic endothelial cells (BAEC) incubated with different concentrations of MG. The glyoxalase1 inhibitor SpBrBzGSHCp2 was used to increase the endogenous levels of MG. For the in vivo study, C57BL6 mice were intraperitoneally injected with a MG solution at steadily increasing concentrations (50 to 75mg/kg) for 7 weeks.

Results: MG incubation induced a 50% reduction of IRS1 phosphorylation, the loss of IRS1-p85 interaction and of the downstream Akt activation in response to insulin, whilst MAPK was more active in both NIH3T3 and BAEC treated with MG. Furthermore, MG was able to inhibit insulin-induced eNOS activation in BAEC, as shown by the decrease of Ser1177eNOS phosphorylation by 3.5-fold together with the increased phosphorylation at the inhibitory Thr495 site of eNOS by 2-fold, as compared to control cells. This was paralleled by a 60% decrease of insulin-induced NO production in BAEC. Similar results were obtained in BAEC treated with the glyoxalase1 inhibitor SpBrBzGSHCp2 compared to control BAEC. Intraperitoneally administration of MG to mice caused insulin resistance (ITT AUC: C57MG 10163 ± 1979 vs C57 7787 ± 1174 mg/dl/120', $p=0.01$) and reduced serum NO by 2.5-fold compared to untreated mice. Western blots of lysates of aortae from MG-treated mice revealed a reduction of insulin-induced Akt activation.

Conclusion: These results suggest that MG impairs insulin signaling in endothelial cells and insulin effect on endothelial NO production both in vitro and in vivo. Understanding the molecular mechanisms by which hyperglycaemia compromises insulin action in vascular cells may allow to develop new strategies to preserve endothelial function in diabetic subjects.

Cardiometabolic side effects of glucocorticoid treatment in humans: role of impaired microvascular function

D.H. Van Raalte, R.E. Van Genugten, M. Diamant, E.H. Serné;
Diabetes Center, Department of Internal Medicine, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: Glucocorticoid (GC) treatment induces several cardiometabolic side effects including insulin resistance, glucose intolerance and hypertension. The mechanisms underlying these side effects are presently largely unknown. Microvascular dysfunction, characterised by impaired capillary recruitment, affects both flow resistance and perfusion, and may contribute to insulin resistance and hypertension, as was shown in obese and diabetic populations. The objective of this study was to assess the role of microvascular dysfunction in GC-induced cardiometabolic side effects.

Materials and methods: We conducted a double-blind randomised placebo-controlled dose-response trial in which 32 healthy normoglycaemic men (age: 21.0 ± 2.1 years, BMI: 21.9 ± 1.7 kg m⁻²) were treated with either prednisolone (PRED) 30 mg q.d. (PRED30), PRED 7.5 mg q.d. (PRED7.5) or placebo (PLB) for two weeks. At baseline and at day 14 of treatment, a hyperinsulinaemic-euglycaemic clamp at 40 mU m⁻² min⁻¹ was performed to measure insulin sensitivity. On the same days, finger nail fold capillaroscopy was performed to assess baseline capillary density and capillary recruitment following arterial occlusion, both in the fasted state and during hyperinsulinaemia. Moreover, blood pressure was recorded before and during treatment.

Results: PRED treatment dose-dependently decreased insulin sensitivity vs. PLB: mean differences: -2.1 ± 0.8 mg kg⁻¹ min⁻¹ ($P=0.021$) for PRED7.5 and -4.5 ± 0.7 mg kg⁻¹ min⁻¹ ($P<0.001$) for PRED30. Capillary recruitment in the fasted state was not affected by PRED7.5 ($P=0.785$) or PRED30 ($P=0.235$) as compared to PLB. Insulin infusion stimulated capillary recruitment by $13 \pm 5\%$ ($P<0.001$) compared to the fasted state, an effect that was non-significantly reduced by PRED7.5 ($P=0.064$ vs. PLB) and abolished by PRED30 ($P<0.001$ vs. PLB). Systolic blood pressure (SBP) was non-significantly augmented by PRED7.5 (2 ± 1.8 mmHg; $P=0.347$), but increased significantly by 6 ± 1.7 mmHg ($P=0.002$) during PRED30 treatment. The treatment-induced decline in insulin-stimulated capillary recruitment was correlated to both changes in insulin sensitivity ($\beta=-0.763$; $P<0.001$) and SBP ($\beta=0.542$; $P=0.002$).

Conclusion: Microvascular function was dose-dependently impaired in healthy men receiving 14 days of GC-treatment, shown by impaired insulin-induced capillary recruitment. Microvascular dysfunction may be involved in a number of GC-induced cardiometabolic side effects, including insulin resistance and hypertension.

iNOS mediates S-nitrosylation of IR, IRS-1 and Akt and insulin resistance in the skeletal muscle of aging rodents

E.R. Ropelle¹, J.R. Pauli¹, D.E. Cintra¹, A. Sanchez², D. Guadagnini¹, B. Carvalho¹, A. Caricilli¹, L.A. Velloso³, M.J.A. Saad³, J.B. Carvalheira³;
¹FCA, UNICAMP, Campinas, ²USP, Ribeirão Preto, ³UNICAMP, Campinas, Brazil.

Background and aims: It is increasingly recognized that protein S-nitrosylation, the addition of a nitric oxide group to cysteine thiols, serves an important role in a wide range of signaling pathways. Accumulating number of evidences demonstrate that exogenous nitric oxide (NO) and the NO produced by inducible nitric oxide synthase (iNOS) can induce S-nitrosylation of proteins involved in the early steps of insulin signaling pathway inducing insulin resistance. The aim of the present study was to examine iNOS expression, the S-nitrosylation of proteins involved in insulin signaling pathway and insulin sensitivity in young and old rodents.

Materials and methods: Pharmacological (L-NIL; 80 mg/kg body weight), physiological (swimming exercise) and genetic (iNOS-null mice) approaches were combined with euglycaemic-hyperinsulinaemic clamp, Western blot and biotin-switch methods to investigate the insulin sensitivity and signaling in the skeletal muscle of young and old rodents.

Results: We found that aging increased iNOS expression and S-nitrosylation of insulin receptor (IR), insulin receptor substrate-1 (IRS-1) and Akt and reduced the insulin sensitivity in the skeletal muscle when compared to young rodents. However, aging-induced S-nitrosylation and insulin resistance were blunted in muscle of aged iNOS-null mice. Furthermore, the treatment with

pharmacological iNOS activity inhibitor, (L-N⁶-(iminoethyl)-lysine acetate (L-NIL) was able to reduce S-nitrosylation and increased the tyrosine phosphorylation of IR, IRS-1 and serine phosphorylation of Akt and restored insulin sensitivity in muscle of aged rodents. Interestingly, a single bout of exercise reduced iNOS expression and S-nitrosylation of IR, IRS-1 and Akt. In parallel, exercise increased the tyrosine phosphorylation of IR, IRS-1 and serine phosphorylation of Akt and restored insulin sensitivity in the muscle of old animals.

Conclusion: These results suggest that aging-associated S-nitrosylation of IR, IRS-1 and Akt mediated by the iNOS activity may be an important contributing factor to the insulin resistance.

A double-blind, randomised trial to evaluate the effects of 300 mg Aliskiren compared to 5 mg Amlodipine on IR and endothelial dysfunction in hypertensive patients with metabolic syndrome

O.M. Troum¹, O. Pimienta¹, C.-M. Yeh², M.F. Prescott², B. Flannery², H.J. Streefkerk³, W.A. Hsueh⁴;

¹University of Southern California, Santa Monica, USA, ²Novartis Pharm Corp, USA, ³Novartis Pharma AG, Basel, Switzerland, ⁴Weill Cornell Medical College, Houston, USA.

Background and aims: This double blind, randomized, parallel study was designed to evaluate the effects of 300 mg Aliskiren (ALI) and 5 mg Amlodipine (AML) on endothelial function in patients (pts) with metabolic syndrome, to explore effects on insulin sensitivity, and to evaluate effects on peripheral arterial compliance/vascular stiffness.

Materials and methods: Main inclusion criteria: Male/female, 18-65y/o, Metabolic syndrome (ATP III criteria) and BMI < 42, Δ MBF $\leq 35\%$, mean Glucose INFusion (GINF) rate ≤ 6.5 mg/kg/min, Impaired Glucose Tolerance or Impaired Fasting glucose, SBP ≥ 130 mmHg and/or DBP ≥ 80 mmHg. Pts with SBP ≥ 160 mmHg and/or DBP ≥ 110 mmHg and with Diabetes were excluded. Endothelial function was measured by the change in myocardial blood flow (MBF) between rest and CPT, using PET scan, at baseline and End of Study (End). Insulin sensitivity was measured by hyperinsulinemic euglycemic clamp at baseline and End. GINF was determined as the arithmetic mean of the glucose infusion rate during the last 30 minutes of the clamp. For Δ MBF and GINF changes from baseline were analyzed by a 2-sample t-test. For arterial compliance, changes from baseline to End for central systolic/diastolic BP and central mean pressure were measured. Oral glucose tolerance test (OGTT) was performed at baseline and End. Change from baseline in arterial compliance parameters, and time-matched change from baseline in OGTT results were subjected to a linear mixed effects model analysis with treatment, time, treatment by time interaction as fixed effects and subject nested within treatment as a random effect. Time-matched change from baseline at each time point was compared between the 2 treatment groups.

Results: 48 pts (all Caucasian Hispanic) were randomized to either 12 weeks treatment with ALI or AML. Both treatments were well tolerated; no deaths or Serious Adverse Events were reported. Two pts on AML progressed into diabetes mellitus during the study, while all pts on ALI remained within pre-diabetic limits. Aliskiren and AML both improved MBF and GINF; however, between treatment differences were not significant. In contrast, OGTT showed an increase in insulin after ALI treatment, whereas a reduction in insulin was observed after AML treatment. No changes in glucose concentrations were observed. Reductions in central systolic pressure, central diastolic pressure, and central mean pressure were statistically significantly greater with ALI treatment, while peripheral BP did not show a difference between treatments. Reductions in UACR and endothelin-1 with ALI were also statistically significant from baseline.

Conclusion: Both ALI and AML improved endothelial function and insulin sensitivity, with no significant difference observed between treatments. Urinary albumin and endothelin-1, as well as central systolic pressure, central diastolic pressure, and central mean pressure improved significantly after ALI treatment. Two pts on AML but none on ALI pts progressed to overt diabetes. Increased OGTT insulin concentrations with ALI suggest that ALI may improve B-cell function in pre-diabetes. However, as the study was not designed to evaluate B-cell function, this mechanism merits future exploration.

Effects of systemic nitric oxide blockade on insulin secretion and action

A. Natali^{1,2}, S. Baldi¹, A. Tulipani¹, M. Rossi¹, M. Macedo², E. Ferrannini¹;
¹Department of Internal Medicine, University of Pisa, Italy; ²Universidade Novade Lisbon, Chronic Diseases Research Centre, Portugal.

Background and aims: In isolated β -cells, nitric oxide (NO) is synthesised in response to glucose and exerts a negative feedback on insulin release. Preliminary *in vitro* data suggest that NO downregulates insulin-degrading enzyme activity, while peripheral NO release from endothelial cells in man has been suggested to favour insulin action. We designed this study to test whether in humans systemic inhibition of endogenous NO synthesis affects insulin secretion and/or insulin action.

Material and methods: Three groups of non-diabetic subjects (n=5 each) underwent two hyperglycaemic (+7 mmol/L) clamp studies, during which either saline or N-(G)-nitro-L-arginine methylester (L-NAME) were co-infused throughout the clamp at rates of 5, 10, and 20 $\mu\text{g min}^{-1}\text{kg}^{-1}$. First phase (1stP), second phase (2ndP), and arginine-induced (ARG) insulin secretion were evaluated from the areas under the plasma C-peptide (AUC-Cp) and insulin (AUC-Ins) concentration curves. Insulin action was evaluated as mean glucose infusion rate of the last 40 min of the clamp either as the M value or as M normalised by the steady-state plasma insulin concentration (M/I).

Results: While saline had no effect on mean blood pressure or heart rate, L-NAME induced a significant, dose-dependent rise in the former (5 \pm 1, 8 \pm 1, and 20 \pm 2 mmHg, respectively, $p<0.01$ by ANOVA) and a drop in the latter (3 \pm 1, 5 \pm 1, and 12 \pm 2 b/min). When insulin secretion was evaluated as AUC-Cp, L-NAME did not affect any of the 3 responses. In contrast, when evaluated as AUC-Ins, L-NAME infusion resulted in a dose-dependent inhibition (as percent of the corresponding saline response) of 1stP (by 112 \pm 13, 85 \pm 6, and 47 \pm 8%, $p<0.05$), 2ndP (by 86 \pm 13, 79 \pm 13, and 48 \pm 13%, $p<0.05$) and ARG (by 102 \pm 11, 107 \pm 11, 61 \pm 9%, $p<0.05$ only for the highest L-NAME dose). Insulin action was impaired only at the highest L-NAME dose (M=54 \pm 8%, $p<0.01$), but this reduction was in proportion to the lower steady-state insulin levels achieved during L-NAME infusion (M/I= 125 \pm 26%, $p=\text{ns}$).

Conclusion: In man, systemic NO blockade does not affect either insulin secretion or peripheral insulin action but drastically increases plasma insulin removal. Whether the loss of this novel function of NO contributes to glucose intolerance remains to be determined.

Liraglutide induced anorexia is not mediated by brainstem GLP-1 neurons

J. Jelsing¹, N. Vrang¹, K. Raun², L.B. Knudsen²;

¹Gubra, Hoersholm, ²Novo Nordisk A/S, Maaloev, Denmark.

Background and aims: The Glucagon-Like Peptide-1 (GLP-1) analogue liraglutide effectively lowers blood glucose as a treatment for type 2 diabetes. Liraglutide also reduces food intake and body weight in diabetes patients and in non-diabetic obese patients as well as in numerous animal models. Liraglutide is approved for the treatment of type 2 diabetes, and is in clinical development for the treatment of obesity. The native GLP-1 hormone has been shown to lower energy intake through a mechanism of increasing feelings of satiety and reducing feelings of hunger. However, the molecular mechanism for these effects are not fully understood and may have both peripheral and central components. Since GLP-1 is produced in the brainstem solitary tract nucleus it is of special interest to explore if those neurons are involved in mediating the effect of peripherally administered liraglutide.

Materials and methods: We have used the immediate early gene c-Fos to identify key appetite regulatory brain areas activated following liraglutide administration. To be able to fully discriminate between effects of drug (liraglutide, 0.1 mg/kg) and effects of feeding, rats were dosed before lights out in the presence (fed) or absence (unfed) of food. Vehicle groups were also included (veh). The study was terminated by perfusion fixation 4 hours later, brains were removed, cut into frozen sections and immunoreacted for c-Fos.

Results: Irrespective of feeding condition liraglutide increased c-Fos in the area postrema, the nucleus of the solitary tract, the lateral parabrachial nucleus and the central nucleus of amygdala, whereas liraglutide decreased the number of c-Fos positive nuclei in the hypothalamic arcuate nucleus. Given the role of brainstem GLP-1 neurons in appetite regulation we speculated that liraglutide induced anorexia could be mediated by activation of these neurons. Interestingly, double immunofluorescence revealed that liraglutide reduced the fraction of activated brainstem GLP-1 neurons when food was present (veh fed 54 \pm 7; lira fed 33 \pm 4%; $P<0.05$). However, in the absence of food none of the GLP-1 neurons expressed c-Fos (veh unfed 0.2 \pm 0.2; lira unfed 0.6 \pm 0.4%) indicating that brainstem GLP-1 neurons were activated by feeding only. Liraglutide administration reduced food intake and hence led to fewer activated GLP-1 neurons. A corresponding effect was observed in the arcuate pool of CART/POMC neurons with an increased fraction of c-Fos activated neurons in fed untreated animals (veh fed 62 \pm 6%; veh unfed 25 \pm 7; $P<0.05$) which was reduced by liraglutide in the fed condition only (lira fed 36 \pm 4%, $P<0.05$; lira unfed 20 \pm 5).

Conclusion: The data demonstrate that acute administration of liraglutide affects key food regulatory areas in the brainstem but does not lower food intake via the endogenous brain expressed GLP-1 hormone. This indicates that liraglutide gains access to a wide spectrum of GLP-1 receptors in the brain.

587

The effect of liraglutide on gastric emptying and body weight is not mediated by vagal afferents nor the area postrema

N. Vrang¹, J. Jelsing¹, K. Raun², L.B. Knudsen²;

¹Gubra, Hoersholm, ²Novo Nordisk A/S, Maaloev, Denmark.

Background and aims: Glucagon-Like Peptide-1 (GLP-1) analogues are emerging as important drugs for the treatment of diabetes. Apart from their insulinotropic and glucagonostatic effects GLP-1 analogues also inhibit gastric emptying leading to reduced post-prandial glucose levels, and reduce food intake leading to a decreased bodyweight. It is, however, still unclear which GLP-1 receptors that mediate the effects on food intake and body weight. Also, the gastric emptying mechanism lack to be coupled to a specific receptor expression. GLP-1 receptors are located in several central areas known to be directly involved in energy homeostasis. Since both vagal afferents and area postrema neurons express GLP-1 receptors and are accessible to peripherally circulating GLP-1 we speculated that these receptor populations could mediate the gastric inhibitory and/or the body-weight lowering effects of the once-daily GLP-1 analogue liraglutide. We used vagal deafferentation

and area postrema lesion to identify what receptor populations are the target for liraglutide.

Materials and methods: The study involved 2 groups of 32 male SPD rats further subdivided into 4 groups (veh sham, lira sham, veh surgery, lira surgery). The surgery groups underwent either a selective vagal deafferentiation (SDA, severed left afferent rootlets coupled with a subdiaphragmatic ablation of the posterior trunk) or an area postrema lesion (APx). After 10 days of recovery the acute effect of liraglutide (0.1 mg/kg, sc) on gastric emptying was assessed using an acetaminophen release assay. Hereafter, all animals continued into a 14 or 21 days bi-daily dosing study (0.2 mg/kg, sc).

Results: Interestingly, neither vagal deafferentiation or area postrema lesion affected the ability of liraglutide to inhibit gastric emptying measured as the area under the acetaminophen curves. The AUC's under the acetaminophen exposure curve for the deafferentiation part were 10117 ± 273 (veh sham) vs 2691 ± 798 $\mu\text{g/ml} \cdot \text{min}$ (lira sham) and 9579 ± 760 (SDA veh) vs 3587 ± 990 $\mu\text{g/ml} \cdot \text{min}$ (SDA lira). The AUC's for the area postrema lesions were 6422 ± 365 (veh sham) vs 870 ± 284 $\mu\text{g/ml} \cdot \text{min}$ (lira sham) and 8263 ± 295 (APx veh) vs 3269 ± 466 $\mu\text{g/ml} \cdot \text{min}$ (APx lira). Similarly, the chronic dosing study revealed that liraglutide induced weight loss was independent of vagal deafferentiation. Body weight change was: veh sham 112 ± 1.6 vs lira sham 102 ± 1.1 and SDA veh 112 ± 0.9 vs SDA lira 100 ± 1.1 %. That was also the case for the area postrema lesion: veh sham 119 ± 1.6 vs sham lira 111 ± 0.7 % and APx veh 113 ± 1.4 vs APx lira 108 ± 1.1 %. The completeness of the vagal deafferentiation and AP lesions were verified anatomically and for the vagal deafferentiation functionally as well, by showing that CCK induced anorexia was prevented in vagally deafferented rats.

Conclusion: In conclusion, the data shows that neither vagal nor area postrema GLP-1 receptors mediate the gastric or food intake inhibitory effects of liraglutide, and suggest that other, presumably centrally located, GLP-1 receptors are key mediators of liraglutide induced weight loss.

588

Peripheral administration of GLP-1 peptides alters cognition and hippocampal synaptic plasticity in obesity-diabetes

V.A. Gault, D.W. Porter, E. Faivre, C. Holscher, P.R. Flatt;
School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: Studies have shown that high fat feeding in rodents adversely affects cognitive function and hippocampal synaptic plasticity. Interestingly, GLP-1 peptides promote hippocampal progenitor cell proliferation, modulate synaptic plasticity, cross the blood brain barrier and receptors for GLP-1 are expressed in neurons within the hippocampus, neocortex and cerebellum. This study examined effects of peripheral administration of established GLP-1 agonists and antagonists on cognitive function and hippocampal synaptic plasticity in high fat fed mice.

Materials and methods: Swiss TO mice (10–14 per group) maintained on a high fat diet (45% fat, 20% protein and 35% carbohydrate) for 18–20 weeks received twice-daily subcutaneous injections of GLP-1(9–36), exendin(9–39) (each at 25 nmol/kg), Liraglutide (200 $\mu\text{g/kg}$), or saline vehicle (0.9% (w/v) NaCl) over a 28-day period. An additional group of mice ($n=10$) on standard rodent maintenance diet (10% fat, 30% protein, 60% carbohydrate) received twice-daily saline injections. Food intake, bodyweight, non-fasting plasma glucose and insulin concentrations were monitored at 2–3 day intervals. Glucose tolerance (18 mmol/kg; *ip*), general locomotor behaviour, an Object Recognition Task to assess memory and learning and *in vivo* electrophysiological long-term potentiation of hippocampal synaptic transmission were performed at the end of the study.

Results: Mice on high fat diet exhibited increased bodyweight (25%; $P<0.001$), hyperglycaemia (3.6-fold increase; $P<0.001$), hyperinsulinaemia (2.6-fold increase; $P<0.001$) and impaired glucose tolerance (46% increase; $P<0.05$) compared with mice on normal maintenance diet. GLP-1(9–36) and exendin(9–39) did not significantly alter bodyweight, food intake, non-fasting plasma glucose and insulin concentrations or glucose tolerance ($P>0.05$). In contrast, Liraglutide treatment resulted in significant time-dependent reduction in bodyweight (7% reduction), whilst improving plasma insulin (1.5-fold increase; $P<0.05$) and normalizing glucose tolerance (28% glucose reduction; $P<0.05$). GLP-1(9–36), exendin(9–39) and Liraglutide (200 $\mu\text{g/kg}$) did not significantly alter general locomotor activity or anxiety levels. In the Object Recognition Task, mice fed high fat diet exhibited a significant decrease (1.3-fold; $P<0.05$) in recognition index compared to lean controls. While mice treated with GLP-1(9–36) and exendin(9–39) did not affect recognition index, Liraglutide-treated animals displayed a marked increase (1.4-fold; $P<0.05$) in recognition index, indicating improved learning and memory ability. In

analysis of *in vivo* long-term potentiation induced in CA1 region of the hippocampus, long-term potentiation was completely abolished in mice fed high fat diet and there was a tendency for exendin(9–39) therapy to worsen the deleterious effects of high fat feeding on long-term potentiation. Interestingly, daily treatment with Liraglutide ameliorated ($P<0.0001$) the detrimental effects of high fat diet on long-term potentiation.

Conclusion: These data demonstrate that GLP-1 agonists, such as Liraglutide, exert beneficial actions on cognition and synaptic plasticity in mice with high fat diet-induced obesity-diabetes.

589

Early undernutrition leads to hypothalamic insulin resistance in adult rats

E. Lizárraga-Mollinedo¹, E. Fernández-Millán¹, J. De Toro-Martín², C. Martínez-Hondurilla², F. Escrivá^{2,1}, C. Álvarez^{2,1};
¹Ciber de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM),
²Bioquímica y Biología Molecular II, Facultad de Farmacia Universidad Complutense, Madrid, Spain.

Background and aims: It is well known that pathologies such as type II diabetes and cardiovascular diseases are rapidly growing in both western and emergent countries, reaching epidemic proportions. They are strongly linked to obesity. Besides genetic background, several circumstances predispose to obesity, mainly caloric dense foods. Paradoxically, epidemiological studies have shown that exposing to undernutrition during critical periods of growing is also associated with a subsequent increased predisposition to develop obesity and it is known that this precondition of food deprivation is detrimental to some peripheral tissues and its metabolic roles. Previous studies in undernourished animal models have evidenced a rise in the insulin responsiveness in peripheral tissues. Since hypothalamus plays a key role in appetite regulation, it can be considered a prime candidate to be affected by early undernutrition. The aim of this work is to analyze the proteins of hypothalamic insulin pathway and other related proteins in adult rats chronically undernourished from foetal stage.

Materials and methods: Food restriction to Wistar Rats was established from the 14th day of pregnancy following a model previously reported. The animals were anesthetized and they were injected into the third ventricle with 10 mU of insulin in 5 μl saline; only 5 μl saline were administered to basal animals. The rats were killed 15 minutes later, and the hypothalamus was removed and frozen. They were submitted to lysis and next analyzed by the Western blotting method.

Results: The content of the main hypothalamic proteins involved in insulin signalling remained unaltered following undernutrition: IR, IRS1/2, Akt and GSK3. Insulin receptor was phosphorylated largely in undernourished rats than in controls, which can be related with a low PTP1B level in the restricted animals. However, after *icv* insulin, the degrees of GSK3, p70 and ERK phosphorylations did not increase in these rats, in contrast with the controls.

Conclusion: Chronic undernutrition from the foetal stage decreases hypothalamic insulin signalling, which implies a condition of insulin resistance at this level of the central nervous system. The altered hypothalamic insulin pathway could decrease the hormone ability to inhibit feeding in the undernourished population. It is likely that this central adaptation may lead to a higher risk to culminate in obesity whether deprived nutritional environment finished and food became plentiful.

Unimpaired insulin signalling in hippocampus from insulinopenic Zucker Diabetic Fatty rats

F. Reis¹, A. Melo¹, E. Carvalho², C. Fontes-Ribeiro¹, F. Pereira¹;
¹Lab. of Pharmacology and Experimental Therapeutics, Medicine Faculty,
²Center for Neurosciences and Cell Biology, Coimbra University, Portugal.

Background and aims: Type 2 Diabetes Mellitus (T2DM) increases the risk for central nervous system disorders like ischemic stroke, dementia and cognitive deficit. The hippocampus, an important player on learning and memory processes, was recently recognized as presenting a high degree of susceptibility to diabetic complications. Impaired insulin signalling has been implied in the brain pathophysiology under a diabetic setting. The aim of this work is to provide, for the first time, a comprehensive neurotoxic profile as well as

to characterize insulin signalling in hippocampus from Zucker Diabetic Fatty rats (ZDF) rats, a model of T2DM.

Materials and methods: Two groups of male ZDF rats, with 26-weeks-old, were evaluated: Control - ZDF/Gmi +/- (445.70 ± 8.16 g) and Diabetic - ZDF/Gmi fa/fa (363.70 ± 11.80). Metabolic markers including glycemia, insulinemia, glycated haemoglobin and insulin resistance (HOMA-IR) were measured to validate this diabetic model. Functional hippocampal changes were evaluated by analysing the following proteins (western-blot): 1) GFAP - astrogliosis marker; 2) receptor for advanced glycation end products - RAGE; 3) BAX, Bcl-2 - apoptotic markers; 4) syntaxin and SNAP-25 - exocytotic machinery markers and 5) insulin signalization pathway: IRβ; IRS-1; IRS-1 pY⁶¹². $P < 0.05$ was considered as significant (ANOVA and Bonferroni post hoc test).

Results: The diabetic rats showed hyperglycaemia (435.20 ± 15.70 mg/dl; $P < 0.001$), higher levels of glycated haemoglobin (10.96 ± 0.20 %; $P < 0.001$) and insulin resistance index (HOMA-IR: 19.45 ± 0.55; $P < 0.001$) and insulinopenia (0.76 ± 0.15 µg/l; $P < 0.05$) when compared with controls (glycaemia: 140.30 ± 0.92 mg/dl; HbA1c: 3.20 ± 0.14 %; HOMA-IR: 5.73 ± 0.95; insulin: 1.58 ± 0.3 µg/l). Regarding hippocampal markers, no changes in protein expression were found in the diabetic rats when compared with the controls.

Conclusion: This insulinopenic diabetic model shows normal hippocampal insulin signalization pathway as well as lack of hippocampal neurotoxic profile at the studied time-point.

591

Relevance of two distinct mechanisms for the antihyperglycaemic action of efaroxan in mice: antagonism to adrenergic α_2 -receptors versus closing of K_{ATP} -channels

Z. Lehner¹, K. Stadlbauer¹, I. Adorjan², A. Fenzl¹, D. Gruber¹, V.A.M. de Cillia¹, K. Frobel², L. Bauer², I. Rustenbeck³, A. Luger¹, C. Fürsinn¹;

¹Dept.Med.III, Div.Endocrinol.Metab., Medical University of Vienna,

²55pharma Drug Discovery & Development AG, Vienna, Austria, ³Institute of Pharmacology and Toxicology, University of Braunschweig, Germany.

Background and aims: The imidazoline efaroxan seems to exert insulinotropic action via two separate mechanisms. Evidence from isolated islets suggests that only the (+)-enantiomer of efaroxan stimulates insulin release via antagonism at adrenergic α_2 -receptors, while an enantiomer-unspecific mechanism, presumably via closing of K_{ATP} -channels, comes in at higher drug concentrations. The present investigations were to find out, how far each of the two mechanisms holds responsible for antihyperglycaemic effects *in vivo*.

Materials and methods: More than 100 oral glucose tolerance tests (OGTT; 3g/kg) were performed in C57BL mice 45min after oral dosing with racemic efaroxan or with one of its enantiomers (purity > 99.5%). Efaroxan preparations were also compared regarding their effects on hyperglycaemia induced by insulin secretion inhibitors that specifically oppose the mechanisms mentioned above (250mg/kg of the K_{ATP} -channel opener diazoxide, p.o.; or 100µg/kg of the α_2 -receptor agonist UK14,304, i.p.), and regarding their effects on oxygen saturation of hemoglobin in capillary blood from the tail tip (as a surrogate parameter of peripheral vasodilation).

Results: A dose of at least 0.03mg/kg (+)-efaroxan was necessary to reduce the total area under the glucose curve in the OGTT (AUC, % decrease vs. vehicle: 0.01mg/kg, -7±4%, ns; 0.03mg/kg, -11±2%, $p < 0.001$; 0.1mg/kg, -26±2%, $p < 0.001$; 0.3mg/kg, -27±2%, $p < 0.001$; 1mg/kg, -30±2%, $p < 0.001$). Similar results were obtained with racemic efaroxan. A subthreshold dose of the (+)-enantiomer with no effect in the OGTT (0.01mg/kg) was sufficient to counteract hyperglycaemia induced by the α_2 -agonist UK14,304 (AUC, g/l*min: 454±6 vs. 387±19, $p < 0.01$), whereas hyperglycaemia induced by the K_{ATP} -channel opener diazoxide was not affected (516±28 vs. 495±17; ns). This clearly attributes low dose-effects of racemic efaroxan to α_2 -antagonistic properties carried by the (+)-enantiomer. In the OGTTs, (-)-efaroxan exhibited 100-fold lower potency than (+)-efaroxan (AUC, % decrease vs. vehicle: 1mg/kg, -1±4%, ns; 3mg/kg, -9±3%, $p < 0.02$; 10mg/kg, -26±3%, $p < 0.001$). In opposition to (+)-efaroxan, a subthreshold dose of (-)-efaroxan (1mg/kg; no effect in OGTT) counteracted hyperglycaemia induced by diazoxide (AUC, g/l*min: 634±15 vs. 484±21, $p < 0.001$), but not by UK14,304 (434±27 vs. 413±21, ns). This indicates that (-)-efaroxan - at variance to low doses of (+)-efaroxan - acts via a K_{ATP} -dependent mechanism. Oxygen saturation in capillary blood was increased by both the racemate and the α_2 -antagonistic (+)-enantiomer, but not by (-)-efaroxan (% saturation after a dose of 3mg/kg; vehicle, 67±3; racemate, 94±2, $p < 0.001$; (+)-efaroxan, 92±1, $p < 0.001$; (-)-efaroxan, 62±3, ns).

Conclusion: Our results show that efaroxan can reduce blood glucose concentrations in mice via two distinct mechanisms, but glucose lowering via

α_2 -antagonism, as carried by the (+)-enantiomer, occurs at much lower doses than glucose lowering via K_{ATP} -channels. Oxygen saturation of tail blood, which probably reflects vasodilatory activity, was affected only by (+)-efaroxan, hinting at a possible α_2 -related mechanism.

592

Carvedilol restores insulin sensitivity in high-sucrose and high-fat diets rats through blockade of the sympathetic nervous system

M.P. Guarino¹, C. Gonzalez², E.C. Monteiro¹, M.M. Carmo¹, S.V. Conde¹;

¹CEDOC, Faculdade Ciências Médicas, Lisbon, Portugal, ²Departamento de Bioquímica y Biología Molecular y Fisiología, Universidad de Valladolid, Spain.

Background and aims: Previous results from our lab have shown that chronic caffeine prevents insulin resistance induced by high fat (HF) and high sucrose (HSu) diets in rats through a decrease in sympathetic nervous system activity. To test the hypothesis that blockade of adrenergic activation prevents per se the development of diet-induced insulin resistance we administered carvedilol (CVD), an antagonist of β_1 , β_2 and also α_1 adrenoceptors, to HF and HSu rats.

Materials and methods: Six groups of Wistar rats aged 9-12 weeks were used. The control group was administered the vehicle 0.5% methylcellulose in drinking water (MC). The HSu group was administered a 35% sucrose in drinking water during 28 days. The HF group was fed a lipid rich diet during 21 days. In each group the animals were randomly divided into two subgroups: treated with 0.2g/l carvedilol in 0.5% methylcellulose and not treated. The insulin tolerance test (ITT) was used to measure insulin sensitivity. The effect of CVD treatment on mean arterial pressure (MAP), fasting insulinemia, fasting glycemia, weight gain, visceral fat, serum free fatty acids, cortisol, nitric oxide and catecholamines were also determined.

Results: HSu and HF diets induced insulin resistance and hypertension which were prevented by carvedilol treatment. Carvedilol significantly increased K_{ITT} from 3.35 ± 0.19 to 5.20 ± 0.12% glucose/min in the HSu animals and from 3.49 ± 0.23 to 4.64 ± 0.27% glucose/min in the HF rats ($p < 0.01$). Carvedilol significantly decreased fasting glycemia in the HSuMC group from 116.5±4.56 mg/dl to 91.9±2.75 mg/dl ($p < 0.01$) but not in the HFMC animals. Both HFMC and HSuMC diets caused a significant increase in plasma insulin levels in comparison with the MC group and this effect was reversed by CVD administration (MC=2.45±0.26µg/l; HFMC=4.88±0.30µg/l; HSuMC=4.36±0.37µg/l; HFCVD= 2.42±0.42 µg/l; HSuCVD=1.76±0.79µg/l; $p < 0.001$). Carvedilol decreased MAP from 113.5±3.2 to 99.0±5.2 mmHg and from 113.0±4.1 mmHg to 99.4±4.6 mmHg in the HSu and HF models, respectively ($p < 0.01$). The effect of the drug on insulin sensitivity was correlated neither to changes in weight gain, visceral fat mass, serum free fatty acids, cortisol, nitric oxide nor circulating catecholamines.

Conclusion: We concluded that the activation of the sympathetic nervous system is involved in the pathogenesis of diet-induced insulin resistance and high blood pressure in HSu and HF rats and that adrenergic blockade prevents these deleterious effects.

Gastrointestinal-mediated glucose disposal in vagotomised subjects

A. Plamboeck^{1,2}, S. Veedfald^{1,3}, C.F. Deacon², A. Wettergren³, L.B. Svendsen³, S. Meisner⁴, C. Hovendahl⁵, J.J. Holst², E.K. Knop¹, T. Vilsbøll¹;

¹Diabetes Research Division, Department of internal medicine, Gentofte Hospital, University of Copenhagen, Hellerup, ²Department of Biomedical Sciences, The Panum Institute, University of Copenhagen, ³Department of Surgical Gastroenterology and Liver Transplantation, Rigshospitalet, University of Copenhagen, ⁴Department of Surgical Gastroenterology, Bispebjerg Hospital, University of Copenhagen, ⁵Department of Surgical Gastroenterology, Odense University Hospital, University of Odense, Denmark.

Background and aims: After secretion, the incretin hormone glucagon-like peptide-1 (GLP-1) is rapidly degraded by the enzyme dipeptidyl peptidase-4 (DPP-4), resulting in less than 15% of the intact biologically active peptide reaching the systemic circulation. This has led to the hypothesis that GLP-1 acts locally, by activating afferent sensory nerve fibers of the vagus nerve before being degraded. We aimed to evaluate the role of vagal

transmission for the effect of GLP-1 on gastrointestinal-mediated glucose disposal (GIGD).

Materials and methods: Eight truncally vagotomised with pyloroplasty (due to duodenal ulcer) subjects (age: 70 ± 2 years (mean \pm SEM); BMI: 24 ± 1 kg/m²; fasting plasma glucose (FPG): 5.8 ± 0.2 mmol/l), 7 subjects previously treated for oesophageal cancer with resection of the cardia including truncal vagotomy and pyloroplasty (age: 64 ± 2 years; BMI: 23 ± 1 kg/m²; FPG: 5.4 ± 0.1 mmol/l) and 5 healthy control subjects (age: 68 ± 2 years; BMI: 25 ± 1 kg/m²; FPG: 5.4 ± 0.2 mmol/l) were examined on three separate occasions: 4h 50-g OGTT, isoglycaemic iv glucose infusion (IIGI) and an additional OGTT with concomitant DPP-4 inhibition.

Results: Isoglycaemia during IIGIs was obtained using 24 ± 2 g and 28 ± 4 g of glucose in subjects with truncal vagotomy associated with surgery for duodenal ulcer and cardia resection, respectively ($p = \text{NS}$), and 17 ± 2 g in healthy control subjects ($p < 0.05$), resulting in GIGD [$100\% \times (\text{glucose}_{\text{OGTT}} - \text{glucose}_{\text{IIGI}}) / \text{glucose}_{\text{OGTT}}$] of 51 ± 4 and $45 \pm 8\%$ in the two vagotomised groups (NS) and $67 \pm 4\%$ in the healthy control subjects ($p < 0.05$). Peak concentrations of plasma glucose were similar in the two vagotomised groups (13.6 ± 0.9 vs 13.3 ± 0.8 mmol/l, $p = \text{NS}$), and higher than in the control group (9.1 ± 0.5 mmol/l, $p < 0.003$). There was no effect of DPP-4 inhibition on PG in any group.

Conclusion: Vagotomised subjects have impaired glucose homeostasis, which may be due to accelerated gastric emptying. Interestingly, GIGD was diminished in these subjects, suggesting that intact vagal innervation is important for the maintenance of normal glucose homeostasis.

Clinical Trial Registration Number: H-A-2009-060

Supported by: EFSD/Novo Nordisk

Conclusion: PRED treatment dose-dependently impaired pancreatic islet-cell function in healthy men, in addition to reduced whole body insulin sensitivity. GC-induced alterations in sympathovagal balance may contribute to their adverse effects on islet-cell function.

Glucocorticoid-induced islet cell dysfunction: a potential role for altered sympathovagal balance?

R.E. Van Genugten¹, D.H. Van Raalte¹, K.A.A. Kwa¹, J.M. Karemaker², M. Diamant¹;

¹Diabetes Center, Department of Internal Medicine, VU University Medical Center, ²Department of Physiology, Academic Medical Center, University of Amsterdam, Netherlands.

Background and aims: Glucocorticoids (GCs) are frequently used anti-inflammatory agents. Prolonged use, however, may induce insulin resistance, glucose intolerance and might eventually result in diabetes. The effects of GCs on pancreatic islet-cell function and the causal mechanisms remain more controversial. Here, we hypothesized that the GC prednisolone (PRED) impairs islet-cell function and that alterations of autonomous nervous system (ANS) balance may contribute to these changes.

Materials and methods: We conducted a double-blind randomised placebo-controlled dose-response trial in which 32 healthy normoglycaemic males (age: 21.0 ± 2.1 years, BMI: 21.9 ± 1.7 kg m⁻²) were treated with either PRED 30 mg q.d. (PRED30), PRED 7.5 mg q.d. (PRED7.5) or placebo (PLB) for 14 days. At baseline and day 14 of treatment, a combined hyperinsulinaemic-euglycaemic and hyperglycaemic clamp with additional arginine stimulation was performed, to assess whole body insulin sensitivity and beta-cell function. Moreover, fasting glucagon levels were determined as a measure of alpha-cell function. Finally, ANS function was assessed by measurement of heart rate variability and subsequent power spectral analysis. HF_{norm} was calculated as a measure of parasympathetic activity, the ratio between LF_{norm} and HF_{norm} (LF/HF ratio) was taken to represent the sympathovagal balance.

Results: PRED dose-dependently decreased insulin sensitivity as compared to PLB: mean differences: -2.1 ± 0.8 mg kg⁻¹ min⁻¹ ($P = 0.021$) for PRED7.5 and -4.5 ± 0.7 mg kg⁻¹ min⁻¹ ($P < 0.001$) for PRED30. PRED tended to increase the beta-cell function parameters 1st- and 2nd-phase glucose-stimulated C-peptide secretion ($\beta = 305$; $P = 0.098$) and ($\beta = 311$; $P = 0.089$) respectively; this effect was abolished when adjusted for insulin sensitivity. C-peptide secretion following arginine stimulation on top of hyperglycaemia ($\text{ASI-iAUC}_{\text{CP}}$) was reduced both by PRED7.5: -2.7 (-5.2 - 0.3) nmol/l•min, $P = 0.05$ and by PRED30: -3.0 (-7.6 - 0.2) nmol/l•min, $P = 0.02$. Fasting glucagon levels were dose-dependently increased: 2.2 ± 0.9 pmol/l ($P = 0.04$) for PRED7.5 and 4.3 ± 1.2 pmol/l ($P = 0.003$) for PRED30. Concerning ANS function, PRED treatment tended to decrease HF_{norm} ($\beta = -325$; $P = 0.08$). Overall, changes in HF_{norm} associated with fasting plasma glucose levels ($\beta = -0.407$; $P = 0.03$) and inversely correlated with fasting glucagon levels ($\beta = -0.337$; $P = 0.07$). The change in LF/HF ratio was negatively associated with the beta-cell function parameter $\text{ASI-iAUC}_{\text{CP}}$ ($\beta = -365$; $P = 0.05$).

Plasma α -hydroxybutyrate and linoleoyl-glycerolphosphocholine as new markers of insulin resistance and fatty liver disease

A. Gastaldelli¹, A. Natali², W.E. Gall³, C. Lerin⁴, M.E. Patti⁵, J. Petrie⁶, B. Balkau^{7,8}, C.H. Anderwald⁹, M. Laville¹⁰, R. Gabriel¹¹, E. Ferrannini², RISC investigators;

¹Metabolism Unit, CNR Institute of Clinical Physiology, Pisa, Italy, ²Internal Medicine, University of Pisa, Italy, ³Metabolon Inc, Research Triangle Park, USA, ⁴Diabetes and Obesity Laboratory, Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain, ⁵Joslin Diabetes Center and Harvard Medical School, Boston, USA, ⁶University of Glasgow, UK, ⁷INSERM CESP, Villejuif, France, ⁸University Paris Sud, France, ⁹University of Vienna, Austria, ¹⁰Université de Lyon, France, ¹¹Universidad Autónoma de Madrid, Spain.

Background and aims: Recently, we have shown that increased levels of plasma α -hydroxybutyrate (α -HB) and decreased levels of plasma linoleoylglycerophosphocholine (L-GPC) are associated with peripheral insulin resistance (measured by the euglycemic hyperinsulinemic clamp technique). Since both α -HB and L-GPC are produced in the liver, with α -HB levels directly related to the rate of hepatic glutathione synthesis, the goal of this study was to test if α -HB and L-GPC are markers for fatty liver disease.

Materials and methods: In the RISC population (1,222 nondiabetic, normotensive subjects, age 44 ± 8 years (mean \pm SD) [range 30–60], BMI 25.5 ± 4.1 kg/m², [range 16.9–43.9]), we measured circulating α -HB concentrations, liver enzymes (ALT, AST, GGT), and plasma L-GPC levels. Fatty liver accumulation was assessed using the recently validated fatty liver index, FLI. Hepatic insulin resistance (Hep-IR) was estimated in 380 subjects as the product of endogenous glucose production (by ²H₂-glucose infusion) and fasting plasma insulin. To assess L-GPC levels directly in the liver, open liver biopsies were performed in the fasting state during elective cholecystectomy from lean subjects without DM2 (n=8) and during gastric bypass from obese subjects with or without DM2 (n=25).

Results: After adjusting for center, sex, and age by multiple linear regression analysis, α -HB was directly related to FLI (partial $r = 0.21$, $p < 0.0001$), whereas L-GPC was reciprocally related to FLI (partial $r = -0.32$, $p < 0.0001$). Furthermore, a high α -HB and a low L-GPC both contributed to a high FLI value independently of center, sex, and age. In the subgroup with tracer measurements - and after adjustment for center, sex, age, and BMI - L-GPC was also reciprocally related to Hep-IR (partial $r = -0.12$, $p = 0.02$). In support of these findings, we further found that hepatic L-GPC were 5-fold lower in the obese group compared to lean controls.

Conclusion: Raised plasma concentrations of α -HB and L-GPC mark for the presence of fatty liver independently of sex and age. Low L-GPC levels are also specifically associated with Hep-IR. Liver L-GPC levels were also found to be significantly lower in obese and T2D subjects.

Nonalcoholic fatty liver disease markers and insulin resistance in type 1 diabetes

L. Duvnjak¹, T. Bulum¹, B. Kolarić², M. Duvnjak³,

¹Vuk Vrhovac Clinic for Diabetes, Endocrinology and Metabolic Diseases, University Hospital Merkur, Medical School, University of Zagreb, ²Medical School, University of Rijeka, Zagreb County Institute of Public Health,

³Division of Gastroenterology and Hepatology, University Hospital Centre "Sestre milosrdnice", Zagreb, Croatia.

Background and aims: Nonalcoholic fatty liver disease (NAFLD) has been associated with the insulin resistance. The aim of this study was to explore the relationship between markers of NAFLD, including concentrations of aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALK), γ -glutamyltransferase (GGT), ferritin and bilirubin, and insulin resistance in type 1 diabetes.

Materials and methods: Three hundred and 53 patients with type 1 diabetes were included. None showed signs of adrenal, thyroid, renal, liver or cardiovascular diseases and received drugs, apart from insulin, that could attenuate glucose metabolism, insulin sensitivity or liver function. Insulin sensitivity was measured by estimated glucose disposal rate (eGDR) calculated with

the equation: $eGDR = 24.31 - (12.22 \times WHR) - (3.29 \times HT) - (0.57 \times HbA1c)$. The units were $mg \cdot kg^{-1} \cdot min^{-1}$; WHR=waist to hip ratio; HT=hypertension. Lower eGDR levels indicated greater insulin resistance. Correlations and multiple logistic regressions analysis were performed to identify relationships between NAFLD markers and eGDR, individual components of insulin resistance and risk of insulin resistance.

Results: AST, ALT, AST-to-ALT ratio, ALK and ferritin significantly correlated with insulin resistance measured by eGDR ($r = -0.13, -0.14, 0.13, -0.18$, and -0.24 respectively, all $p < 0.05$). Subjects in the upper quartile of the eGDR had significantly reduced levels of AST (median 19 vs 22 U/L, $p = 0.007$), ALT (median 18 vs 23 U/L, $p < 0.001$), ALK (median 61 vs 73 U/L, $p < 0.001$), GGT (median 14 vs 19 U/L, $p < 0.001$) and ferritin (median 31 vs 100 $\mu g/L$, $p < 0.001$), and significantly increased levels of AST-to-ALT ratio (median 1.0 vs 0.88, $p = 0.02$) compared to patients in the lowest quartile. In a multiple logistic regression models adjusted for age, sex, duration of diabetes and BMI, higher AST, ALT and ALK levels was associated with an increased risk for development of insulin resistance (OR=1.03, 1.02, and 1.01 respectively, all $p < 0.05$). The risk of insulin resistance increased by a factor of 1.77 for subjects in the 4th quartile of AST, 2.61 for ALT and 2.68 for ALK, compared to those in the 1st quartile.

Conclusion: We demonstrated that NAFLD markers are associated with insulin resistance measured by clinical parameters (eGDR) in type 1 diabetes. After adjustment for covariates, ALT, AST and ALK were independent predictors of insulin resistance. These findings indicate that an increased level of ALT, AST and ALK could represent an additional marker of insulin resistance in type 1 diabetic patients who might be considered at high risk for the development of hepatic and other manifestations of insulin resistance syndrome.

Hepatocyte SHP-1, a key PTPase in the development of diet-induced insulin resistance

E. Xu¹, A. Charbonneau¹, Y. Rolland¹, B. Neel², N. Beauchemin³, A. Marette¹,

¹Department of Medicine, Faculty of Medicine, Laval University, Québec,

²Division of Stem Cell and Developmental Biology, Ontario Cancer

institute, Toronto, ³Departments of Biochemistry, Medicine and Oncology, Goodman Cancer Research Centre, Montréal, Canada.

Background and aims: We have previously reported that the SH2 domain-containing protein tyrosine phosphatase 1 (SHP-1) is expressed in both liver and skeletal muscle and modulates glucose homeostasis by negatively interfering with insulin signaling. However, the potential role of SHP-1 in obesity-linked insulin resistance and type 2 diabetes (T2D) has not yet been examined. Here we have confirmed that **Materials and methods:** SHP-1 is upregulated in the livers of obese insulin-resistant mice fed a high-fat diet (HFD) for 8 weeks as compared to mice on standard chow (SD). Given that SHP-1 is expressed in several cell types in liver tissue, notably hepatocytes, Kupffer cells, macrophages, and endothelial cells, the precise role of hepatocyte SHP-1 in promoting insulin resistance and T2D was investigated by generating hepatocyte-specific SHP-1 knockout mice (Heshp1KO) using the Cre/LoxP system. Both Heshp1KO and their SHP-1 LoxP-containing littermates (WT) were fed SD or HFD for 8 and 16 weeks before metabolic phenotyping. Even on a SD diet, Heshp1KO mice already exhibited improved glucose tolerance and lower fasting glycemia.

Results: After HFD-feeding for 8wk and 16wk, although the glucose tolerance was comparable in both groups of mice, the Heshp1KO mice were significantly less hyperinsulinemic with consistently lower fasting glycemia when compared to their WT counterparts. Fast-refeeding experiments also showed reduced diet effect on post-prandial levels of glucose, triglyceride, and cholesterol in Heshp1KO mice. These metabolic improvements occurred without any alterations in body weight gain, fat composition, or food intake between Heshp1KO mice and their WT littermates. To specifically assess hepatic versus peripheral insulin sensitivity, we also conducted hyperinsulinemic-euglycemic clamp studies and found that the ability of insulin to suppress liver glucose output was improved in Heshp1KO mice as compared to their WT controls on either diet. However, no significant changes were observed for insulin-dependent peripheral glucose disposal. Consistent with the metabolic data, insulin-mediated Akt S473 and T308 phosphorylation was impaired in both liver and isolated hepatocytes of HFD-fed WT mice, but this defect was prevented in HFD-fed Heshp1KO animals.

Conclusion: These results provide strong evidence that hepatocyte SHP-1 is a major negative regulator of insulin signaling and glucose metabolism, contributing to the development of hepatic insulin resistance in obesity. This research is supported by CIHR.

Activity of hepatic AMP-activated protein kinase in type 2 diabetes mellitus and human nonalcoholic fatty liver disease

S. Döcke, C. von Loeffelholz, A.F.H. Pfeiffer;

Clinical Nutrition, German Institute of Human Nutrition (DIFE) Potsdam-Rehbrücke, Nuthetal, Germany.

Background and aims: The AMP-activated protein kinase (AMPK) represents an ubiquitously expressed molecular fuel sensor that coordinates anabolic and catabolic pathways in response to cellular stress. However, no previous studies have investigated hepatic AMPK protein in humans. The aim of the current study was to evaluate the regulation of AMPK at the mRNA and protein level in the context of nonalcoholic fatty liver disease (NAFLD) and type 2 diabetes mellitus (T2DM). To assess AMPK activity, phosphorylation at Thr172 at the catalytic alpha subunit and activation of AcetylCoA-Carboxylase (ACC) as a direct downstream phosphorylation target were investigated.

Materials and methods: 30 well characterized participants undergoing partial hepatectomy were enrolled into a cross-sectional study, n=11 metabolically healthy subjects and n=19 suffering from a pathologic glucose metabolism (Impaired Fasting Glucose, n=6; Metabolic Syndrome, n=7; T2D, n=6). Liver tissue was sampled intrasurgically under perfused conditions to avoid metabolic artifacts due to hypoxia. Hepatic steatosis and inflammation was determined by histological evaluation and liver fat content was quantified by measuring liver tissue triacylglycerol (TAG). Transcription levels of selected AMPK isoforms were determined by quantitative real time PCR and alphaAMPK protein, Thr172 phosphorylation, ACC1, and ACC activity were analyzed by means of Western immunoblotting.

Results: Patients with pronounced hepatic steatosis revealed significantly higher measured TAG levels ($P=0.004$) and a higher NASH Activity Score (NAS, $P<0.001$) as compared to patients with $<10\%$ liver fat. Estimated insulin sensitivity was negatively associated with the NAS ($r^2=-0.44$; $P=0.027$). No significant effect of pronounced liver steatosis on hepatic transcript levels of selected AMPK subunits was observed ($P>0.05$, respectively). However, liver alphaAMPK protein ($P=0.013$), and phosphorylation at Thr172 ($P=0.027$) was significantly reduced with hepatic steatosis. A significant reduction of alphaAMPK protein levels ($P=0.013$) and Thr172 phosphorylation ($P=0.011$) was further detected in patients suffering from T2D vs. subjects with normal glucose metabolism. No significant differences were found concerning either hepatic ACC1, nor Ser79 phosphorylated ACC ($P>0.05$, respectively).

Conclusion: AMPK activity and protein levels were reduced with hyperglycemia and hepatic steatosis in human liver. According to the results of the current study, AMPK apparently underlies an extensive posttranslational regulation in human liver tissue, while ACC showed no significant differences.

In vivo postprandial lipid handling in liver and muscle of diabetic rats is disturbed

R.A.M. Jonkers¹, L.J.C. van Loon², K. Nicolay¹, J.J. Prompers¹;¹Biomedical NMR, Eindhoven University of Technology, ²Department of Human Movement Sciences, Maastricht University Medical Centre, Netherlands.

Background and aims: Intracellular lipid (ICL) accumulation in liver and muscle is strongly related to the development of insulin resistance and type 2 diabetes (T2D). It is unknown, however, whether excessive lipid accumulation is a consequence of an increased lipid uptake, a decreased lipid utilization, or a more structural imbalance between uptake and utilization. We applied a ^1H - ^{13}C magnetic resonance spectroscopy (MRS) method in combination with the administration of ^{13}C -labeled lipids in a rat model of T2D to study *in vivo* lipid handling in insulin-resistant liver and muscle at different stages in the pathogenesis of T2D.

Materials and methods: Four groups of n=6 male Zucker diabetic fatty rats were used for this study: obese, pre-diabetic fa/fa rats and lean, non-diabetic fa/+ littermates at the age of 6 weeks, and obese, diabetic fa/fa rats and lean, non-diabetic fa/+ littermates at the age of 12 weeks. ^1H - ^{13}C MRS measurements were performed in liver and tibialis anterior muscle at baseline and 4, 24 and 48 h after oral administration of 1.5 g $[\text{U-}^{13}\text{C}]$ Algal lipid mixture per kg body weight. Total and ^{13}C -labeled ICL content were determined from the MR spectra. Statistical analysis was performed using ANOVA for repeated measures (SPSS).

Results: At baseline, total ICL content was higher in fa/fa rats compared with fa/+ rats in both liver (Figure 1A) and muscle (Figure 1B), and at both ages. Total ICL content did not change after the administration of ^{13}C -labeled lipids. Both in pre-diabetic and in diabetic fa/fa rats, hepatic lipid uptake was increased compared with non-diabetic fa/+ rats, whereas the depletion of ^{13}C -labeled lipids in the liver did not seem to be largely affected (Figures 1C and 1D). Likewise, in muscle of diabetic fa/fa rats, lipid uptake was higher than in muscle of fa/+ rats (Figure 1F). In contrast, lipid uptake in muscle of younger, pre-diabetic fa/fa rats was lower than in controls (Figure 1E). In muscle of both pre-diabetic and diabetic fa/fa rats, ^{13}C -labeled lipid depletion appeared to be impaired compared with controls.

Conclusion: In both insulin-resistant liver and muscle of fa/fa rats, postprandial lipid handling was found to be disturbed when compared with controls. In the pre-diabetic state, muscle appeared to be protected from massive lipid uptake, whereas lipid uptake in the liver was largely increased. In contrast, after developing full-blown diabetes, lipid uptake was highly elevated in both liver and muscle.

Resistance exercise improves liver fat and glucose control in people with non-alcoholic fatty liver disease

K. Hallsworth, G. Fattakhova, K.G. Hollingsworth, C. Thoma, S. Moore, C.P. Day, R. Taylor, M.I. Trenell; Newcastle University, UK.

Background and aims: The accumulation of fat in the liver is a direct cause of insulin resistance and is central to the pathogenesis of Type 2 diabetes. Non-alcoholic fatty liver disease (NAFLD) is also associated with an increased risk of cardiovascular disease and advanced liver disease. Lifestyle interventions remain the cornerstone of NAFLD management. However, the evidence underpinning the impact of exercise on liver fat and its mediators is poorly characterized. This is the first study to define the effect of resistance exercise on liver fat and glucose control in adults with fatty liver disease.

Materials and methods: 19 adults with NAFLD were randomised to 8 weeks resistance exercise ($n = 11$) or standard care ($n = 8$). Liver fat, glucose control, lipid oxidation during sub-maximal exercise, and abdominal fat were assessed respectively by ^1H -magnetic resonance spectroscopy, frequently sampled oral glucose tolerance test (fsOGTT), indirect calorimetry and MRI before and after the intervention. The exercise group undertook resistance training 3 times per week.

Results: There was no change in body weight in either group (0.1 ± 0.4 vs. $0.9 \pm 0.7\%$ change, $p > 0.05$). Liver fat was significantly reduced with exercise but not in control (17 ± 3 vs. 15 ± 3 vs. 17 ± 3 to $17 \pm 3\%$ HTGC, $p < 0.05$). Resistance exercise significantly improved fasting glucose (6.0 ± 0.6 to 5.2 ± 0.3 vs. 5.9 ± 0.8 to 6.4 ± 1.0 mmol/L, $p < 0.05$) and glucose area under the curve during the fsOGTT compared with control (-10 ± 3 vs. $11 \pm 6\%$ change, $p < 0.01$). Fat oxidation, shown by a reduced RQ and assessed during 60 minutes sub-maximal exercise, was significantly increased in exercise but not control (RQ 0.93 ± 0.0 to 0.90 ± 0.0 vs. 0.90 ± 0.0 to 0.89 ± 0.0 , $p < 0.05$). There was no change in visceral (3 ± 3 vs. $-4 \pm 4\%$ change, $p > 0.05$) or subcutaneous (-2 ± 2 vs. $2 \pm 2\%$ change, $p > 0.05$) fat in either group.

Conclusion: Resistance exercise offers a time efficient alternative to aerobic exercise and is effective in decreasing liver fat content, increasing fat oxidation and improving glucose control in adults with NAFLD, independent of body weight or abdominal obesity.

Exercise as a treatment strategy for non-alcoholic fatty liver disease: impact on vascular health and hepatic steatosis

C.J.A. Pugh¹, H. Jones¹, V.S. Sprung¹, G.J. Kemp², A. Irwin², V.L. Adams², D.J. Green^{1,3}, N.T. Cable¹, P. Richardson⁴, A.M. Umpleby⁵, D.J. Cuthbertson²; ¹Research Institute for Sport and Exercise Science, Liverpool John Moores University, ²Magnetic Resonance and Image Analysis Research Centre, University of Liverpool, UK, ³School of Sport Science, Exercise & Health, University of Western Australia, Perth, Australia, ⁴Department of Hepatology, Royal Liverpool University Hospital, ⁵Department of Diabetes, Endocrinology and Internal Medicine, King's College London, UK.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is characterised by the accumulation of triglycerides in the liver and is associated with liver-related morbidity and mortality. Nevertheless, the leading cause of death in these patients is cardiovascular disease (CVD). Flow mediated dilation (FMD) provides information regarding endothelial cell health and is an early marker of CVD which is directly linked to the risk of myocardial infarction. The efficacy of exercise training in reducing hepatic fat in NAFLD patients is poorly characterised and its impact on vascular function has not previously been reported. We hypothesised FMD would be impaired in NAFLD and that exercise would reduce hepatic fat and improve FMD.

Materials and methods: Eleven NAFLD patients and ten healthy controls volunteered. Whole body magnetic resonance imaging quantified visceral and subcutaneous fat and ¹H magnetic resonance spectroscopy determined hepatic fat. Brachial artery FMD, cardiorespiratory fitness and fasting glucose, lipids and alanine transaminase (ALT) were assessed in all subjects. All NAFLD patients then underwent a 16-week supervised exercise intervention (moderate intensity, 30–45 min, 3–5 times per week) after which all assessments were repeated. Differences between NAFLD and controls, and the changes with exercise were analysed using t-tests. Data are presented as mean±SE.

Results: NAFLD and controls were matched for age (49±4 vs 46±3 yrs; P=0.50) and BMI (30±1 vs 29±1 kg/m²; P=0.50). Hepatic (22.3±5.1 vs 2.6±0.7%; P=0.003) and abdominal visceral (6.0±0.8 vs 3.3±0.4 l; P=0.006) fat was elevated and FMD was impaired (5.2±0.8 vs 9.1±1.0%; P=0.01) in NAFLD patients when compared to controls. Following the exercise intervention, hepatic fat decreased by 30% (22.3±5.1 vs 15.7±3.6%; P<0.004) and FMD significantly improved (5.2±0.8 vs 8.0±0.6%, P=0.002) in NAFLD patients. This was accompanied by a reduction in abdominal subcutaneous fat (8.0±0.8 vs 7.6±0.8 l; P=0.02) and significant improvements in fitness ALT, BMI, body mass, hip and waist circumference (P<0.003). No changes were evident in lipid profiles, visceral or total subcutaneous fat following exercise.

Conclusion: This is the first study to demonstrate the therapeutic effects of exercise training on hepatic steatosis and vascular health in NAFLD patients. Currently, there is no effective pharmacological treatment to decrease hepatic fat in this group at high risk of CVD. Therefore, these data strongly support the efficacy of exercise training as a leading preventive strategy in NAFLD.

Habitual physical activity is associated with physical fitness but not with glycaemic control in people with type 1 diabetes

J.J. Valletta^{1,2}, A.J. Chipperfield², G.F. Clough¹, C.D. Byrne¹;

¹School of Medicine, ²School of Engineering Sciences, University of Southampton, UK.

Background and aims: Regular daily physical activity is encouraged by clinicians as part of the patient's diabetes management. It is however unclear if physical activity protects the individual from diabetes-related complications. Increased levels of physical fitness reduce the risks of macrovascular disease and improve microvascular function, while better glycaemic control reduces the risk of microvascular dysfunction. In our study, we examine the association between habitual physical activity, physical fitness and glycaemic control in a free-living cohort of people with type 1 diabetes.

Materials and methods: 23 adults (12 female) with type 1 diabetes have been studied (age=37±11y, BMI=26.5±5kg.m⁻², diabetes duration=16±11y, HbA_{1c}=7.7±1.3%, mean±SD) in an open, non-randomised, uncontrolled trial. Habitual physical activity was monitored by a SenseWear Pro2 armband (BodyMedia, USA), while glycaemic control was assessed by the Guardian Real-Time Continuous Glucose Monitoring System (CGMS) (Medtronic, USA) for up to 12 days (8±3 days), to obtain a 'snapshot' of the individual's daily lifestyle. The participants were free to partake in any activity, and decide on any therapeutic decision which affected their blood glucose. Physical fitness was quantified by the BMI, percentage body fat measured by DEXA scan, muscle strength measured by hand dynamometer and maximal oxygen consumption (VO_{2max}) attained while exercising on a treadmill under the Bruce protocol. Resting muscle blood flow (Q_r) was also measured by venous occlusion plethysmography on the leg. Pearson correlation coefficients are quoted.

Results: There was an association between the average daily total energy expenditure (TEE) and BMI (r=-0.63, p=0.001), percentage body fat (r=-0.67, p=0.0004), muscle strength (r=0.41, p=0.05) and VO_{2max} (r=0.66, p=0.0009; adjusted for age). The percentage average daily time spent performing moderate intensity activities, defined here to be between 3 to 6 METs was correlated with BMI (r=-0.49, p=0.02), percentage body fat (r=-0.60, p=0.002) and VO_{2max} (r=0.63, p=0.002; adjusted for age). No association was found between TEE and daily mean blood glucose (r=-0.20, p=0.36) or daily glycaemic variability quantified by: a) the blood glucose standard deviation (r=0.07, p=0.76) and b) the coefficient of variation (standard deviation normalised by the mean) (r=0.23, p=0.28). There was also no association between TEE and resting Q_r (r=0.11, p=0.64).

Conclusion: Using an objective quantitative measure to assess daily energy expenditure in free living subjects with type 1 diabetes, we have shown that increased levels of habitual physical activity are associated with better cardio-respiratory fitness. Surprisingly, no association was shown between habitual physical activity and a measure of continuous glycaemic control. This finding may be attributable to individuals' extra carbohydrate ingestion to avoid physical activity-induced hypoglycaemia causing hyperglycaemia. We speculate that although increased levels of physical activity energy expenditure confer protection against macrovascular disease, our data suggest that increased levels of physical activity energy expenditure may have little impact on risk of microvascular disease because habitual physical activity had little effect on glycaemia in people with type 1 diabetes.

Influence of exercise on phenotypic characteristics and metabolomic response in patients with type 1 diabetes

L. Brugnara¹, S. Murillo¹, M. Balfegó², M. Vinaixa³, S. Sarmino³, M.A. Rodríguez³, X. Correig³, A. Novials²;

¹CIBERDEM - Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, Barcelona, ²IDIBAPS, Hospital Clinic de Barcelona, ³Metabolomics Platform / Universitat Rovira i Virgili- IISPV-, Tarragona, Spain.

Background and aims: Regular exercise in people with type 1 diabetes (T1D) does not necessarily lead to improved control. Indeed, the metabolic distur-

bances associated with sustained exercise may lead to worsening control unless great care is taken to adjust carbohydrate intake and insulin dosage. Metabolomic is becoming widely spread used as a new and powerful tool for discerning significant changes at metabolic level. In this study we wanted to identify: 1) the effects of regular exercise practice on phenotypic characteristics, and 2) the impact of acute exercise on the serum metabolome of patients with T1D compared to controls.

Material and methods: A total of 45 type 1 diabetic patients without chronic complications and 45 controls were included. From each group individuals were classified as non competitive athletes (≥ 3 sessions of exercise per week) or sedentary. We obtained data of fitness levels (maximal test on a cycle-ergometer), body composition (DEXA), glycemic control and dietary intake. Further, 10 male with T1D (35.1 ± 2.7 years old) and 11 controls (32.7 ± 2.8 years old) with similar cardio-respiratory capacity ($VO_{2\max}$ 33.4 ± 7.1 mL $\text{kg}^{-1} \cdot \text{min}^{-1}$ vs. 33.9 ± 9.1 , respect.) were selected to perform an acute test of exercise (30 min of cycle-ergometer at 80% of $VO_{2\max}$). Fasting serum samples were withdrawn prior and at the end of the exercise and were analysed using two different platforms: ^1H NMR and gas chromatography- mass spectrometry.

Results: In the table below are summarized the phenotypic characteristics of the total population. Athletes (T1D and controls) showed better fitness capacity and lower total and abdominal fat, comparing to sedentary groups. In type 1 diabetes group, athletes elicit a tendency to better HbA1c (7.3 ± 1.2 vs. 7.7 ± 1.3) higher total energy intake (2096 ± 434 vs. 1832 ± 466 kcal/day) and a significant increase in carbohydrate consume (200 ± 52 vs. 161 ± 56 g/day, $p=0.02$) in comparison to sedentary counterparts. In the acute exercise test, T1D presented elevated levels of insulinemia before (18.6 ± 14.6 UI/L) and after 30 min (25.1 ± 21.5). In the untargeted metabolomic analysis we identified significant increments of indicators of tricarboxylic acid cycle (malate, fumarate, succinate, citrate, α -ketoglutarate), lypolysis (glycerol) and fatty acid oxidation (oleic acid, palmitoleic acid, linoleic acid) in both groups, greater in control than in diabetes.

Conclusions: Subjects with T1D and controls presented similar metabolic characteristics, and the blunted response to exercise in T1D group is probably consequence of hiperinsulinemia due to insulin treatment.

Increased skeletal muscle mitochondrial respiration in patients with type 2 diabetes following dietary and exercise interventions

A. Pazderska¹, K. Wanic¹, D. O'Hanlon¹, D. Cooper², N. Collura¹, K.J. Clarke³, D.J. O'Gorman⁴, R.K. Porter³, A. Zorzano^{5,6}, J.J. Nolan¹;

¹Metabolic Research Unit, St James's Hospital, Trinity College Dublin,

²School of Health and Human Performance, Dublin City University, ³School of Biochemistry and Immunology, Trinity College Dublin, ⁴School of Health and Human Performance, Dublin City University, Ireland, ⁵Institute for Research in Biomedicine, Barcelona, ⁶Departament de Bioquímica i Biologia Molecular, Facultat de Biologia, Universitat de Barcelona, Spain.

Background and aims: Type 2 diabetes is characterized by insulin resistance, associated with mitochondrial dysfunction in skeletal muscle. Diet-induced weight loss and aerobic exercise intervention lead to improvements in insulin sensitivity. We compared mitochondrial respiration in muscle biopsies from sedentary patients with type 2 diabetes following either diet or exercise intervention.

Materials and methods: 12 patients with type 2 diabetes (mean age 44.4 ± 3.15 years; BMI 36.4 ± 1.8 kg/m²; weight 108.1 ± 6.6 kg) participated in either intervention, four of whom completed both. Both diet and exercise were designed to cause a 2,500 calorie deficit per week. High resolution respirometry was used to measure oxygen flux capacity in isolated mitochondria from vastus lateralis muscle biopsies taken pre and post interventions. Results represent mean \pm SEM. Non-parametric tests were used for statistical analysis.

Results: Aerobic training significantly increased maximal oxygen consumption (2.6 vs. 3.0 L/min; $p=0.008$) and reduced fat mass (44.9 vs. 42.6 kilograms; $p=0.011$). Aerobic training resulted in increased mitochondrial state 3 respiration (749.1 vs. 1408.5 pmol O₂/mg protein; $p=0.036$) and maximal uncoupled respiration (818.4 vs. 1531.5 pmol O₂/mg protein; $p=0.036$). Following the dietary intervention, subjects lost weight (111.8 vs. 106.8 kg; $p=0.028$) and fat mass (50.0 vs. 46.8 kg; $p=0.046$), while $VO_{2\max}$ was unchanged (2.26 vs. 2.34 L/min; $p=0.39$). Dietary intervention resulted in increased mitochondrial state 3 respiration (642.2 vs. 1085.9 pmol O₂/mg protein; $p=0.018$) and maximal uncoupled respiration (803.1 vs. 1172.7 pmol O₂/mg protein; $p=0.028$). Insulin sensitivity measured by OGIS was 303.0 and 352.7 pre and post exercise, 290 and 318 pre and post diet, not reaching statistical significance in either group.

Conclusion: Skeletal muscle mitochondrial respiration is substantially improved in obese sedentary patients with type 2 diabetes by both diet and aerobic exercise, and to a greater extent with exercise.

Resistance alone or combined resistance plus aerobic exercise training increases IRS-1 expression in muscle of type 2 diabetic subjects

M.M.P. Jorge¹, V.N. Oliveira¹, A.L.D. Diniz¹, E.R. Ropelle², J.B. Carnevalheira², F.S. Espindola¹, P.T. Jorge¹, B. Geloneze²;

¹Internal Medicine, Federal University of Uberlandia, Minas Gerais, Uberlandia, ²Internal Medicine, State University of Campinas, São Paulo, Brazil.

Background and aims: Exercise training is known to improve insulin sensitivity and recent research has reported that combined exercise can be the most effective modality. The purpose of this study was to compare the effects of different exercise training on IRS-1, GLUT-4, JNK2, NFkB tissue expression and IKK fosforilation on skeletal muscle of type 2 subjects.

Materials and methods: Forty eight type 2 diabetics were randomly assigned to three groups of training (3 times/week, 60 min/session) designated as aerobic group (n=12), resistance group (n=12), combined group (n=12) and a control group (n=12). Inclusion criteria was being type 2 diabetes according ADA diagnostic criteria, age between 30 and 70 years old and BMI ranging from 25 and 40 kg/m². Exclusion criteria include current insulin therapy, conditions that could preclude physical activity and corticosteroid use. Muscle microbiopsies were performed before and after training (between 60 and 96 hours after the last bout of exerciser) to quantify IRS -1, GLUT-4, JNK2, NFkB expression and IKK fosforilation on skeletal muscle.

Results: After training GLUT-4, JNK2, NFkB expression and IKK fosforilation did not change but IRS-1 expression increased by 65% in the resistance ($p < 0.05$) and by 89,7% in the combined group ($p < 0.01$). We used the analysis of variance (Two-way ANOVA) to assess significant differences between the groups and bonferroni post-tests to compare the mean before and after the training.

Conclusion: The increased IRS-1 expression on skeletal muscle of type 2 diabetes persists longer than sixty hours after training on the resistance and combined group despite a normal GLUT-4 muscle expression. The inhibitory effect of exercise on inflammatory pathways like JNK2, NFkB expression and IKK fosforilation was not seen 60 to 96 hours after the last bout of exercise. This persistent effect of resistance and combined exercise training on IRS-1 expression could be responsible for the best effect related on improvements of insulin signaling transduction in these modalities of exercise.

High altitude trekking preceded by training improves glycaemic control and insulin sensitivity in patients with type 2 diabetes mellitusP. de Mol¹, M.J. Fokkert², S.T. de Vries³, E.J.P. de Koning⁴, B.D. Dikkeschei², R.O.B. Gans⁵, C.J. Tack¹, H.J.G. Bilo⁶;¹Internal Medicine, 463, Radboud University Nijmegen Medical Centre,²Clinical Chemistry, Isala Clinics, Zwolle, ³Cardiology, Tjonderschans Hospital, Heerenveen, ⁴Endocrinology and Nephrology, Leiden University Medical Centre, ⁵Internal Medicine, University Medical Centre Groningen,⁶Internal Medicine, Isala Clinics, Zwolle, Netherlands.

Background and aims: Little is known regarding the effects of high altitude trekking in type 2 diabetes mellitus. We investigated the effects of high altitude trekking preceded by exercise training on glycemic control, plasma lipids and insulin sensitivity in patients with type 2 diabetes mellitus.

Materials and methods: Thirteen individuals with complication-free type 2 diabetes mellitus took part in a 13 day expedition to the summit of Mount Toubkal (4167m), Morocco, after six months exercise training. Following baseline maximal exertion ergometer testing, participants received an individualized training advice. During the exercise training and at high altitude, energy expenditure, body weight, fasting glucose, HbA_{1c}, plasma lipids and insulin sensitivity (HOMA-IR) were determined. Additionally, continuous glucose monitoring and acute mountain sickness scores (AMS) were measured at altitude.

Results: Exercise training reduced body weight (-3.5 ± 4.2 kg; $p=0.006$), triglycerides (-0.9 ± 0.8 mmol/L; $p=0.025$), fasting glucose (-0.9 ± 0.9 mmol/L; $p=0.026$) and hypoglycemic medication and increased exercise capacity ($+0.3 \pm 0.3$ W/kg; $p=0.0047$). These changes persisted at the end of the high altitude trekking part. All participants reached the summit at 4167 m. At 3200m altitude, insulin sensitivity was improved compared to values prior to the start of exercise training (3.35 ± 1.85 vs. 1.92 ± 0.85 ; $p=0.011$). Additionally, total cholesterol (-1.2 ± 1.4 mmol/L; $p=0.014$) and LDL-cholesterol (-0.5 ± 0.9 mmol/L; $p=0.012$) were reduced compared to values prior to the start of exercise training. Frequency and duration of hyper- or hypoglycemic episodes (CGMS) remained unchanged at high altitude compared to sea level. At altitude, fasting glucose decreased ($p=0.043$), acute mountain sickness scores remained low and energy expenditure increased ($p<0.01$). (Fig.1).

Conclusion: High altitude trekking preceded by 6 months exercise training can be achieved and improves plasma lipids, insulin sensitivity and glycemic control in patients with complication-free type 2 diabetes.

Figure 1: Daily energy expenditure (upper panel), fasting glucose (n=10) (middle panel) and acute mountain sickness score during the 13-day expedition. Altitude presented refers to the highest altitude reached that specific day. (shaded area, right Y-axis) Data are presented as mean \pm SD. Note: Day 0 refers to baseline measurements after completion of the preparation period at sea level. Day 1, 10 and 13 represent resting days.

Exercise training in patients with type 2 diabetes mellitus induces tissue specific changes in (ectopic) fat contentJ.T. Jonker¹, P. de Mol², S.T. de Vries³, R.L. Widya⁴, H.E. Kan⁴, S. Hammer⁴, R.O.B. Gans⁵, L.D. Dikkeschei³, A. Webb⁴, E.J.P. de Koning⁶, H.J.G. Bilo³, H.J. Lamb⁴;¹Endocrinology and Metabolism, Leiden University Medical Center,²UMCN, Nijmegen, ³Isala Clinics, Zwolle, ⁴Radiology, Leiden UniversityMedical Center, ⁵UMCG, Groningen, ⁶Nephrology, Leiden University

Medical Center, Netherlands.

Background and aims: Ectopic fat accumulation in type 2 diabetes is associated with insulin resistance, lipid abnormalities and increased risk for cardiovascular disease. Lifestyle changes are a pillar of therapy. Although changes

in diet have beneficial effects on ectopic fat accumulation, this is less clear for effects of exercise training. Therefore, the purpose of the present study was to assess the effects of a 7-months exercise program on (ectopic) fat accumulation in heart, liver, abdomen, and skeletal muscle.

Materials and methods: We included 12 patients with type 2 diabetes mellitus (mean \pm SEM: age 46 ± 2 years; BMI 28.7 ± 1.2 kg/m²). The training program consisted of 7-months individualized training and ended with climbing the Toubkal mountain (the highest peak in the Atlas Mountains). Before training and again after climbing the mountain, patients were studied. Abdominal fat volume was measured using magnetic resonance (MR) imaging. Myocardial, hepatic and myocellular triglyceride (TG) content were measured using proton MR spectroscopy.

Results: A 7-months exercise program in patients with type 2 diabetes mellitus significantly reduced visceral abdominal fat volume from 348 ± 57 ml (mean \pm SEM) to 219 ± 33 ml ($P<0.01$). Hepatic triglyceride content decreased from $6.8\pm2.3\%$ (mean \pm SEM) to $4.6\pm1.6\%$ ($P<0.01$). Exercise did not change myocardial TG content ($0.61\pm0.13\%$ to $0.60\pm0.13\%$, $P>0.05$). Skeletal muscle intramyocellular lipids/ creatine ratio did not significantly change (3.17 ± 0.67 (mean \pm SEM) at baseline; 4.11 ± 0.76 ($p>0.05$) at follow up).

Conclusion: A 7-month exercise intervention in patients with type 2 diabetes mellitus decreases visceral abdominal fat volume and hepatic TG content. Myocardial and myocellular lipid content remained unchanged. Therefore, exercise intervention in patients with type 2 diabetes mellitus induces tissue-specific changes in ectopic fat distribution.

Association between physical activity estimated by the international physical activity questionnaire and UKPDS cardiovascular risk score in type 2 diabetes

L. Laviola, S. Di Leo, F. Procino, A. Cignarelli, M. Barbaro, G. Stefanelli, G. Garruti, F. Logoluso, R. Giorgino, F. Giorgino;

University of Bari, Italy.

Background and aims: Physical activity (PA) is the most effective strategy for the prevention of type 2 diabetes mellitus and an indispensable tool for the treatment of diabetes-associated metabolic abnormalities. However, quantitative analysis of PA in patients with type 2 diabetes is not simple and standardized, and limited data are available on the association between PA and cardiovascular risk in type 2 diabetes. The objective of this study was to correlate the daily energy expenditure from PA, estimated by the International Physical Activity Questionnaire (IPAQ), and the risk of developing cardiovascular disease, calculated by the UKPDS risk engine, in subjects with type 2 diabetes.

Materials and methods: PA-associated energy expenditure, expressed in Metabolic Equivalents (METs), was estimated in 576 type 2 diabetic patients

(324 male, 252 female; mean age, 63 years; body mass index, 29.5 ± 5.5 kg/m²; HbA1c, 7.03 ± 1.2), using the IPAQ. The questionnaire was firstly self-compiled and then revised by an interviewer with the patient. Metabolic and clinical data were obtained from each patient and UKPDS risk score was calculated.

Results: Mean energy expenditure was found to be high in 3.3% (≥ 3000 METs-min/week), moderate in 40.8% (600–3000 METs-min/week), and low in 55.9% of the population (≤ 600 METs-min/week), respectively, according to the IPAQ Guidelines for Data Processing and Analyses. When the population was divided into quartiles of METs, calculated risk for total coronary heart disease (CHD) was found to be 20.72% in the 1st quartile vs. 16.27 in the 4th quartile ($p = 0.051$), fatal CHD risk 15.84% vs. 11.50% ($p < 0.05$), and stroke risk 15.45% vs. 10.47% ($p < 0.05$), respectively.

Conclusion: Evaluation of physical activity with a structured questionnaire correlates with the estimated cardiovascular risk and may contribute to the phenotypic profiling of type 2 diabetic patients.

609

Association between physical activity level and diabetic complications among Bangladeshi type 2 diabetic subjects

K.R. Ahmed¹, M.S. Bukht², S.H. Habib³,

¹Dept of Health Education and Health Promotion & International Health, Bangladesh Institute of Health Sciences & University of Oslo, ²Dept of Health Education and Health Promotion, Bangladesh Institute of Health Sciences, ³Health Economic Unit, Bangladesh Diabetic Society, Dhaka, Bangladesh.

Background and aims: Physical activity exerts numerous beneficial health effects, and the evidence favoring a physically active lifestyle in the treatment of chronic diseases is substantial. Physical activity is a cornerstone of type 2 diabetes management, but is often underutilized. Regular physical activity may prevent diabetic complications through beneficial effects on glycemic control, insulin sensitivity, blood pressure, lipid profile, and endothelial function. However, physical activity could also cause adverse effects or patients may not be able to exercise due to complications. No such study has so far been done about the relationship between physical activity and diabetic complications in a Bangladeshi population. The aim of the study was to assess the association of physical activity with the presence of diabetes related complications among Bangladeshi type 2 diabetic subjects.

Materials and methods: The cross-sectional study was conducted in the OPD of BIRDEM, a tertiary diabetic care hospital. A group of 977 subjects were randomly selected and followed up. A structured questionnaire was administered to collect socio-demographic information. Diabetes was diagnosed following the WHO study group criteria. The level of physical activity was categorized into light and moderate. The WHO recommended Asian criteria was used to identify general obesity as healthy weight (BMI 18.5–22.99 kg/m²), overweight (23.0–24.99 kg/m²) and obese (25.0 and above kg/m²). Retinopathy was detected by fundal photography, CKD by serum creatinine and hypertension was diagnosed clinically. Univariate and multivariate generalized linear models were used to assess the associations of physical activity with diabetes related complications.

Results: Out of the 977 subjects investigated, 468 were male and 509 were female (mean \pm SD, age 56 ± 8 years). In the study subjects 74% were engaged in light physical activity and of them 65% subjects were obese. On the other hand 26% were involved in moderate activity and of them 61% subjects were obese. Among the male 387 (82.7%) were engaged in light work and 81 (17.3%) were involved in moderate work. On the other hand 336 (66%) and 173 (34%) female were involved in light and moderate works respectively. On Univariate analysis, light physical activity level showed significant association with all the three diabetes related complications ($p < 0.001$). And in the middle age group (46–60 yrs), the risk of developing hypertension was 2 times higher in light compared to moderate activity group. For CKD the corresponding risk is 3 times higher. Multivariate analysis showed low level of physical activity was strongly associated with complications like retinopathy [$p = 0.00$, (95% CI, 0.02–0.08)] & hypertension [$p = 0.01$, (95% CI, 0.34–0.86)] in the females. Low level of physical activity was also found to be strongly associated with retinopathy [$p < 0.001$, (95% CI, 0.01–0.11)] in the male group.

Conclusion: A large number of urban of Bangladeshi population are involved only light physical activity which is leading to obesity and it seems to have a strong association with diabetes related complications in this population.

Strength training and insulin sensitivity in patients with end-stage renal disease undergoing dialysis

S. Molsted^{1,2}, I. Eidemark³, J.L. Andersen⁴, A.P. Harrison¹;

¹LIFE, Frederiksberg C, ²Hillerød Hospital, ³Rigshospitalet, ⁴Bispebjerg Hospital, Copenhagen, Denmark.

Background and aims: Insulin resistance is common in patients undergoing dialysis and has associations with protein degradation and cardiovascular disease. The clinical implications are a loss of muscle protein as well as an increased morbidity and mortality. The aims of the present study were to investigate the effects of high-load strength training on insulin sensitivity in such patients, and to measure any benefits of protein supplementation.

Materials and methods: 23 patients (aged 52 ± 3 ; mean \pm SE: 10/13 male/female; BMI 23.9 ± 0.9 kg/m²) on hemodialysis ($n = 19$) or peritoneal dialysis ($n = 4$) were recruited to a control period of 16 weeks before participating in 16 weeks of strength training. The training consisted of 5 minutes of warm-up and up to 5 sets of three obligatory exercises three times a week: leg press, leg extension and leg curl. The period of rest between each set was of 60–90 seconds in duration. During the intervention period the load was increased, and the repetition maximum decreased from 15 to 6. The progression in training was adjusted according to changes in strength during the intervention period. The patients received an isocaloric drink immediately after each training session, which was randomly assigned to provide either a protein or non-protein source. Insulin sensitivity was tested using the 2-hour OGTT after an over-night fast. Plasma glucose and insulin were tested at -30 min; -15 min; 0 min; 30 min; 60 min; 90 min; and 120 min.

Results: At baseline the glucose tolerance was normal for 9 patients, impaired in 11 patients, and 3 patients had type 2 diabetes. Body weight was unchanged during the control period and increased significantly after the intervention (from 72.8 ± 3.7 to 73.9 ± 3.8 kg, $p = 0.05$; Wilcoxon Test). Fasting, and 2-hour blood glucose measurements remained unchanged during the control and the training periods (during training, fasting from 5.3 ± 0.1 to 5.5 ± 0.2 mmol/l, and 2-hour from 8.9 ± 0.6 to 8.5 ± 0.7 mmol/l). Likewise, insulin values remained unchanged during the control period, but were significantly decreased after training (fasting from 65 ± 8 to 53 ± 7 pmol/l, $p = 0.01$, and 2-hour from 423 ± 70 to 326 ± 52 pmol/l, $p < 0.05$). The effects on fasting insulin were found to be associated with baseline fasting insulin values ($r = 0.654$, $p = 0.001$). In parallel with the decrease of insulin, significant improvements were seen in muscle power (33 \pm 5% increase, $p < 0.001$) and in muscle strength, physical function, and quality of life (data not shown). Finally, an initial unadjusted analysis did not reveal any benefits of combining the training period with supplementing protein intake.

Conclusion: This simple high-load strength training program was found to be associated with a significant improvement in insulin sensitivity in patients undergoing dialysis. The most relevant exercise method in the treatment of insulin resistance has been considered to be aerobic training. However, the findings of the present study would suggest that strength training is also a very relevant method.

Impact of body weight on exercise capacity and changes in metabolic parameters during spiroergometry in children and adolescents

I.V. Wagner¹, K. Dittich¹, W. Kiess¹, S. Erbs², A. Körner¹;

¹University Hospital for Children and Adolescents, ²Heart Center, Leipzig, Germany.

Background and aims: Physical fitness is supposed to be reduced in obese children, most likely due to reduced physical activity. Regular exercise is known to improve metabolic parameters such as insulin resistance. Therefore the aim of our study was to compare exercise capacity and acute exercise-related changes in metabolic parameters between lean and obese children.

Materials and methods: We evaluated 65 children (34 girls, 31 boys) aged 14.5 ± 2.9 years stratified into lean (BMI SDS 0.16 ± 0.55 , $n = 33$) and obese (BMI SDS 2.54 ± 0.54 , $n = 32$) by spiroergometry. Children were asked to cycle to maximum exhaustion applying a two minute step programme of 0.5W/body weight adapted to the 50th centile of height. Exercise parameters were standardized to age and sex references and are given in %. Blood samples were drawn at baseline and after the test.

Results: Physical performance, assessed by the highest intensity in Watt achieved, was significantly better in lean compared to obese children

(118.6 ± 5.18 % vs. 81.03 ± 3.62 %; $p < 0.0001$). Similarly, maximum oxygen uptake ($\text{VO}_{2\text{max}}$), which is independent of training condition and motivation, was significantly reduced in obese children (81.27 ± 3.23 vs. 114.67 ± 4.27 %; $p < 0.0001$). At maximum effort, the respiratory quotient (RQ) was 1.105 ± 0.01 in the lean compared to 1.045 ± 0.01 in the obese children, hence indicating that obese children stopped cycling before the maximum physical capacity was reached ($p < 0.0001$). This observation was confirmed by the increase in lactate levels that were almost doubled in the lean compared to the obese group (5.74 ± 0.54 vs. 2.89 ± 0.46 ; $p < 0.0001$). The anaerobic threshold (AT) is indicating how quickly the metabolism switches to an anaerobic state. After the AT was reached the obese group terminated cycling earlier (3.53 ± 0.39 vs. 5.82 ± 0.57 ; $p = 0.0025$). Basal glucose (5.41 ± 0.19 vs. 4.52 ± 0.20 ; $p = 0.0025$) and insulin levels (463.20 ± 105.1 vs. 181.61 ± 33.63 ; $p = 0.010$) were significantly higher in the obese subjects. During exercise, insulin ($p = 0.0003$) and glucose ($p = 0.05$) levels were reduced to a greater extent in obese individuals (insulin -146.58 ± 74.75 ; glucose -0.22 ± 0.16) compared to -29.82 ± 31.22 (insulin) and 0.30 ± 0.21 (glucose) in the lean group. The levels of free fatty acids and triglycerides showed a slight increase in the lean subjects and a reduction in the obese cohort after exercise (not significant). Finally, blood pressure and heart rate returned more rapidly to initial values post exercise during the recovery phase in lean compared to obese children ($p = 0.009$).

Conclusion: Obese children showed a significant reduced exercise capacity with lower physical performance. Interestingly, we demonstrated a significant and immediate improvement in the metabolic profile by acute exercise. In summary our results further underline the beneficial effects of increased physical activity on metabolic and cardiovascular risk in obese children.

A natural compound suppresses hepatic gluconeogenesis and lipid synthesis by activation of AMPK

Y. Leng, S. Huang, J. Shen, Y. Wang, Y. Hu;

Shanghai Institute of Materia Medica, Chinese Academy of Sciences, China.

Background and aims: YL01, a natural compound has been identified to activate AMPK and increase glucose uptake and free fatty acid oxidation in L6 myotubes in our previous study. In the present study, the effect of YL01 on hepatic gluconeogenesis and lipid synthesis was evaluated and its possible mechanisms were explored.

Materials and methods: Measurement of glucose production was performed in primary hepatocytes under glucagon stimulated state to examine the effect of YL01 on hepatic gluconeogenesis. Fatty acid and sterol synthesis in primary hepatocytes were assayed by measuring [^{14}C] acetate incorporation into lipids. Activation of YL01 on the AMPK signaling pathway was investigated by western blot analysis. Pyruvate tolerance test was performed to evaluate the in vivo effect of YL01 on gluconeogenesis in C57 mice.

Results: YL01 dose dependently inhibited glucagon stimulated gluconeogenesis and insulin induced fatty acid and sterol synthesis in primary hepatocytes. $10 \mu\text{M}$ YL01 reduced gluconeogenesis, fatty acid and sterol synthesis by 18.7%, 26.8% and 40.2%, respectively. YL01 significantly increased AMPK and ACC phosphorylation in primary hepatocytes in a dose dependent manner. The YL01 suppression of hepatic gluconeogenesis and lipid synthesis was fully blocked by the pretreatment with compound C, an AMPK inhibitor. Single oral administration of YL01 at dose of 300mg/kg in C57 mice significantly increased AMPK and ACC phosphorylation in liver. Moreover, administration of YL01 caused significant reduction in blood glucose levels after pyruvate loading, suggesting the inhibitory role of YL01 on gluconeogenesis in vivo.

Conclusions: Our results demonstrated that YL01 inhibited hepatic gluconeogenesis and lipid synthesis by activation of AMPK, which suggested that it might be a therapeutic candidate for the treatment of T2DM and metabolic syndrome.

613

Impact of Lactobacillus casei Shirota supplementation on insulin sensitivity and beta cell function in subjects with metabolic syndrome

N.J. Tripolt¹, B. Leber², D. Blattl², M. Eder¹, T.R. Pieber¹, V. Stadlbauer³, H. Sourij¹;

¹Department of Endocrinology and Metabolism, ²Division of Transplantation Surgery, ³Division of Gastroenterology and Hepatology, Medical University Graz, Austria.

Background and aims: Based on animal studies, intake of probiotic bacteria was suggested to improve glucose homeostasis by reducing endotoxaemia and inflammation. We hypothesized that Lactobacillus casei Shirota (LcS) supplementation might have an impact on glucose tolerance and indices of insulin sensitivity and β -cell function in subjects with the metabolic syndrome and insulin resistance.

Materials and methods: In a single-centre, prospective, randomized-controlled pilot study, 30 subjects with metabolic syndrome received either Lactobacillus casei Shirota 3 times daily for 12 weeks or served as controls with standard medical therapy. A 75-g oral glucose tolerance test (oGTT) was performed and blood samples were collected to determine plasma glucose, serum insulin and serum c-peptide. Insulin sensitivity was assessed by homeostasis model assessment (HOMA-IR), insulin sensitivity index (ISI), Matsuda-Index (ISO-GTT) and QUICK-index. Beta-cell function was quantified as the ratio of incremental insulin to glucose responses over the first 30 min during the OGTT, the HOMA- β index and by 1st and 2nd phase insulin secretion indices.

Results: Insulin sensitivity index (ISI) was significantly improved after 3 months of probiotic supplementation (0.058 ± 0.021 vs. 0.038 ± 0.025 , $p < 0.01$) but not significantly different to the control group. Likewise the ratio of incremental insulin to incremental glucose responses over the first 30 minutes during the OGTT significantly decreases during the treatment in the LcS group (73.2 ± 64.6 to 47.7 ± 44.2 , $p < 0.05$), but again without a significant difference to the control group. No improvements were seen in further indices calculated.

Conclusion: In conclusion, intake of LcS for 12 weeks in subjects with metabolic syndrome did not clearly affect insulin sensitivity or β -cell function in this pilot trial.

S-nitrosothiols as potential pharmacological targets on the treatment of insulin resistance

A.B. Fernandes¹, I.S. Lima¹, M.P. Macedo^{1,2},

¹Physiology, CEDOC - Faculty of Medical Sciences, ²Portuguese Diabetes Association - Research Center (APDP-RC), Lisbon, Portugal.

Background and aims: It has been shown in fasted Wistar rats that co-administration of NO and GSH, via portal vein, was able to promote an increase in insulin sensitivity of 125.3±18.6%. From this result it was proposed that increasing hepatic glutathione and nitric oxide levels forms nitrosothiols (RSNOs), which are release into the bloodstream, acting on extra-hepatic tissues by increasing insulin sensitivity. An endocrine function of RSNOs has already been established by other authors, hinting to the possibility the previous hypothesis that the synthesized RSNOs in the liver will act on periphery. These observations highlight these molecules as potential pharmacological drugs in the treatment of insulin resistance, therefore our hypothesis is that co-administration of NO and GSH or administration of RSNOs is able to overcome the insulin resistance induced by a high-sucrose diet.

Materials and methods: 12 week old Wistar rats (control vs. high sucrose) were used. The high-sucrose group consisted in animals fed with a high-sucrose diet (35% (w/v)) for a 4 week period (8-12 weeks of age). Insulin sensitivity was assessed by a rapid euglycaemic insulin sensitivity test. Insulin sensitivity was determined in the fasted state and i) after a standard meal, ii) after GSH (GSH-E: 1 or 2 mmol/kg) + NO (SIN-1: 50 or 100 μ mol/kg) administration into the portal vein or an S-nitrosothiol (S-nitrosoglutathione-GSNO: 50 μ mol/kg or 100 μ mol/kg) intravenous administration. Insulin and C-peptide levels were determined by ELISA Kit.

Results: Insulin sensitivity in the control animals increased 89.1±15.3% after a meal, but this potentiation was not observed in the high sucrose diet (10.3±8.9%, **, $p<0.01$) GSH (1mmol/kg) and NO (50 μ mol/kg) administered in fasted animals, directly to the portal vein, increased insulin sensitivity by 125.3±18.6%. On the other hand the administration of both drugs to the high-sucrose model was unable to increase insulin sensitivity even when we doubled the dose. RSNOs administration increased insulin sensitivity in both controls and high sucrose groups. However, full potentiation (100.1±38.5%) was only observed in the high sucrose diet when we doubled the dose of GSNO (100 μ mol/kg). Plasma C-peptide and insulin levels remained unchanged after GSNO administration which indicates that this drug is not affecting insulin secretion or insulin clearance.

Conclusion: The results presented herein allow us to conclude that in the high sucrose animal model the insulin resistance observed was not overcome by administration to the liver of GSH and NO, indicating inability of the liver to synthesize RSNOs. On the other hand, GSNO administered to the periphery was able to overcome the insulin resistance observed in this animal model, and this mechanism seems to be independent of insulin secretion. Our *in vivo* results showed for the first time that S-nitrosothiols induces increases in insulin sensitivity, indicating these drugs as potential pharmacological tools in the treatment of peripheral insulin resistance.

Red grape polyphenols prevent deleterious metabolic effects induced by fructose

M. Hokayem¹, E. Blond^{2,3}, J.-F. Brun^{1,4}, C. Fedou^{1,4}, J.-P. Cristol⁴, F. Michel⁴, J. Mercier^{1,4}, J. Goudable⁵, C. Bisbal¹, K. Lambert¹, A.-M. Dupuy⁴, M. Laville^{2,3}, A. Avignon^{1,4},

¹INSERM U1046 Physiologie et Medecine Experimentale du Coeur et des Muscles, Montpellier, ²Centre de Recherche en Nutrition Humaine Rhone Alpes, Lyon, ³Centre Hospitalier Lyon Sud, ⁴Centre Hospitalo Universitaire Montpellier, ⁵UMR INSERM 870 - Régulations métaboliques, nutrition et diabètes, Lyon, France.

Background and aims: Studies have shown that dietary fructose induces dyslipidemia and insulin resistance. In this work we looked at whether the insulin resistance induced by fructose was associated with oxidative stress. We also evaluated the effects of a natural red grape extract on the prevention of metabolic abnormalities caused by fructose.

Materials and methods: 35 overweight and obese 1st degree relatives of type 2 diabetic subjects [20 women / 15 men ; BMI 29.1± 2.2 kg/m² (mean ± SD) ; age 49.2 ± 8.4 years] were randomized in a double blind study between a grape extract (GE) group (2g/day) and a placebo (P) group for a period of 9 weeks. During the last week, both groups received a fructose load (3g/kg lean body mass/day) to be consumed in aqueous form during the 3 major daily meals. Our volunteers were studied before and after the week of fructose overload.

Results: Body weights remained stable whereas fasting plasma triglyceride concentrations increased similarly in both groups (GE 36%, P 31%). However, glucose disposal measured by the hyperinsulinemic euglycemic clamp was decreased in the P group (7.37 ± 2.36 vs 6.64 ± 2.38 mg/kg/min, $p=0.01$) but not in the GE group (6.72 ± 3.09 vs 6.50 ± 1.99 mg/kg/min, NS). Overnight urinary F2-isoprostanes (a marker of oxidative stress) were increased after fructose in the P group (475 ± 165 vs 554 ± 183 pmol/mmol creatinine, $p=0.01$) whereas they were decreased in the GE group (513 ± 187 vs 473 ± 148 pmol/mmol creatinine, $p=0.05$). For all subjects, insulin sensitivity before fructose was inversely correlated with urinary F2-isoprostane levels ($r=-0.46$, $p<0.01$) and insulin sensitivity fluctuations after fructose were negatively correlated with changes in urinary F2-isoprostane levels ($r=-0.32$, $p=0.05$).

Conclusion: These data suggest that fructose induced insulin resistance might in part be secondary to oxidative stress and can be prevented by a polyphenolic rich red grape extract in a population of overweight/obese adults. Therefore our results help better understand the mechanistics behind insulin resistance in order to counterattack the ever growing worldwide diabetes epidemic.

Mechanism of action of VVP808: a novel insulin sensitising agent

K.R. Walder¹, N. Konstantopoulos¹, K. Windmill¹, J. Molero¹, G. Krippner²,

¹Metabolic Research Unit, Deakin University, Waurn Ponds, ²Verva Pharmaceuticals, Geelong, Australia.

Background and aims: We used gene expression signature technology to identify a family of compounds with insulin sensitising activity. The aim of these studies was to characterise the effects of these compounds in animal models of insulin resistance and diabetes, and to investigate the molecular mechanism of action of these compounds.

Materials and methods: The VVP800 family of compounds was tested in diet induced obese (DIO) mice, db/db mice and STZ rats. The lead compound, VVP808, was administered by single daily oral gavage to animals for 12-40 days at a range of doses, and efficacy was assessed by measuring body weight, blood glucose, insulin and HbA1c concentrations, and by conducting hyperinsulinemic-euglycemic clamps.

Results: VVP808 reduced fasting blood glucose concentration ($p=0.00004$) and HbA1c levels ($p=0.04$) in db/db mice, and improved glucose tolerance in diet-induced obese (DIO) mice ($p<0.05$). VVP808 also reduced body weight by up to 14% ($p<0.01$) and epididymal fat pad weight by up to 48% ($p=0.01$) in DIO mice. In STZ diabetic rats, VVP808 (50 mg/kg/d for 12 days) had no effect on fasting blood glucose concentration. However, VVP808 significantly enhanced the glucose-lowering effects of exogenous insulin (0.5U/kg) in an insulin tolerance test (by 2.2-fold after 30 min ($p=0.045$) and by 2.4-fold after 60 min ($p=0.038$)). Data from hyperinsulinemic-euglycemic clamp studies

in DIO mice showed that treatment with VVP808 (50 mg/kg/d for 14 days) increased the glucose infusion rate by 27% ($p=0.005$), and this was associated with a 23% decrease in endogenous glucose production ($p=0.04$). We are currently conducting a range of studies to identify the molecular mechanism of action of VVP808 including ligand capture affinity chromatography studies using analogues of VVP808 and protein lysates extracted from livers of mice treated with VVP808, and microarray pathway analysis studies in tissues of animals treated with VVP808.

Conclusion: VVP808 is a novel insulin sensitising agent that acts primarily on the liver to suppress endogenous glucose production.

C-peptide enhances *in vitro* and *in vivo* insulin action

Y. Sato¹, A. Chibalin², O. Khokhor¹, M. Kubota³, J. Wahren²;

¹Department of Health Science, Aichi Gakuin University, Nisshin, Japan,

²Department of Molecular Medicine and Surgery, Karolinska Institutet,

Stockholm, Sweden, ³Department of Human Health Sciences, Kyoto University, Japan.

Background and aims: *In vitro* studies have shown that C-peptide interacts with hexameric insulin and facilitates its disaggregation into the physiologically active monomeric form. With the aim to further investigate this effect under *in vivo* conditions we have employed the euglycemic hyperinsulinemic clamp technique in rats and examined skeletal muscle and liver biopsy material after subcutaneous administration of both insulin and C-peptide either in a mixture or as separate injections.

Material and methods: Male Wistar rats (age 6 weeks, 145–165g) were used. Regular insulin (I) (1.2 U/kg) was injected subcutaneously (s.c.) together with 29 nmol/kg rat C-peptide (C). I and C were administered either as a physical mixture or separately into two s.c. depots. Rats were awake and allowed to move freely within a large cage during the study. During a 60 min baseline period the ambient glucose level was established and subsequently clamped ± 0.3 mM by frequent blood glucose analyses and adjustment of a variable i.v. glucose infusion for approximately 2 h. In some experiments the study was terminated at 30 min post I and C injection, anaesthesia commenced and biopsy samples were obtained from liver and hindlimb muscles and frozen immediately. Akt and GSK3 phosphorylation in liver and muscle were examined using Western blot technique. Finally, Na^+ , K^+ -ATPase activity was assessed as ouabain-sensitive $^{86}\text{Rb}^+$ uptake by L6 myotubes before and after incubation with insulin with or without the presence of C-peptide.

Results: Subcutaneous injection of a mixture of I and C resulted in a 30% greater ($P<0.01$) and 15% ($P<0.05$) longer stimulation of whole body glucose utilization than observed after injection of equimolar amounts of I and C into separate depots. Plasma concentrations of insulin were higher 30 min after injection of combined I and C (15.2 ± 2.8 ng/mL) compared to after separate injections of I and C (10.1 ± 1.3 ng/mL, $P<0.03$). Insulin-stimulated phosphorylation of Akt/PKB in liver but not muscle increased 32% more ($P<0.06$) after injection of I and C in mixture compared to separate injections. Likewise, phosphorylation of GSK3 was augmented by 50% ($P<0.05$) following administration of I and C mixture compared to separate injections. Exposure of L6 myotubes to 1 nM C-peptide for 15 min stimulated ouabain-sensitive $^{86}\text{Rb}^+$ uptake by 31% ($P<0.05$), while 1 nM of insulin had no effect. Stimulation of myotubes by pre-mixed equimolar C-peptide and insulin (1 nM) elicited 20% additional increase in ouabain-sensitive $^{86}\text{Rb}^+$ uptake ($P<0.05$) in comparison to the effect 1 nM C-peptide alone. This additive effect was lost when insulin and C-peptide were added separately to myotubes.

Conclusion: Subcutaneous co-administration of insulin and C-peptide results in increased insulin availability and augmented insulin effects both at the level of glucose uptake and intracellular signaling and enzyme activation. These effects may be attributed to augmented disaggregation of hexameric insulin into its physiologically active monomeric form.

618

Isomaltulose tightens pre-exercise glycaemia and produces similar run performance in type 1 diabetes

R.M. Bracken¹, B. Gray¹, R. Page¹, D.J. West², J.W. Stephens³, S.C. Bain³;

¹Swansea University, Sports and Exercise Science Research Centre, ²Sport and Exercise Sciences, Northumbria University, Newcastle Upon Tyne,

³Swansea University, Diabetes Research Group, UK.

Background and aims: Recent literature has shown that pre-exercise ingestion of the low glycaemic index (GI) CHO isomaltulose can increase blood glucose (BG) concentrations less before exercise and protect against hypoglycaemia following exercise through lesser suppression of lipid oxidation compared to a high GI CHO in type 1 diabetes individuals (T1DM). However, it is not known what effect low GI CHO consumption has on exercise performance. This study compared the alterations to metabolic and performance responses to aerobic running following ingestion of a low- and high-GI CHO. **Materials and methods:** With ethical approval, 7 individuals (34 ± 5 years, 70 ± 2 kg, HbA_{1c} 76.6 ± 6.5 mmol.mol⁻¹) completed this study. After preliminary testing, participants attended the laboratory twice and were provided with 0.6 g.kg^{-1} body mass of either dextrose (DEX) or isomaltulose (ISO, Palatinose®) immediately after they had administered a 50% reduced dose of their rapid-acting insulin. After 2-h rest participants completed a 26 minute discontinuous incremental treadmill protocol (4 min running; 1.5 min rest at 31, 41, 53, 69 and 80% VO_2max) before completing a 10 min run on a non-motorised treadmill where participants were instructed to complete as much distance as possible in this time. Capillary blood samples were obtained prior, during and after exercise and were analysed immediately for BG and lactate (GEM, Instrumentation Laboratories). Data was analysed by repeated-measures ANOVA with post-hoc testing where appropriate and expressed as mean \pm SEM. Statistical significance was accepted at $P<0.05$.

Results: Resting blood glucose concentrations were similar between conditions. Relative peak BG was lower after ingestion of ISO compared to DEX (ISO 5.6 ± 0.4 vs. DEX 10.3 ± 0.7 mmol.l⁻¹, $P<0.05$), and the time to reach this peak value took longer in ISO (86 ± 8 min) compared to DEX (64 ± 4 min) ($P<0.05$). Changes in mean BG throughout the 2 h rest period were lower in ISO than DEX (ISO 4.6 ± 0.4 vs. 7.8 ± 0.8 mmol.l⁻¹, $P<0.05$), as were both the rest incremental area under the curve (IAUC) (ISO 483.9 ± 40.5 vs. DEX 847.6 ± 72.4 mmol.min.l⁻¹, $P<0.05$) and total IAUC (ISO 627.1 ± 67.8 vs. DEX 1057.9 ± 119.8 mmol.min.l⁻¹, $P<0.05$) over the length of the trial. BG reductions throughout the submaximal exercise were similar between both CHO (ISO -1.9 ± 0.5 vs. DEX -1.0 ± 0.5 mmol.l⁻¹, $P>0.05$) as were the BG changes in the 10 min run (ISO 0.7 ± 0.4 vs. DEX 0.7 ± 0.3 mmol.l⁻¹, $P>0.05$). Resting blood lactate concentrations were similar between conditions however, following ISO ingestion blood lactate was higher over the 2 h rest period ($P<0.05$). There were no differences in lactate concentrations between CHO once exercise began. Distance covered during the 10 min run was similar between conditions (ISO 1.14 ± 0.09 vs. DEX 1.15 ± 0.09 km, $P>0.05$).

Conclusion: Pre-exercise ISO ingestion of 0.6 g.kg^{-1} BM with 50% reduction of rapid-acting insulin caused a smaller rise in blood glucose concentration before exercise and resulted in a similar performance during a 10 minute run. Pre-exercise consumption of ISO is an effective CHO for those exercising T1DM individuals wishing to improve glycaemic control without loss of exercise performance.

Effects of vitamin D₃ on beta cell function and insulin resistance in children at increased risk of type 1 diabetes

J. Raab¹, C. Winkler², F. Meier-Stiegen³, J. Försch¹, A.-G. Ziegler^{3,2};

¹Forschergruppe Diabetes e. V. ²Institute of Diabetes Research, Helmholtz Center Munich, Neuherberg, ³Competence Network Diabetes Mellitus, Klinikum Rechts der Isar, University of Technology, Munich, Germany.

Background and aims: Studies in subjects at risk for type 2 diabetes as well as animal studies suggest that vitamin D affects β -cell function and insulin resistance. The relationship of Vitamin D levels especially of 1,25(OH)₂ vitamin D₃ (the active form of vitamin D) and β -cell function in healthy children has never been studied. Vitamin D status and supplementation of Vitamin D during early childhood has been associated with type 1 diabetes (T1D) risk. A priori β -cell function and insulin resistance may also play a role in the development of type 1 diabetes. The aim of our study was to determine whether

vitamin D3 status is associated with β -cell function and insulin resistance in children at increased risk for T1D.

Materials and methods: 1,25(OH)₂ vitamin D3 (vitamin D3) was measured in fasting serum samples taken from 156 children participating in the TEENDIAB Study, a prospective cohort study that follows children aged 8–12 years with a family history of T1D during puberty to the age of 18 years. Each child underwent an intravenous glucose tolerance test (median age 10.5 years). Fasting and stimulated insulin and C-peptide was determined at time points 1, 3, 5, 7, 10 min (after glucose load) using an automated immunoassay analyzer (AIA 360; Tosoh, San Francisco, CA). First phase insulin response (FPIR) was calculated as the sum of the serum insulin concentrations at 1 and 3 minutes after glucose load. C-peptide and insulin response during IVGTT were evaluated as area under the curve (AUC) by using the TAI's formula. Insulin resistance was estimated by homeostasis model assessment of insulin resistance (HOMA-IR).

Results: Median observed vitamin D3 serum concentrations were 38 ng/l (IQR: 32–44 ng/l). Vitamin D3 serum concentrations were positively associated with fasting insulin ($p=0.032$), fasting C-peptide levels ($p=0.007$) and were correlated with HOMA-IR ($p=0.042$). Furthermore when serum vitamin D3 levels were categorized into tertiles (first tertile: 17–34 ng/l, second tertile: 35–42 ng/l, third tertile: 43–61 ng/l) those children with the highest vitamin D3 concentration (third tertile) had a significantly higher fasting C-peptide level compared to the children in the second or first tertile (median C-peptide 1.5 ng/ml vs 1.4 ng/ml vs 1.1 ng/ml, $p=0.006$). These associations remained significant after adjusting for age and gender ($p=0.022$). Vitamin D3 serum levels were not associated with stimulated insulin secretion (FPIR ($p=0.4$), AUC insulin ($p=0.4$) and AUC C-peptide ($p=0.2$)).

Conclusion: This is the first study showing an association of the active form of vitamin D3 with β -cell function and insulin resistance in children aged 8–12 years at increased risk for T1D.

Elevated plasma levels of SPARC in patients with newly diagnosed type 2 diabetes mellitus

Y. Zhang¹, L. Li¹, G. Yang³;

¹Department of Clinical Biochemistry, ²Department of Clinical Biochemistry, ³Department of Endocrinology, the Second Affiliated Hospital, Chongqing Medical University, China.

Background and aims: SPARC (secreted protein acidic and rich in cysteine), firstly identified in bone, is also known as osteonectin and BM-40. Although it is expressed in most tissues, adipose tissue cells are the major source of circulating SPARC in subjects with obesity. As an extracellular regulatory macromolecule regulating cell-matrix interaction, SPARC is a multifunctional protein involved in osteogenesis, angiogenesis, wound healing, tumorigenesis, and fibrosis in kidney and liver. Recently, SPARC is suggested as a key player in the pathogenesis of obesity and type 2 diabetes mellitus. However, the pathophysiologic roles of SPARC in glucose metabolism are not well understood. In the present study, plasma levels of SPARC in normal, impaired glucose regulation (IGR) and T2MD subjects were evaluated to better understand its clinical importance. The relationships between circulating plasma SPARC levels and body mass index (BMI), blood lipids, blood glucose, plasma insulin, HOMA-IR, and other factors, were also examined.

Materials and methods: Fifty-four newly diagnosed type 2 diabetic subjects (T2MD), fifty-three subjects with impaired glucose regulation (IGR), and fifty-three normal subjects were enrolled in this study. Plasma SPARC levels were measured with an Enzyme-Linked Immunosorbent Assay (ELISA) under overnight fasting conditions. The relationships between plasma SPARC and several metabolic factors, such as body mass index (BMI), blood lipids, blood glucose, plasma insulin levels and other factors were also assessed.

Results: SPARC levels were higher in subjects with T2MD compared with IGR and control subjects [(16.7 \pm 6.9 vs. 14.0 \pm 8.0) μ mol/L, $P<0.05$ and (16.7 \pm 6.9 vs. 11.7 \pm 4.4) μ mol/L, $P<0.01$]. However, there was no difference in plasma SPARC levels between subjects with IGR and the controls. Plasma SPARC levels were correlated positively with BMI, the percentage of fat (FAT%), Triglyceride (TG), Fasting plasma insulin (FINS), 2h plasma insulin after glucose overload (2hINS), and HOMA-insulin resistance index (HOMA-IR) by simple regression analysis. TG and HOMA-IR were independent related factors influencing plasma SPARC levels by multiple regression analysis ($Y=1.002X_{TG}+1.233X_{HOMA-IR}+9.07$).

Conclusion: Our results showed an increased SPARC level in obese and T2DM subjects suggesting that SPARC may play a role in pathogenesis of both obesity and diabetes. However, further studies need to clarify the biological mechanisms involving SPARC in the pathogenesis of T2DM.

Suppressive effect of hyperinsulinaemia on serum IL-18 concentration in young, healthy subjects

M. Strackowski¹, M. Karczewska-Kupczewska¹, A. Adamska¹,

A. Nikolajuk^{1,2}, N. Kaminska¹, M. Zielinska¹, M. Górska¹, I. Kowalska¹;

¹Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Białystok, ²Department of Prophylaxis of Metabolic Diseases, Polish Academy of Sciences, Olsztyn, Poland.

Background and aims: IL-18 is a proinflammatory and proatherogenic cytokine which is associated with obesity, insulin resistance and cardiovascular disease. It is supposed that insulin might have anti-inflammatory action, however, its effect on IL-18 is unclear. The aim of the present study was to estimate serum IL-18 concentration in young healthy population, its regulation by hyperinsulinemia and relationship with insulin sensitivity and glucose and lipid oxidation.

Materials and methods: We studied 36 healthy male subjects (mean age, 24.50 \pm 2.67; mean BMI, 25.77 \pm 3.70 kg/m²). Serum IL-18 concentration was measured before and after 2 hour euglycemic hyperinsulinemic clamp. In 18 subjects, clamp was prolonged to 6 hours and at the end an additional measurement of serum IL-18 was taken. RQ and glucose and lipid oxidation

(LOx) were assessed with indirect calorimetry in the baseline state and every 2 hours of the clamp.

Results: Hyperinsulinemia decreased serum IL-18, this effect was present in both 2 and 6 hours of the clamp (both $p < 0.001$). Additionally, serum IL-18 slightly decreased from 2 to 6 hour ($p = 0.044$). Both 2 hour and 6 hour serum IL-18 values were positively related to plasma NEFA in the respective time-points ($r = 0.43$, $p = 0.033$ and $r = 0.52$, $p = 0.028$). Both 2 hour and 6 hour serum IL-18 were also negatively related to RQ ($r = -0.40$, $p = 0.018$ and $r = -0.54$, $p = 0.02$) and positively to LOx ($r = 0.46$, $p = 0.006$ and $r = 0.66$, $p = 0.004$) in the respective time-points. Six-hour IL-18 value was negatively related to insulin sensitivity calculated for the 6th hour of the clamp ($r = -0.53$, $p = 0.025$), serum adiponectin in the 6th hour of the clamp ($r = -0.54$, $p = 0.02$) and positively to the body weight ($r = 0.49$, $p = 0.038$). Additionally, the change in serum IL-18 in response to insulin was inversely related to the white blood cell count ($r = -0.52$, $p = 0.027$) and the neutrophil cell count ($r = -0.56$, $p = 0.016$), i.e., the higher the cell count, the lower the decrease in IL-18.

Conclusion: Our data show that serum IL-18 is negatively regulated by hyperinsulinemia, suggesting anti-inflammatory effect of insulin. IL-18 is related to decreased insulin sensitivity mainly through its association with lipid oxidation.

Maternal fasting visfatin change and fasting active amylin change predict maternal HOMAR change and weight change respectively during pregnancy

G. Valsamakis¹, D. Papatheodorou¹, M. Markopoulos², A. Margeli³, I. Papassotiropoulos³, G. Creatsas², G. Mastorakos¹;

¹Endocrine Unit, ²2nd Dept Obs & Gynae, ³Clinical Biochemistry, Aghia Sophia Children's University Hospital, Vrilissia/Athens, Greece.

Background and aims: The increase of maternal weight and insulin resistance during pregnancy are risk factors for gestational diabetes. Adipocytokines and pancreatic hormones affect insulin resistance, glucose balance and food intake. This study looks for predictors among changes of adipocytokines, pancreatic hormones, insulin resistance indices and maternal weight during pregnancy.

Materials and methods: 100 healthy pregnant Caucasian women, aged 28.2 ± 3.8 (mean \pm SD) years, body mass index 24 ± 2.6 kg/m², were randomly seen during each trimester. Each visit they had anthropometrics, fasting plasma sampling for pancreatic hormones (glucagon, active amylin, pancreatic polypeptide-PP) and adipocytokines (adiponectin, visfatin, leptin) and a 75g oral glucose tolerance test (OGTT) for glucose and insulin at 0,15,30,60,90,120 min. Five women developed gestational diabetes (based on WHO criteria) and were separated. OGTT derived indices of carbohydrate metabolism such as insulin resistance (HOMAR), insulin sensitivity (ISI), predicted indexes of first phase and second phase of insulin secretion (1st PHIS, 2nd PHIS) were calculated.

Results: Maternal weight increased significantly during all trimesters of pregnancy ($p < 0.05$). Serum visfatin increased significantly from the 2nd to the 3rd trimester ($p = 0.05$). HOMAR index increased significantly in the 3rd compared to the 1st and 2nd trimester ($p < 0.05$) while the ISI index decreased significantly in the 3rd compared to the 1st and 2nd trimester ($p < 0.05$). At 1st trimester visfatin correlated positively with weight ($p = 0.04$, $r = 0.73$). Leptin correlated positively with weight ($p = 0.0001$, $r = 0.85$), 1st PHIS ($p = 0.004$, $r = 0.65$), and 2nd PHIS ($p = 0.008$, $r = 0.57$) and negatively with ISI ($p = 0.007$, $r = -0.59$). Active amylin correlated positively with 2nd PHIS ($p = 0.04$, $r = 0.42$) negatively with HOMAR ($p = 0.004$, $r = -0.69$). At 2nd trimester glucagon correlated negatively with HOMAR ($p = 0.04$, $r = -0.45$) and adiponectin ($p = 0.03$, $r = -0.93$). Active amylin correlated negatively with glucagon ($p = 0.04$, $r = -0.45$). The longitudinal regression model taking in consideration all three trimesters revealed maternal fasting visfatin change as the best positive and negative predictor of insulin resistance (HOMAR) ($p = 0.0002$, t -value = 4.48) and sensitivity (ISI) ($p = 0.002$, t -value = -3.65) changes, respectively, among changes of glucagon, PP, active amylin, leptin, and adiponectin levels. The longitudinal regression model taking in consideration all three trimesters revealed maternal fasting active amylin change as the best negative predictor ($p = 0.02$, t -value = -2.41) of maternal weight change among changes of glucagon, PP, visfatin, leptin, and adiponectin levels.

Conclusion: The present study shows the impact of maternal fasting active amylin change (anorectic factor) into maternal weight change and of maternal fasting visfatin change (insulinomimetic action) into insulin resistance

change during normal pregnancy. Further studies are needed to investigate the importance of the above predictors into gestational diabetes as early biomarkers of HOMAR change and weight change

623

Cathepsin K predicts glycaemic control and beta cell function in impaired glucose tolerant men: a new link between skeleton and energy homeostasis?

B. Buday¹, B.N. Literáti¹, P.F. Pach², E. Kulcsár¹, M. Vitai¹, É. Péterfai¹, L. Korányi¹;

¹Department of Metabolism, DRC, Balatonfüred, ²University of Pannonia, Veszprém, Hungary.

Background and aims: Cathepsin K (Cat K) is a cysteine protease that have been shown to participate in bone resorption, adipogenesis and energy homeostasis. Inhibition or deficiency of Cat K reduced insulin and glucose levels and inhibited body weight gain in mice. Only few clinical data are available about the metabolic role of Cat K in humans, and these are contradictory. Our aim was to compare Cat K levels in normal and impaired glucose tolerant men, to assess its relationship to energy homeostasis, insulin and glucose metabolism.

Materials and methods: 53 healthy and glucose intolerant male subjects (aged 43.3 ± 13.1 years) were examined who were previously non-treated for diabetes. OGTT, ivGTT and hyperinsulinemic euglycemic clamp were done to assess glucose tolerance, insulin secretion and sensitivity. Full metabolic profiling, lipoproteins, adipocytokines, serum Cat K, osteocalcin (OCN), osteoprotegerin (OPG) and nuclear factor κ B ligand (RANKL) were measured. Body composition mass was determined by DEXA.

Results: Based on the OGTT, 21 subjects were normal (NGT) and 32 subjects glucose intolerant (GI = IFG/IGT or 2DM). Serum Cat K levels were somewhat higher in the NGT than in the GI group (11.6 ± 8.2 vs. 7.97 ± 4.76 pmol/l, $p = 0.058$). Serum Cat K levels showed strong positive bivariate correlation with indicators of the 1st phase insulin secretion of ivGTT, i.e. acute insulin response (AIR, $r = 0.38$, $p = 0.01$) and insulinogenic index (IGI, $r = 0.41$, $p = 0.004$), negative correlation with fasting glucose levels ($r = -0.28$, $p = 0.05$), HbA1c ($r = -0.36$, $p = 0.01$) and fasting free fatty acid levels ($r = -0.33$, $p = 0.02$). These correlations were unaffected if data were adjusted with age, body mass index (BMI) and body fat percent (BFP). If the two groups were assessed separately this correlation stayed significant only in the GI group. No correlations were observed between serum Cat K levels and clamp measured muscle glucose utilization, BMI or BFP. With feature selection (variable ranking) analysis serum Cat K level was ranked as 10.5/67.7 (average merit 0.051 ± 0.02) to determine AIR, ranked even higher than ivGTT or OGTT glucose or HbA1c% levels. Similar results were found for IGI.

Conclusion: We found that serum Cat K levels predict β cell function in GI men independent of body composition or insulin sensitivity. This finding differs from earlier data with mice. Further studies are needed to elucidate the exact metabolic role of Cat K in "OCN - insulin axis" in humans, especially the effect of its pharmaceutical inhibition on pancreatic insulin secretion.

Overproduction of hepatokine selenoprotein P contributes to hypoadiponectinaemia in type 2 diabetes

H. Misu, K. Ishikura, Y. Takeshita, T. Ota, S. Kaneko, T. Takamura;

Department of Disease Control and Homeostasis, Kanazawa University, Japan.

Background and aims: We have recently identified selenoprotein P (SeP) as a liver-derived secretory protein that causes insulin resistance in the liver and skeletal muscle. We have reported that serum levels of SeP are elevated in patients with type 2 diabetes compared with control subjects. Additionally, we have shown that SeP impairs insulin signal transduction in the hepatocytes and myocytes. However, it is unknown whether and, if so, how SeP acts on adipose tissue. The present study tested the hypothesis that SeP is related to hypoadiponectinemia in patients with type 2 diabetes.

Materials and methods: We compared serum levels of SeP with those of adiponectin and other clinical parameters in 36 patients with type 2 diabetes. Additionally, we treated 3T3-L1 adipocytes with purified SeP to assess the direct action of SeP on adiponectin production. We also measured levels of blood adiponectin in SeP knockout mice.

Results: Circulating SeP levels were positively correlated with fasting plasma glucose ($r = 0.35$, $P = 0.037$) and negatively associated with both total and high-molecular adiponectin in patients with type 2 diabetes ($r = 0.355$, $P = 0.034$; $r = 0.367$, $P = 0.028$). SeP was a predictor of high-molecular adiponectin, independently of age, body weight, and quantitative insulin sensitivity index ($\beta = -0.357$, $P = 0.017$). Treatment with purified SeP protein concentration-dependently reduced adiponectin and PPAR γ gene expression in 3T3-L1 adipocytes. SeP knockout mice exhibited an increase in blood adiponectin levels when fed regular chow or a high sucrose, high fat diet.

Conclusion: These results reveal that overproduction of liver-derived secretory protein SeP contributes to hypo adiponectinemia in patients with type 2 diabetes, and suggests that the failure of the inter-organ network, via hepatokines and adipocytokines, underlies the pathology of type 2 diabetes.

Inverse correlation between serum levels of selenoprotein P and those of adiponectin in patients with type 2 diabetes.

Background and aims: Nesfatin-1, derived from the nucleobindin2 (NUCB2) precursor, containing 82 amino acid, is highly conserved in humans, rats and mice. It has been reported that nesfatin-1 suppresses nocturnal food intake and body weight gain when injected into the third brain ventricle, conversely, infusion of NUCB2 antisense oligonucleotide stimulates food intake. However, its patho-physiological role in humans remains unknown. The aim of the present study was to investigate plasma nesfatin-1 levels and the association between plasma nesfatin-1 levels and various metabolic parameters in humans.

Materials and methods: 54 subjects with newly diagnosed type 2 diabetes mellitus (nT2DM), 53 subjects with impaired glucose regulation (IGR) and 53 control subjects were enrolled in this study. Plasma nesfatin-1 level was measured by ELISA. The relationship between plasma nesfatin-1 levels and metabolic parameters was also analyzed.

Results: plasma nesfatin-1 levels were elevated in subjects with both nT2DM and IGR compared to the controls (1.91 ± 0.79 vs 1.80 ± 0.80 vs 1.41 ± 0.58 $\mu\text{g/L}$, $P < 0.01$). Simple regression analysis showed that in subjects with IGR and nT2DM, plasma nesfatin-1 positively correlated with body mass index (BMI), Glycosylated hemoglobin (HbA_{1c}), fasting blood glucose (FBG), 2 h blood glucose after glucose overload (2h-PBG), fasting plasma insulin (FINS), the homeostasis model assessment of insulin resistance (HOMA-IR), multivariate logistic regression analysis revealed that plasma nesfatin-1 was significantly associated with IGR and nT2DM, even after controlling for anthropometric variables and lipid profile.

Conclusion: plasma nesfatin-1 concentrations were found to be elevated in subjects with both IGR and nT2DM and to be related to several clinical parameters known to be associated with insulin resistance.

Background and aims: The novel adipokine vaspin (visceral adipose tissue derived serine protease inhibitor) is suggested to link obesity, insulin resistance (IR) and type 2 diabetes (T2D), but so far its pathophysiological role remains largely unknown. We treated db/db-mice to study the effects of recombinant vaspin on insulin sensitivity. In human studies we analyzed the relationship between serum vaspin concentrations and metabolic traits. Finally, we investigated whether variability in vaspin serum concentrations might be explained by its genetic variants.

Materials and methods: In animal studies, five db/db-mice for each test were treated with vaspin (1mg/kg body weight i.p.) or saline in the control group. Then glucose tolerance tests (2g/kg body weight i.p.) and hyperinsulinemic-euglycemic-clamps were performed. In human genetic studies vaspin was sequenced in DNA samples from 48 unrelated Caucasian subjects. Twenty-eight single nucleotide polymorphisms (SNPs) representative for their linkage disequilibrium groups ($r^2 > 0.8$ and minor allele frequencies > 0.05) were genotyped in 1046 clinically well-characterized Sorbs from Germany for subsequent association studies on metabolic traits including IR and insulin secretion indices. Serum vaspin concentrations were determined by ELISA.

Results: Treatment of db/db-mice with recombinant vaspin resulted in an improved glucose tolerance and an increased glucose infusion rate during the steady state of the clamp (all $P < 0.05$). In human studies, serum vaspin levels correlated with gender, waist-to-hip-ratio (WHR), 2-hr glucose, insulin (fasting, 30min, 2-hr), HOMA-IR and QUICKI (all $P < 0.05$). Additionally there was a strong association of vaspin SNPs with serum vaspin concentrations (with six SNPs reaching P-values between 10^{-8} and 10^{-14}). Also, genetic variants were nominally associated with WHR, 30min glucose, 2-hr insulin, AUC_{Glucose} and IR indices (adj. for age, sex and BMI).

Conclusion: Our data demonstrate the insulin sensitizing effect of vaspin. Moreover, they suggest a role of vaspin genetic variants in the pathophysiology of IR, which might be mediated through their effects on vaspin serum concentrations.
